Abstract. The final assembly of Gondwanaland following Rodinia breakup during the Neoproterozoic-Cambrian period was marked by tectonic mode switch leading to the transformation of a passive margin in the east to an active subduction margin. This period was marked by subduction of the Pacific plate leading to the initiation of the Delamerian Orogeny in South Australia at c. 515 Ma, culminating at c. 490 Ma. Most studies have attempted to constrain the timing of deformation through dating of magmatic intrusions as proxies for deformation, however, relatively few studies strived to date minerals in fabrics that developed during deformation. As opposed to existing age constraints on the timing of cessation of the Delamerian Orogeny at c. 490 Ma, the work presented here identifies new protracted periods of active regional tectonics in the eastern Mt. Lofty Ranges. This was first observed in the underlying Backstairs Passage Formation overlain by the Tapanappa Formation of the Cambrian Kanmantoo Group through ultra-high vacuum $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology and ^{39}Ar diffusion experiments conducted on mica separates. It is observed that younger ages up to c. 468 Ma are recorded in the stratigraphically older Backstairs Passage Formation, while the overlying Tapanappa Formation bears no $^{40}\text{Ar}/^{39}\text{Ar}$ apparent ages younger than c. 486 Ma. In addition, age data reveals a period of fluid activity at c. 497-493 Ma resulting in micaceous intrusions locally and regionally. The methodology adopted here involves compilation of the age information with microstructural analyses where the age interval of c. 493-487 Ma is interpreted as post peak-metamorphism garnet growth event. This period is likely associated with retrograde metamorphism and is co-eval with Cu-mineralization in the region at c. 492-485 Ma. A second generation of retrogressed biotite growth at the expense of garnet has been identified. Importantly, there are differences in metamorphic grade and timing of deformation between the stratigraphically older the Backstairs Passage Formation and the younger Tapanappa Formation. This can be explained through macroscopic and/or microscopic processes. Two interpretations are proposed here- first involving the lower activation energy of the Backstairs Passage Formation as a measure of argon retentivity, and therefore younger ages, and the second considering proximity of the two formations to the metamorphic core of the belt at Reedy Creek and the effect of dissipated heat affecting record of argon ages in each unit. These newly identified young ages indicate the protracted nature of the Delamerian Orogeny than previously documented.

1 Introduction

40 Constraining the timing of deformation events in an orogenic system is a complex task and requires a rigorous assessment and complete understanding of the structural controls that have prevailed in the region for the lifespan of the orogenesis. Conventional methods include dating of magmatic intrusions as proxies for timing the deformation phases i.e., dating of pre-, syn- and post- magmatic bodies bracketing the deformation interval. For this purpose, U-Pb geochronometer is one of the most widely applied tools to date a variety of U-rich minerals (zircon, monazite, titanite etc.), where ages are interpreted to reflect the timing of emplacement of an intrusion. Ideally, however, absolute age dating should be undertaken on minerals that define deformation fabrics within an orogen, as a complimentary tool to the bracketing approach of using igneous intrusions. $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology on fabric forming minerals has been undertaken in many orogenic settings for this purpose (e.g., Gibson et al., 1992; Burt et al., 2000; Foden et al., 2002; Rutherford et al., 2006; Forster and Lister, 2009) In this study, we employ $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology on micas within schistose rocks and associated mica-bearing veins in order to provide age constraints on the timing of orogenic activity of an orogenic belt in southern Australia, the Delamerian Orogen.

55 The Delamerian Orogen of South Australia was active during the Late Cambrian-Early Ordovician period (Foden et al., 1999; Foden et al., 2002). It is part of one of the largest known systems of orogenies on Earth, *the Pan- African Orogenies*, which included accretion of numerous microcontinents to form the supercontinent, Gondwanaland (Turner et al., 1996; Rozendaal et al., 1999; Boger and Miller, 2004; Gray et al., 2006). The Delamerian Orogeny deformed and metamorphosed the Neoproterozoic rocks of the Adelaide Superbasin, the basal Normanville Group and the Late-Cambrian rock package of the overlying
60 Kanmantoo Group. These were deposited in an extensional/transpressional setting prior to the Delamerian Orogeny, accompanied with small volumes of mafic magmatism (Foden et al., 1999). The sedimentation of the Kanmantoo Group accumulated over a short period of time during Early- to Mid-Cambrian (~522-514 Ma, Foden et al., 2002; Foden et al., 2006; Mauger et al., 2018; Foden et al., 2020). The culmination of Delamerian Orogeny was followed by extension of the lithospheric mantle concluding with the intrusion of
65 A-types granites, mafics and volcanics (Turner et al., 1996; Foden et al., 1999; Foden et al., 2020).

One of the key regions within the Delamerian Orogen is the Kanmantoo Mine area where the timing of Cu-Au mineralisation, alteration events and associated structural controls are not fully understood. Monazite microprobe Th-U-Pb dating of drill core sample suggested an age of c. 492 Ma for Cu-mineralisation (Wilson, 2009), post-dating the timing of peak metamorphism. Arbon (2011) and Kimpton (2018) suggested the presence of two distinct chlorite alteration events at c. 503 Ma and c. 501 Ma, each associated with a period of distinct mineralisation episode in the area. The specific relationship between mineralisation and other alteration events at the Kanmantoo Mine and adjoining areas, and Delamerian Orogeny structures have not been fully deciphered. Several studies have been undertaken to correlate the timing of events,
70 whether thermal, deformation and/or metamorphic events in the Kanmantoo Mine area to those of Delamerian Orogeny phase(s) (Fanning, 1990; Perkins and Walsh, 1993; Turner et al., 1993; Drexel and Preiss, 1995; Gray and Webb, 1995; Turner et al., 1996; Turner et al., 1998; Foden et al., 1999; Ireland et al., 2002; Jenkins et al., 2002), however no $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology work in this region has been undertaken so far.

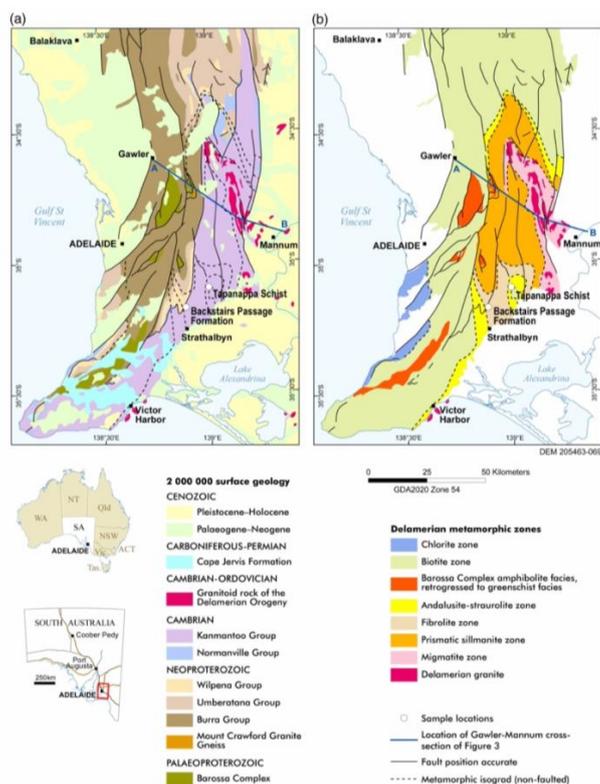

80 This study has undertaken direct dating of Delamerian deformation by employing $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology and ^{39}Ar diffusion experiments on fabric forming minerals (micas) so as to contribute to our understanding of mineral systems and deformation in the region. These local area constraints can be extended towards understanding of the broader Delamerian Orogen, and thus, can aid in deciphering the nature of
85 orogenesis.

2 Geological setting

2.1 Background

90 The Delamerian Orogeny initiated after the cessation of the sedimentation in the Kanmantoo trough (Parker, 1986; Jago et al., 2003; Foden et al., 2006), due to major tectonic mode switch from extensional to compressional tectonics (Flöttmann et al., 1998; Foden et al., 2006). The Delamerian Orogeny is characterised by three stages of deformation conventionally recognised as D₁, D₂ and D₃ (Jenkins and Sandiford, 1992; Flöttmann et al., 1998; Jago et al., 2003), and metamorphic grade increasing from chlorite to migmatite zone from west to east (Fig. 1).

95 The orogenesis commenced during Middle- to Late- Cambrian period as a response to subduction followed by back-arc extension (Turner et al., 1996; Foden et al., 2020). The first craton-ward D₁ thrust event is timed at ~515 Ma (Foden et al., 2006), and maximum age of D₁ deformation event as 502.4±4 Ma constrained through $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the muscovite defining the axial planar S₁ fabric of the middle amphibolite metapelite of the Cambrian Kanmantoo Group (Foden et al., 2020). Estimation on the occurrence of D₂ event is bracketed at ~506-500 Ma (Perkins and Walsh, 1993; Foden et al., 2006), and D₃ event to have lasted from ~495-486 Ma (Drexel and Preiss, 1995; Ireland et al., 2002; Foden et al., 2006).

105

Figure 1. Geology of the Mt Lofty Ranges, part of the Delamerian Orogen, showing location of samples analysed in this study (white circles), modified from Reid et al. 2022. (a) 1:2 million scale South Australian state-wide geology dataset. (b) Delamerian metamorphic isograds of the Mt Lofty Ranges (after Offler and Fleming, 1968; Mancktelow, 1990; Dymoke and Sandiford, 1992; Preiss, 1995).

110

The Kanmantoo Group occupies a key position along the Cambrian paleo-pacific margin of southern Gondwana and deposited in a rift basin overlying the Adelaidean stratigraphic units after the lithosphere underwent extension, with sedimentation concluding prior to initiation of the Delamerian Orogeny. The Kanmantoo Group lies disconformably over the Normanville Group forming a 7-8 km thick pile (Jenkins and Sandiford, 1992; Foden et al., 1999). The group consists of metamorphosed clastic turbidites with occasional psammitic beds up to 5 metres in thickness (Haines et al., 2001), and forms a major element of the Adelaide Superbasin (Burt and Phillips, 2003).

115

2.2 Kanmantoo Group stratigraphy

120

Stratigraphic sub-divisions of the Kanmantoo Group by Jago et al. (2003) proposed two subgroups (bottom to top), the Keynes Subgroup consisting of the Carrickalinga Head Formation and the Backstairs Passage Formation overlain by the Bollaparudda Subgroup which is host to the Talisker Formation, and base metal deposits of the Tapanappa Formation.

125

Backstairs Passage Formation overlies the basal unit of Kanmantoo Group- Carrickalinga Head Formation and represents a shallow water unit of the Kanmantoo Group. The dominant lithology is laminated to cross-bedded, medium-grained sandstone (Jago et al., 2003). This unit hosts strata bound Pb-Zn sulphides (galena, sphalerite, pyrrhotite).

130

The Paringa Garnet Schist unit of the Tapanappa Formation is a garnetiferous zone within the Kanmantoo Group, well exposed in the Kanmantoo Mine area. The formation predominantly comprises of massive to laminated, fine- to coarse-grained greywacke grading rapidly into thin, light- to dark-grey laminated

135 siltstones. Within this unit, mineralisation is hosted within the andalusite-garnet schist unit comprising bands
of garnet-rich phyllites interbedded with meta-greywackes. The formation of this mineralised schist unit is
attributed to the percolation of exhalative fluids, precipitating metal-rich chemical sediments (Flottmann et
al., 1996).

3 Kanmantoo Mine area

3.1 Local geology

140 The Kanmantoo Cu-Au deposit and proximal area(s) are associated with three major rock types: quartz-
mica schist, quartz-biotite-garnet-andalusite±chlorite±staurolite rock, and biotite-garnet-chlorite±staurolite
schist which hosts much of the sulphide mineralisation (Pollock et al., 2018), and occurs within the garnet-
andalusite-biotite schist and garnet-andalusite-biotite-staurolite schist. In addition to this, exhalative rocks
145 were recognised by Toteff (1999) in quartz-mica schist and garnet-andalusite-biotite schist within 3 km of
the Kanmantoo Mine manifested as spessartine garnet-quartz rocks, banded iron formation, magnetite-rich
andalusite schist and albitite.

3.2 Regional mineralization, metamorphism and veins

150 The mineralisation at the Kanmantoo Mine and proximal areas is hosted by the Tapanappa Formation and
occurs predominantly as chalcopyrite along with variable levels of disseminated pyrrhotite, magnetite,
pyrite, covellite, chalcocite and sphalerite (Seccombe et al., 1985; Parker, 1986; Oliver et al., 1998; Schiller,
2000; Abbot, 2005), with debated origin of mineralisation (Oliver et al., 1998; Lyons, 2012; Mauger et al.,
2018) whether a consequence of post-Delamerian igneous intrusions during Early Ordovician (483±2.5 Ma;
155 Kimpton, 2018), a pre-metamorphic, syn-sedimentary origin (Seccombe et al., 1985) or a syn-metamorphic
genesis (Thomson, 1975).

The eastern Mt. Lofty Ranges is a complex region with numerous thrust faults, shear zones and folds. The
Kanmantoo Mine area lies within the regional Kanmantoo Syncline which is a D₂ structure plunging ~15°S.
160 Within the Kanmantoo Syncline, the western limb bears indistinct bedding and shear planes subparallel to
the S₂ schistosity while the eastern limb has clearly defined bedding with occasional shear planes (Schiller,
2000; Pollock et al., 2018). The S₂ schistosity (associated with D₂ event) is the best-preserved fabric in the
region, generally trending north-south (Spry et al., 1988; Oliver et al., 1998). The D₃ event in the Kanmantoo
Mine area is usually observed as gentle crenulations and kinks (Schiller, 2000). The Kanmantoo Mine area
165 lies in the andalusite-sillimanite zone (Fig. 1b), and the metamorphic character can be best described as
Buchan-style metamorphism, consisting of high-T, low-P conditions exemplified by the presence of
andalusite indicating peak conditions of 550°-600°C and pressures of 3-5 kbar (Offler and Fleming, 1968;
Mancktelow, 1990; Dymoke and Sandiford, 1992). At Kanmantoo Mine and proximal areas, numerous
episodes of tectonic activity are observed supported by the identified multiple mineral (garnet, staurolite,
andalusite) growth events, intrusion of deformed and undeformed felsic and quartz veins (c. 495-483 Ma,
170 Kimpton, 2018), presence of aluminous segregations dated at c. 498 Ma (Kimpton, 2018), and late-stage
Cu- and Au-Bi mineralisation in the region. In general, the rocks at Kanmantoo Mine are host to two
generation of staurolites and garnets interpreted to have formed in response to extensive metasomatic
activities. Locally, during late- to post- peak-metamorphic period, Cu-mineralisation occurred at c. 492-485
Ma, co-eval with post-Delamerian extensional regime at c. 490 Ma (Lyons, 2012).

175 Numerous igneous intrusions characterised as syn- to post-Delamerian Orogeny (Foden et al., 2006) have
been observed within 50 km radial radius of the Kanmantoo Cu-Au deposit. Various deformed and
undeformed quartz, felsic and quartz-muscovite veins, rich and devoid of aluminous segregations occur
within the region, often concordant and occasionally discordant to bedding. Majority of these veins overprint
180 all pre-existing pervasive features in the host rocks. Gum (1998) observed quartz-muscovite veins 10 km
west of the deposit intruding along late shear zones and documented the quartz-muscovite vein-rich
Monarto granite. Regionally, variety of late-stage intrusions have been identified.

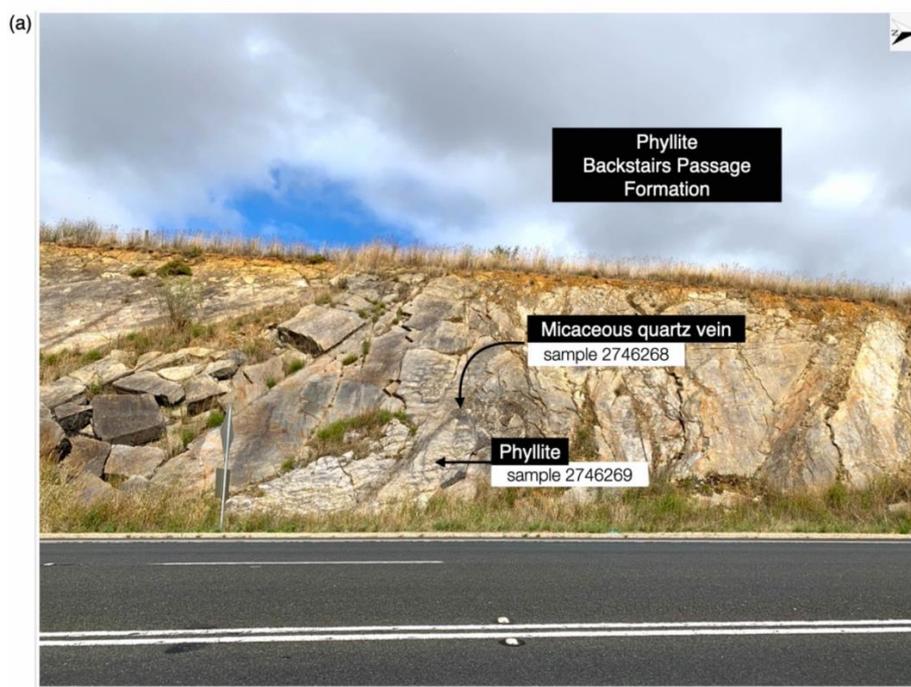

4 Methodology

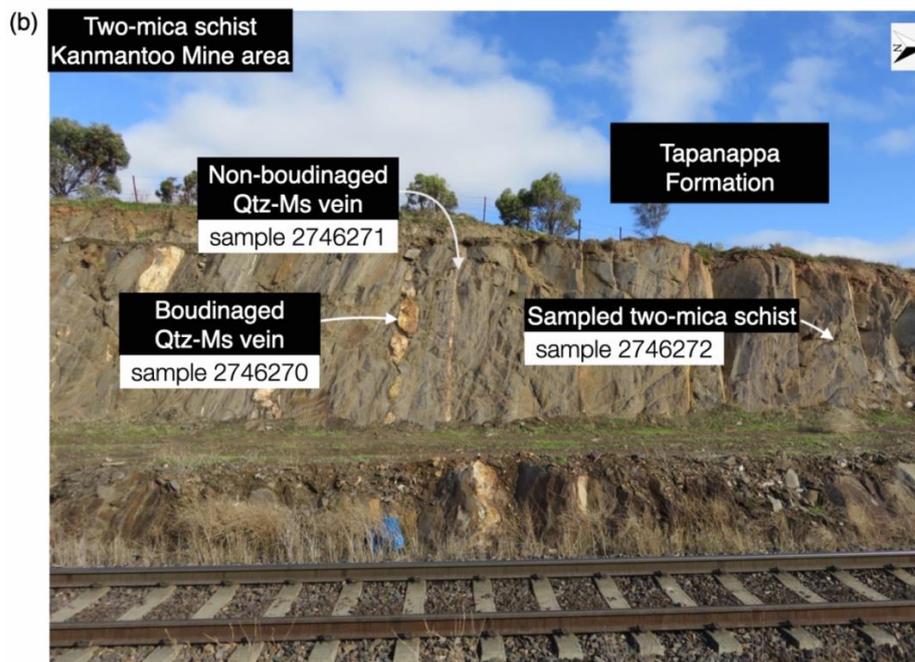

4.1 Sample selection, microstructure and microchemistry

185 Samples were selected to address the problem in question—determining the timing of Delamerian
deformation events in units near Kanmantoo Mine, located approximately 2 km south of the town of
Kanmantoo, and constrain the timing of depositional/deformation near Long Valley Road by undertaking
⁴⁰Ar/³⁹Ar geochronology.

190 To do this, we sampled a phyllite (sample 2746269) near Long Valley Road representative of the Backstairs
Passage Formation unit truncated by quartz-muscovite vein (sample 2746268) (Fig. 2a). In addition to this,
we also sampled a two-mica schist (sample 2746272) representing regional schist of the Tapanappa
Formation from a zone between two coarse-grained psammitic units (Fig. 2b) displaying well-defined mica
foliation which locally develops late-stage crenulations. The unit is host to numerous veins, from which two
representative quartz-muscovite veins were sampled- sample 2746270 which is a boudinaged variety and
195 sample 2746271 which is non-boudinaged (undeformed) quartz-muscovite vein. Table 1 presents sample
summary for this study.

200 **Figure 2.** (a) Backstairs Passage Formation of Kanmantoo Group outcropping at Long Valley Road (35°10'36" S, 138°53'26" E) and (b) Tapanappa Formation of Kanmantoo Group in cross section view outcropping near Kanmantoo Mine (35°06'04"S, 138°59'56"E).

Sample	Lithology	Stratigraphic unit	Mineral analysed	Location	Latitude	Longitude
2746268	quartz-muscovite vein	Backstairs Passage Formation	white mica	Long Valley Road	35°10'36"S	138°53'26"E
2746269	phyllite	Backstairs Passage Formation	biotite-white mica composite	Long Valley Road	35°10'36"S	138°53'26"E
2746270	boudinaged quartz-muscovite vein	Tapanappa Formation	white mica	Kanmantoo Mine area	35°06'04"S	138°59'56"E
2746271	non- boudinaged quartz-muscovite vein	Tapanappa Formation	white mica	Kanmantoo Mine area	35°06'04"S	138°59'56"E

Table 1. Sample details

205 Microstructure analyses were conducted on two polished thin sections from the host rock formations (sample 2746268 and 2746272) on a LEICA DC 500 microscope at the Research School of Earth Sciences, Australian National University (ANU) followed by microchemistry analyses performed on silicates from sample 2746272 JEOL 8530F Plus Electron Probe Microanalyzer at the Centre for Advanced Microscopy, ANU. All analyses were operated with an accelerating voltage of 15kV, a beam current of 10nA, and a beam diameter of 10µm with a counting time of 30s. A maximum of 3 analyses per grain was performed on each sample. The results are discussed later in the paper.

210

4.2 Sample preparation and neutron irradiation

215 The first step in sample preparation is sample selection by physical segregation of structures e.g., biotite forming fabric in the sample or different generations of white mica present. Following sample selection, desired mineral aliquots were prepared by standard crushing and sieving followed by routine magnetic separation methods at varying amperage to obtain clean and pure separates. The final step was to handpick the grains under a binocular microscope to acquire the purest fraction possible (>99% purity). Once packed, the samples were then subjected to neutron irradiation in the core of the reactor with suitable flux monitors to calculate J-factor, and salts (K₂SO₄ and CaF₂) to correct for isotopic interferences. Irradiation of sample

220

batches was done at UC Davis MNRC nuclear reactor in California employing a biotite standard GA-1550 (K-Ar age of 99.18 ± 0.142 Ma; intercalibration from Spell and McDougall, 2003). The samples presented in this study were analysed in two sample batches, ANU CAN#33 and CAN#35. Complete analytical details are provided in Supplement 1.

225

Following irradiation, once the samples 'cooled' to acceptable radiation levels, they were subjected to $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology at the Research School of Earth Sciences, ANU, involving temperature-controlled furnace step heating diffusion experiments on individual mineral separates, through an ultrahigh-vacuum extraction line connected to a *Thermo Fisher* ARGUS-VI multi-collector mass spectrometer.

230

Prior to measurement, each mineral aliquot id dropped into a temperature-controlled resistance-furnace, and then warmed for a minimum period of 12 hours at c. 350-400°C under ultra-high-vacuum (UHV) conditions to clean the aliquot of deeply penetrated volatiles in fast-diffusion pathways. Flux monitors were analysed employing laser fusion technique using a CO_2 continuous wave laser and step-heating experiments were carried out in temperature-controlled furnace ranging from 450°C to 1450°C involving 30 steps to allow revelation of high-resolution age gradients. After each heating step, gas is released into the mass spectrometer and 51 simultaneous measurements made of the counts (on each Faraday cup) for isotopes ^{36}Ar , ^{37}Ar , ^{38}Ar , ^{39}Ar , ^{40}Ar for approximately 10 minutes. These are then used in a complex data calculation using *Noble 2020* software which in essence removed the effect of isotopic interferences, system background, mass discrimination and atmospheric contamination and then allowed the calculation of age. ^{40}K abundances and decay constants used were calculated as in Renne et al. (2011). Detailed results for each step-heating experiment are presented in Supplement 2, with summary of these ages presented in Table 3. Weighted mean ages are calculated using three or more steps based on Pearson's chi statistics within 95% confidence limit and calculated using the in-house developed software eArgon (see Muston et al., 2021) for detailed description of the statistical method employed.

235

240

245

A proper step-heating schedule is vital for extracting maximum information from the mineral. Loss of crucial data can occur if carefully planned schedules are not employed for e.g., an experiment starting at a high temperature could result in obscuring useful data due to mixing of gas from domains of variable retentivity (thus variable ages) or employing few steps could conceal age gradients that may otherwise emerge in an experiment with generous number of steps.

250

5 Results

5.1 Field observations

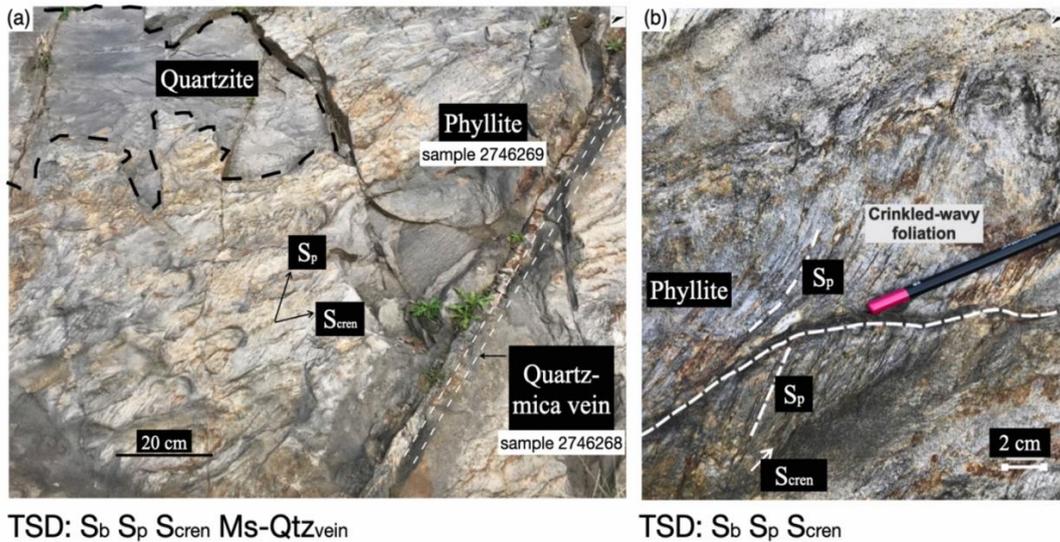

The Backstairs Passage Formation unit of the Kanmantoo Group is dominated by massive exposures of foliated phyllite trending roughly N-S. Here, the micaceous unit is underlain by coarse quartzite (bedding S_b ; 336/50E; strike/dip) (Fig. 3) host to abundant quartz-mica veins, joints and intense weathering. Two sets of cross cutting fabrics are observed- a primary foliation fabric (S_p) truncated by younger crenulation fabric (S_{cren}) are observed in the phyllitic unit (Fig. 3b). Reverse younging (graded bedding) is observed in the underlying quartzite unit.

255

260

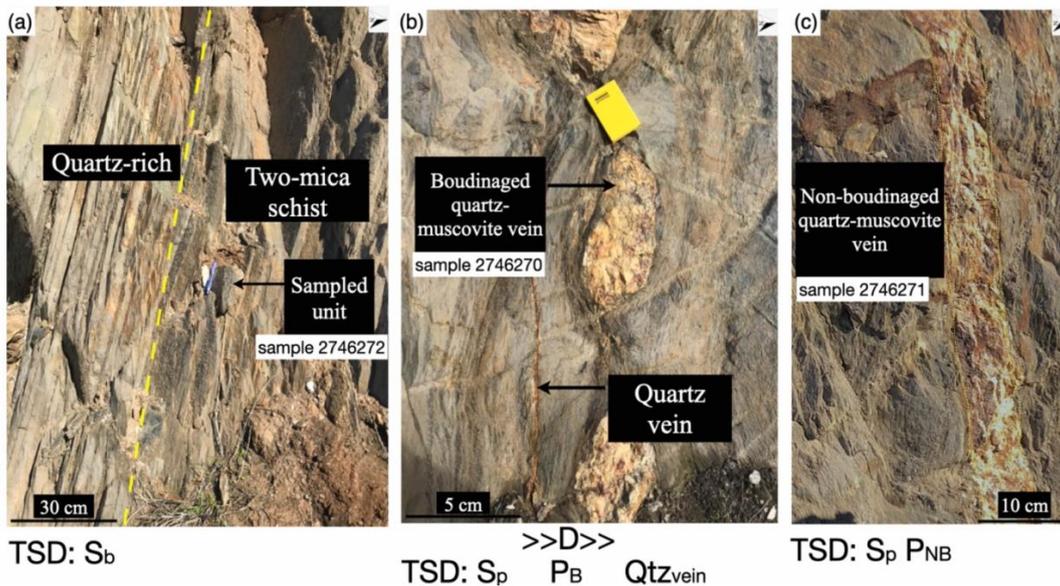

Backstairs Passage Formation

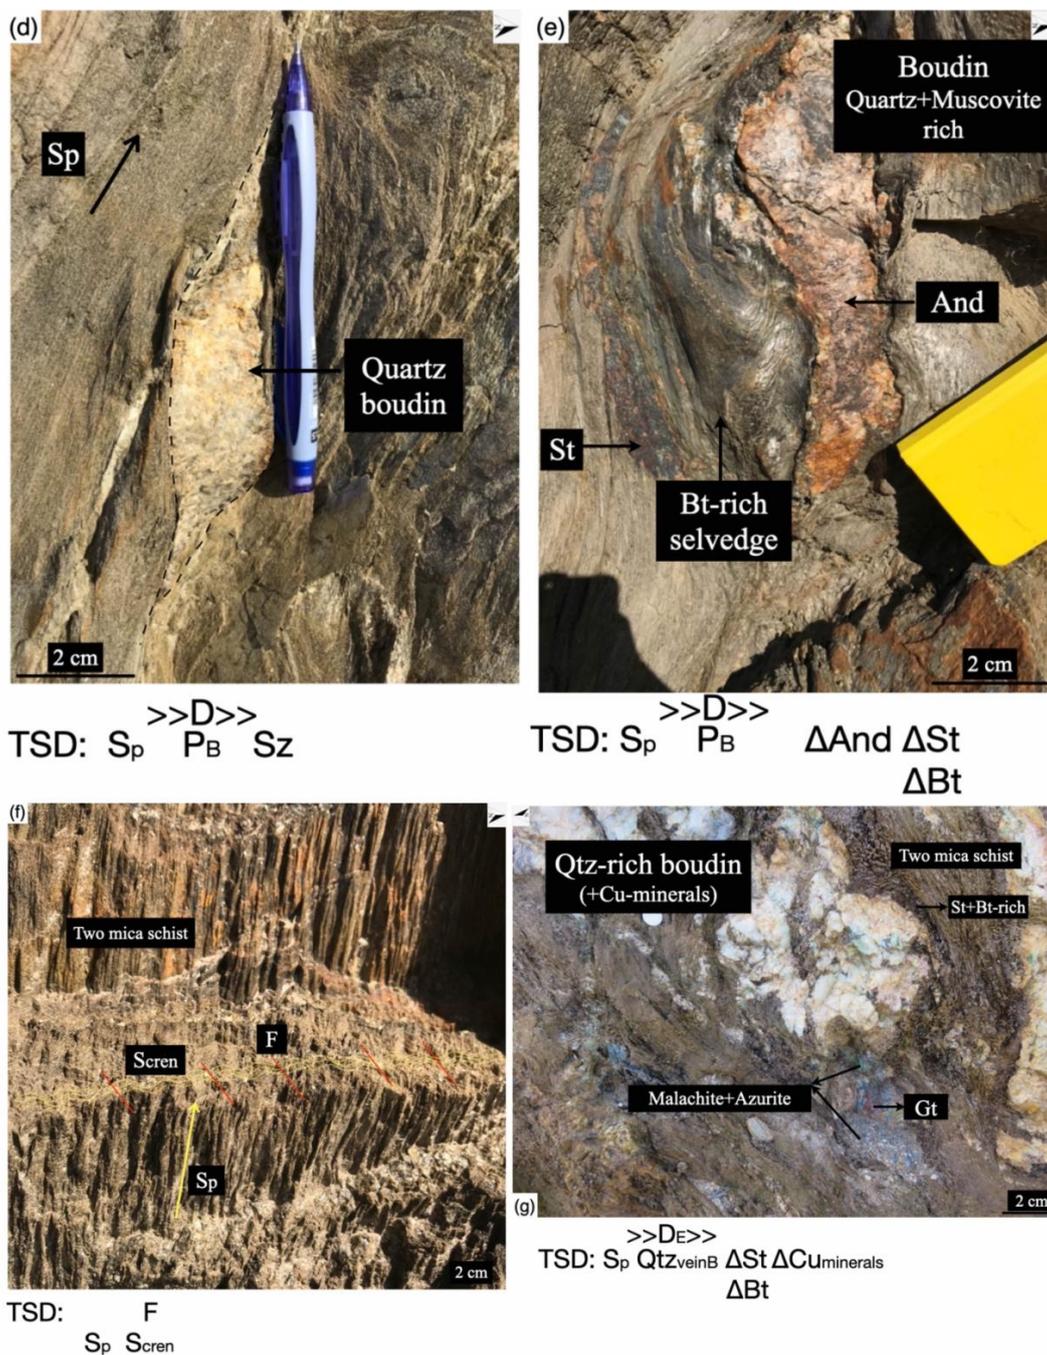

265 **Figure 3.** Field exposures of the Backstairs Passage Formation unit at Long Valley Road with tectonic sequence diagrams at the bottom. (a) host phyllite underlain by quartzite and truncated by quartz-muscovite vein. (b) two sets of fabrics observed in the phyllite. (S_b : bedding, S_p : primary foliation fabric, S_{scen} : secondary crenulation fabric).

270 The Tapanappa Formation has extensive exposures near the Kanmantoo Mine. The dominant lithology is strongly foliated, rheologically less competent two-mica schist roughly trending N-S, packed between quartz-rich psammitic units (Fig. 4). Here, the primary fabric (S_p) (174/76E; strike/dip) defined by biotite-white mica schistosity is parallel to the bedding (S_b) (026/66E). At most places, schistosity is concordant with bedding, however this is not a consistent feature of the outcrop.

Tapanappa Formation

275

280

Figure 4. Field exposures of the two-mica schist at Kanmantoo Mine area with their respective tectonic sequence(s) written at the bottom of each image. (a) two-mica schist, (b) boudinaged quartz-muscovite vein intruding the schist, (c) non-boudinaged quartz-muscovite vein. (S_p : bedding, P_B : boudinaged vein, D : unknown deformation event, S_p : primary fabric, P_s : non-boudinaged vein), (d) quartz boudin, (e) quartz-mica boudin with a biotite-staurolite rich selvage, (f) late stage S_{ren} fabric associated with a folding event and (g) malachite and azurite in quartz boudins.

285 The unit has schistosity layer parallel quartz vein(s) and quartz-muscovite vein(s), which at some places
are orthogonal to the fabric. Unmineralized to mineralised and deformed (boudinaged) to undeformed veins
occur throughout the unit (Fig. 4d). The massive, boudinaged quartz-muscovite veins occasionally contain
pink andalusite and rare garnet. The melt selvage at the host-quartz-muscovite vein contact is biotite-rich
with rare staurolite occurrences (Fig. 4e); however, this is not observed for pure quartz veins. Several
boudinaged, schistosity parallel quartz veins are associated with Cu-mineral phase(s). Later stage
290 crenulations, S_{cren} , possibly associated with a younger deformation event, are observed occasionally (Fig.
4f), gently folding the early schistosity along with late-stage faults displacing the quartz-muscovite veins.
The unit shows patchy Cu-mineralisation with disseminated azurite and malachite precipitates (Fig. 4g).
Locally, irregular occurrences of pygmatic, unmineralized quartz veins discordant to schistosity are
indicative of crumpling of an original planar vein by subsequent compression of the incompetent host.

295 **5.2 Microstructure analyses**

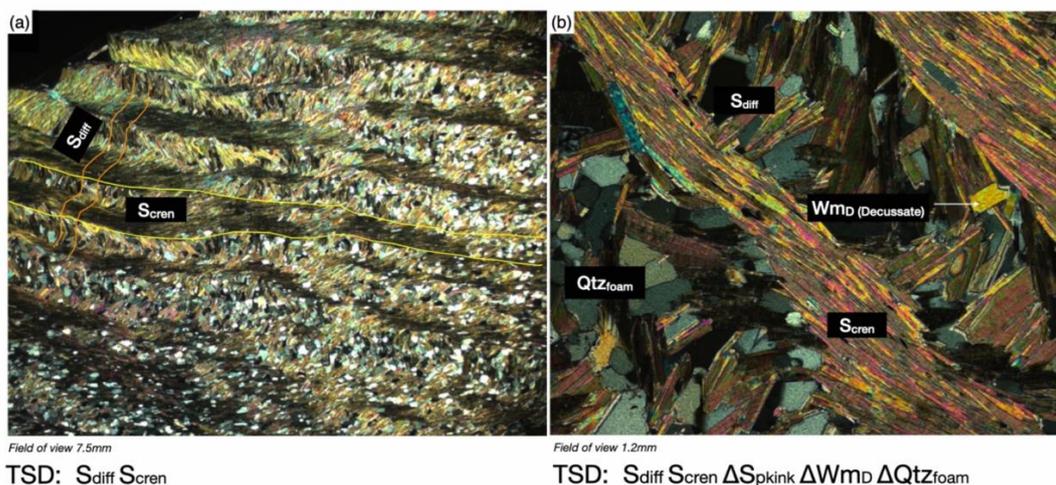

5.2.1 Importance of microstructures

300 Microstructural analyses help in studying the textural relationships in a sample, determination of
deformation/thermal events indicated through the presence of index minerals and in understanding the
intragrain character of the minerals present. High power transmitted light microscopy was undertaken on
thin sections to study the minerals presents, deformation characteristics and recrystallisation (if any),
preservation of relict minerals and relative grain sizes present. This is a key step in $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology
because the modification(s) in original microstructures and newly produced microstructures is correlated to
the variation(s) in ages reflected in the age spectrum of the mineral, where different ages can often be
305 correlated with different event(s) and/or element(s) of a microstructure.

In routine, age determination and interpretation are preceded by careful examination of the target mineral
(in this case biotite, white mica and mica composites) by optical microscopy and microchemical analyses.
Following this, microprobe analyses were conducted on thin section for phase characterisation and
determination of chemical character for minerals described in detail in section 5.4. Results for
310 microchemical analyses are presented for sample 2746272 (two-mica schist, Tapanappa Formation) only.
Sample 2746269 (phyllite, Backstairs Passage Formation) was not subjected to microchemical analyses
due to its very fine-grained texture.

5.2.2 Backstairs Passage Formation, Long Valley Road

315 The sample is a phyllite with interlayered biotite-white mica grains. At the outcrop scale, two sets of cross-
cutting fabrics were observed (Fig. 3), which are also visible at the microscopic scale (Fig. 5). The younger
fabric, biotite-mica rich crenulation cleavage domain (S_{cren}) is regularly spaced, parallel and anastomosing.
 S_{cren} sharply truncates the older differentiated cleavage fabric (S_{diff}) and is nearly orthogonal to it. This
younger fabric is not penetrative and is observed only in the top half of thin section (Fig. 5a) corresponding
320 to the top layer of the sampled unit. Within this sample area, S_{diff} is observed to merge and transition
smoothly into S_{cren} occasionally, where the sample is dominantly mica-rich and quartz-poor. In the
microlithons, the S_{diff} fabric is defined by interlayered biotite+white mica that display gentle to strong kinking,
and occasional strong bending (microfolds) of the mica-flakes. The microlithons contain interstitial quartz
with foam texture (Fig. 5b) indicative of a later heating event resulting in post-crenulation crystallization.
325 Overall, the crenulation cleavage generates microfolds in the older planar fabric and is suggestive of
polyphase deformation in this sample.

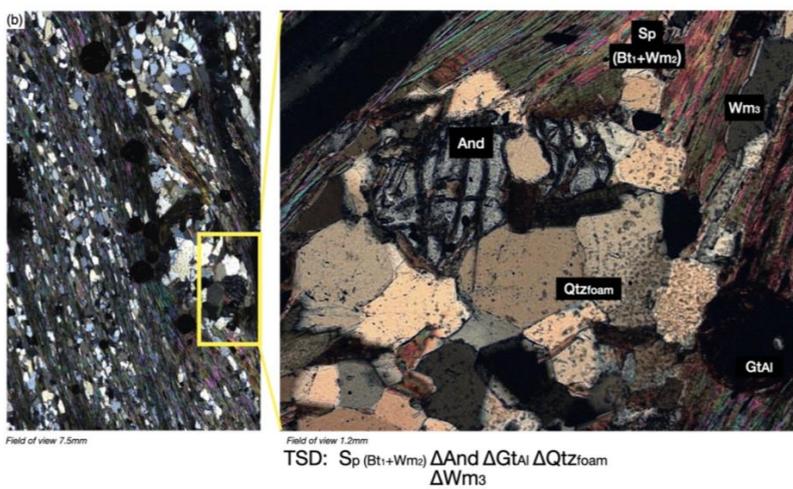

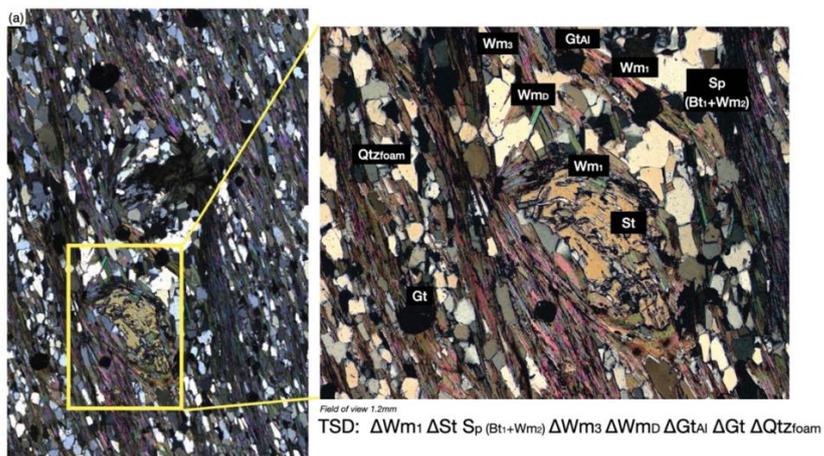

330 **Figure 5.** Microstructure observations of phyllite, Backstairs Passage Formation. (a) two sets of fabrics in the phyllite and (b) quartz
foam texture in the microlithons and late-stage decussate white-mica. (S_{diff}: differentiated cleavage, S_{cren}: crenulation cleavage, ΔS_{pkink}:
kinking of primary fabric S_{diff}, ΔW_{mD}: growth of decussate white mica, ΔQtz_{foam}: formation of quartz foam texture).

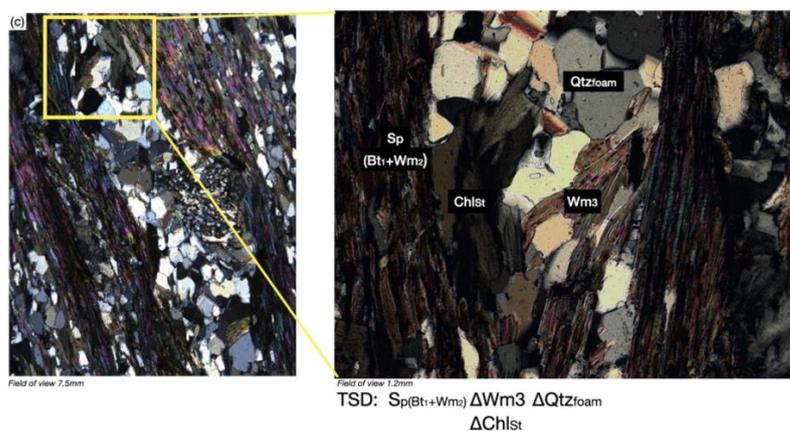

5.2.3 Tapanappa Formation, Kanmantoo Mine area

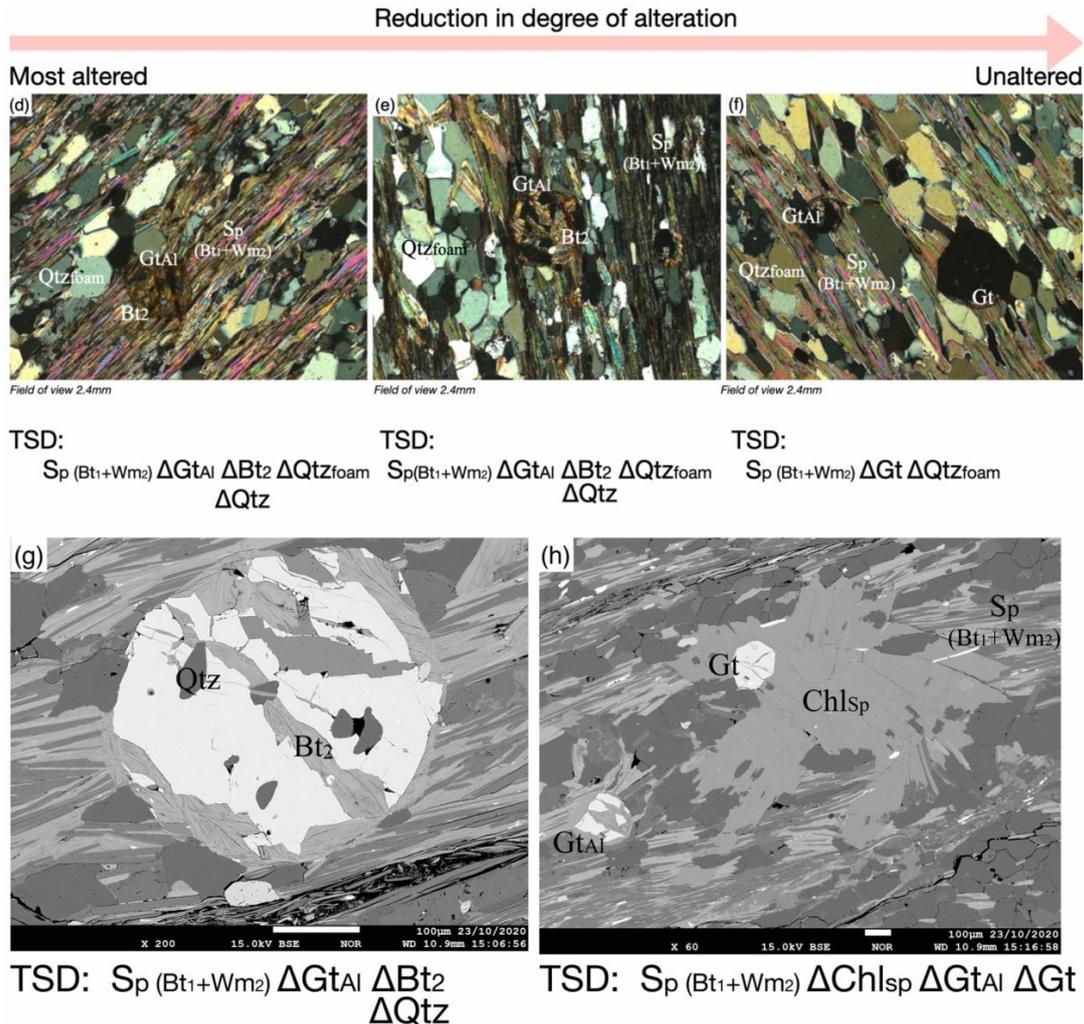

335 The two-mica schist consists of interlayered biotite+white mica, quartz, garnets, chlorite, rare relict
poikiloblastic staurolites and sulfides. The staurolites grow over a relict, older fabric demonstrated by white
mica inclusion trails (termed as first generation, Wm₁; the subscript denotes generation sequence). The
sample displays a prominent schistosity (S_p) defined by fine-grained intercalated biotite+white mica
(Bt₁+Wm₂), some altering to chlorite (Chl_{Sp}) (Fig. 6h), occasionally displaying a decussate texture. Chlorite
340 (Chl_{Sp}) is observed overgrowing this foliation at places, possibly at the expenses of micas, and is likely
distinct to the chlorite growing in the staurolite pressure-shadow (Chl_{St}) (Fig. 6c).

The schistosity (younger) wraps around relict staurolite pods, breaking down to white mica, foam textured
quartz, minor chlorite (Chl_{St}) and scarce, heavily fractured andalusite grains with sericite along fractures,
345 likely to have formed co-eval with, and in response to the deformation forming S_p fabric and destabilising
staurolites (Fig. 6b). The white mica (Wm₃) forms a coarse rim around relict staurolite grains, thus
preventing their further consumption (Fig. 6a). The S_p fabric bears a different orientation relative to the
inclusion trails in the staurolites. The white micas in the staurolite pressure-shadows are coarser and are
not aligned to the external S_p fabric (Fig. 6a). Cross cutting this third generation of white micas are the
350 decussate ones (Wm_D) (Fig. 6a), interpreted as last in the sequence of white mica formation. Small,
euhedral to subhedral garnets overgrow the primary schistosity absent any obvious deformation features,
and are interpreted to have formed during the last stages of deformation history (Fig. 6d-f). The schist bears
two types of garnets, fractured and altered (Gt_A), non-fractured and unaltered (Gt), suggestive of two
355 episodes of garnet growth. Back scattered electron imaging (BSE) of the fractured garnets shows
precipitation of secondary biotite±chlorite±polygonal quartz mostly in and around fractures, and
occasionally biotite±chlorite rimming the garnet core (Fig. 6d-g).

 chlorite overgrowing S_p , Chl_{Sp} : chlorite growing in staurolite pressure shadow, Gt : garnet, Gt_{Al} : altered garnet)

5.3 Tectonic Sequence Diagrams (TSDs)

375 Here, we have adopted the method of Tectonic Sequence Diagrams or TSDs proposed by Forster and Lister (2008), that allows the systematic recording of all deformation and metamorphic events (e.g., mineral growth events), subsequent overprinting events (if any) and estimating their duration. Tectonic sequence diagrams allow easy representation of maximum information from one key location/outcrop, that can be correlated to features on regional scale with an added advantage of adding any information later obtained. Thus, later recorded events (if any) can be easily added to or omitted from any part of the tectonic sequence diagram using annotations as outlined in Table 2.

Annotation	Description
S_b	Bedding

S_p	Primary fabric (foliation/schistosity)
S_{cren}	Secondary fabric (crenulation cleavage)
P_B	First quartz-muscovite vein (boudinaged) event
P_{NB}	Second quartz-muscovite vein (non-boudinaged) event
Qtz_{vein}	Undeformed quartz-vein
Qtz_{veinB}	Boudinaged quartz vein
D	Unspecified deformation event
F	Folding related to unspecified deformation event
ΔBt₁	Growth of first-generation biotite
ΔBt₂	Growth of second-generation biotite
ΔGt₁	Growth of first-generation garnet
ΔGt₂	Growth of second-generation garnet
ΔAnd	Andalusite mineral growth event
ΔSt	Staurolite mineral growth event
Qtz-MS_{vein}	Quartz-muscovite vein
ΔQtz_{foam}	Quartz (foam-texture)
ΔChl_{sp}	Chlorite overgrowing S _p fabric
ΔChl_{st}	Chlorite growing in staurolite pressure shadow
ΔWm_D	Decussate white-mica growth event
>>_p>>	Duration of specific event e.g., deformation
S₂	Two events in a sequence occurring synchronously, one below the other; biotite growth during S ₂ fabric
ΔBt1	

380 **Table 2.** Annotation used in tectonic sequence diagram for structural features and mineral growth events

Delamerian Orogenesis is a complex event, the nature and lifespan of which has not been fully worked out. The exposures observed at both locations are puzzling and, therefore their structural analyses are imperative. Therefore, there was a need for considering older numerical schemes as secondary and new methods of recording sequences to be adapted.

385 Here, we have produced a simplified tectonic sequence diagram for both units, the phyllite of Backstairs Passage Formation, and the two-mica schist of Tapanappa Formation, where multiple event sequences inferred through generations of fabrics and intrusions observed at key points have been determined in a single outcrop. Thin section analyses provide constraints on the relative timing of events, and information on structures that are not observed at hand-specimen scale. Therefore, the presented final sequence also includes microstructural input observed during detailed petrographic analyses.

390 The TSD inferred from observations as outcrop scale of the phyllite of Backstairs Passage Formation matches well with that observed as microstructure scale. From Fig. 3 the sequence is defined as:

$$S_b S_p S_{cren} Qtz-MS_{vein}$$

400 At microstructure scale (Fig. 5), the sequence is defined as:

$$S_p S_{cren} \Delta S_{pkink} \Delta Wm_D \Delta Qtz_{foam}$$

The final tectonic sequence thus becomes:

405 $S_b S_p S_{cren} \Delta S_{pink} \Delta W_{mD} \Delta Q_{tzfoam} Q_{tz-MS_{vein}}$

The Tapanappa Formation at the Kanmantoo Mine area has an intense bedding parallel foliation fabric (S_p), which locally diverges from bedding (S_b). S_p has layer parallel quartz-muscovite veins (deformed and undeformed) with secondary mineral(s) precipitating at vein-host contact. From Fig. 4 the inferred compiled sequence at outcrop scale is defined as:

415 $S_b S_p F Q_{tz_{veinB}} P_B \Delta And \Delta St S_z P_{NB} Q_{tz_{vein}} \Delta C_{Uminerals}$
 $S_{cren} \Delta Bt$

At microstructural scale (Fig. 6), more complex relationships are observed. The observed sequence is defined as:

420 $\Delta W_{m1} \Delta St S_p \Delta W_{m3} \Delta W_{mD} \Delta Chl_{Sp} \Delta Gt_{Al} \Delta Gt \Delta Bt_2 \Delta Q_{tzfoam}$
 $\Delta And \Delta Qtz$
 ΔChl_{St}

Integrating field and microstructural observations, the final sequence becomes:

425 $S_b \Delta W_{m1} \Delta St S_p \Delta W_{m3} \Delta W_{mD} \Delta Chl_{Sp} F Q_{tz_{veinB}} P_B \Delta And \Delta St \Delta Gt_{Al} \Delta Gt \Delta Bt_2 \Delta Q_{tzfoam} P_{NB} Q_{tz_{vein}} \Delta C_{Uminerals}$
 $\Delta And \Delta Bt \Delta Qtz$
 ΔChl_{St}

430 *Note: The parts of segments in italics signify the uncertainty in the sequence of event(s).*

5.4 Mineral compositions

435 Electron-microprobe analyses of silicates (garnet, biotite, muscovite, chlorite and quartz) were obtained from the Tapanappa Schist of the Kanmantoo Mine area. Complete details of analytical setup are provided in Supplement 3 and representative major and minor elements for the mineral phases of the Tapanappa Schist are provided in Supplement 4 in the electronic supplement. In summary, the garnets in the sample show a narrow range of MgO wt.% compositions (2.36-2.43 wt.%), are rich in total FeO ranging between ~29-31 wt.% and MnO compositions between ~7-8 wt.%. The biotite mica in the sample shows a compositional range with values of 9-10 wt.% MgO and 17-18 wt.% FeO along with consistent minor concentration of TiO₂ of ~1.5 wt.%.

5.5 ⁴⁰Ar/³⁹Ar age spectra results

445 Age spectrum analyses were undertaken using eArgon multifunctional software designed in-house at the Research School of Earth Sciences, Australian National University, that allows data representation using different plot types. Here, data has been analysed using the age-spectrum plot and Arrhenius plot, where the age-spectrum represents apparent ages (Ma) in a mineral as a function of ³⁹Ar release with temperature increments in steps and therefore, makes it possible to identify different age populations. The Arrhenius plot analyses was undertaken in conjunction with the age spectrum analyses and allows for identification of distinct age domain(s) within a mineral and estimation of their activation energies (E_a) and closure temperatures (T_c). This was achieved by employing The Fundamental Asymmetry Principle (FAP) of Forster and Lister (2010) in which steps in a heating experiment are divided by rank order and slope of the line corresponds to an activation energy value. This approach allows for estimation of diffusion parameters for the age domain in question with values less than or equal to the actual value.

5.5.1 Backstairs Passage Formation, Long Valley Road

455 Sample 2746269 is a phyllite from the Backstairs Passage Formation unit composed of biotite-white mica composite grains, and abundant quartz with two sets of deformation fabrics. Biotite-white mica composites from this sample present a simple age spectrum rising asymptotically from a minimum age of c. 388 Ma to

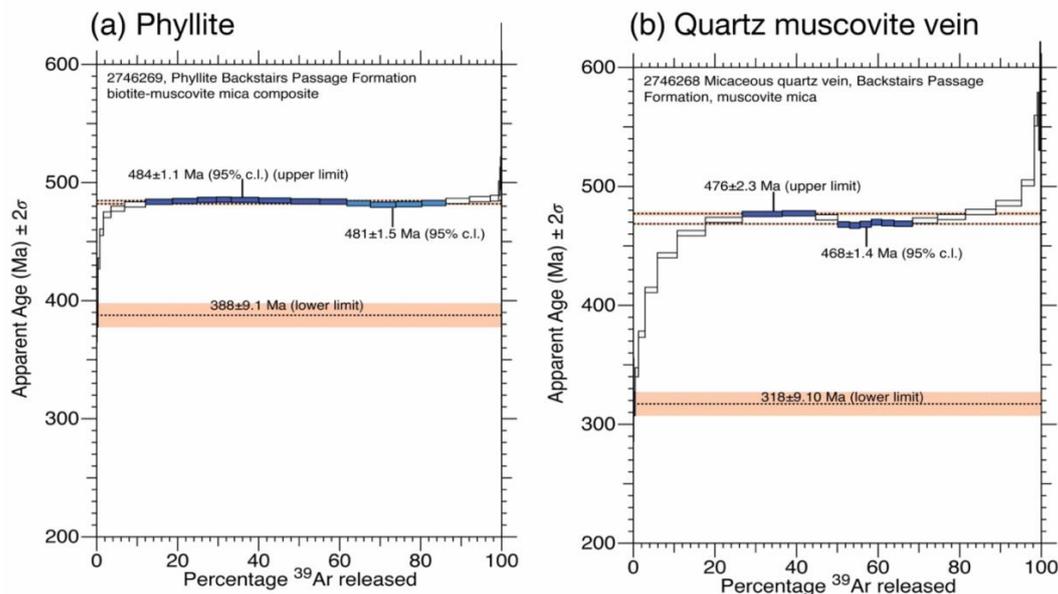

460 an upper limit age of 484 ± 1.1 Ma at $\sim 20\%$ ^{39}Ar release (Fig. 7a). The spectrum shows a subtle dip around
60% gas release with a minimum age of 481 ± 1.5 Ma. Following this, there is a gradual increase in apparent
age reaching a maximum of c. 506 Ma in the high temperature steps of the experiment. In summary, ages
range from c. 484-481 Ma with ^{39}Ar gas release from ~ 10 -95%. A correlation is observed between the Ca/K
ratio plot and age spectrum where a spike in Ca/K ratios (degassing of fluid inclusion/contaminant etc that
may contribute $^{40}\text{Ar}_E$) at c. 30% ^{39}Ar release is observed (Fig. A2, Supplement 1), that contributes to the
465 sub-plateau age of c. 484 Ma identified in the age spectrum.

The biotite-white mica grains in the thin section show intimate growth in the two sets of deformation fabrics,
 S_{diff} and S_{cren} . The modal abundance of decussate white mica in the sample is relatively low, and thus it
would be safer to assume no to minimal contribution from this white mica to the age spectrum. The age
variation evident in the age spectrum could be due to mica composite contributions from the two sets of
470 deformation fabrics. However, the relatively smaller age variation observed in the age spectrum is
suggestive of continuous biotite-white mica growth during fabric formation. Therefore, the ages obtained in
the age spectrum display variations preserved in the individual minerals forming the composite crystals that
could degas preferentially during step-heating experiments, and therefore, we cannot disregard the
complexity introduced through the composite nature of the mineral separate used.

475 Sample 2746268 is a micaceous quartz vein (Fig. 7b). The age spectrum for white mica from this sample
rises from a minimum age of c. 318 Ma, reaching an upper limit age of 476 ± 2.3 Ma, followed by a dip in
apparent ages at 50% ^{39}Ar release, where a minimum semi-plateau age of 468 ± 1.4 Ma is observed.
480 Towards the high-temperature steps of the experiment, the age spectrum displays unusually older apparent
ages at $\sim 95\%$ ^{39}Ar release, and thus, these steps are not employed for age assessment purposes. This
could be due to abrupt degassing of any trapped contaminants or material that is not rich in radiogenic
argon as the radiogenic argon content decreases from 80% to 20% rapidly (Fig. A1, Supplement 1). The
closure temperature value estimates of 313° - 329°C are obtained for this sample using Arrhenius plot
485 analyses (Supplement 1). The Ca/K ratio plot shows degassing of a potential Ca-rich component (fluid
inclusion/contaminant decrepitation that may contribute $^{40}\text{Ar}_E$) at c. 54% ^{39}Ar release with a Ca/K ratio of
c. 1.5, corresponding effects of which are observed in the age spectrum and $\%^{40}\text{Ar}^*$ radiogenic plot with
very similar overall pattern in the two plots (Supplement 1).

Backstairs Passage Formation

490 **Figure 7.** Age spectra from (a) biotite-white composite from phyllite and (b) white mica from quartz-muscovite vein of Backstairs
Passage Formation

5.5.2 Tapanappa Formation, Kanmantoo Mine area

495 Sample 2746272 (Fig. 8a) is a two-mica schist displaying a disturbed age spectrum. Biotite-white mica
composite grains from this sample display an age spectrum stepping upwards from a minimum age of c.
203 Ma. A mica sub-spectrum is observed in the first 20% of ^{39}Ar release with two steps defining an age of
496±1.7 Ma. Following this, a subtle decline in apparent ages at ~20% ^{39}Ar release with an age of 488±1.6
500 Ma. The spectrum then rises gradually, reaching an upper limit age of 506±2.3 Ma at ~60% ^{39}Ar release.
Following this, a gradual fall in apparent ages is observed, with two steps at ~84% ^{39}Ar gas release defining
an age of 498±1.6 Ma. The higher temperature steps of the experiment are avoided for age interpretation
due to very low radiogenic argon content (~60%) (Fig. A5, Supplement 1). There exists a good correlation
between age spectrum and Ca/K ratio plot (Supplement 1). No obvious correlation is observed with Cl/K
ratio plot.

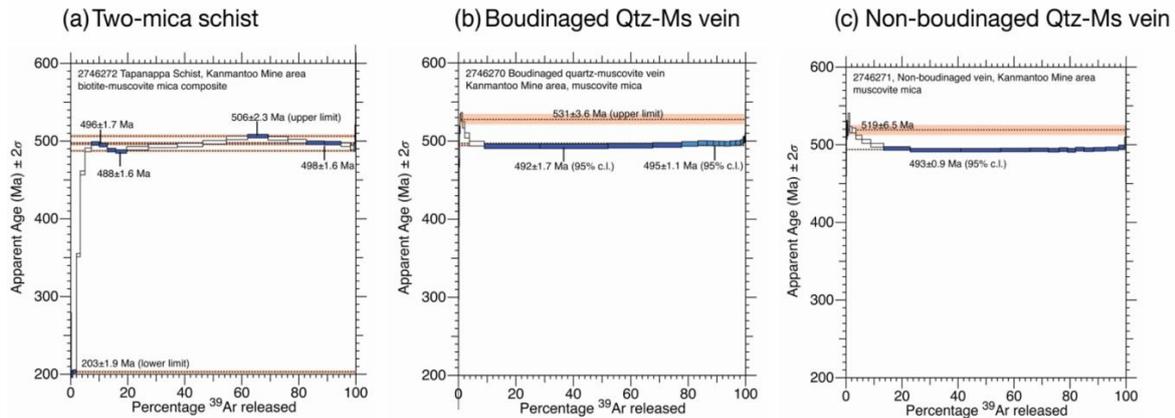

505 Sample 2746270 is a boudinaged quartz-muscovite vein truncating the host two-mica schist. White-mica
dated from this quartz-muscovite vein delivers a simple age spectrum with an older apparent age of 531±3.6
Ma defined by two steps as observed in the muscovite sub-spectrum in the first 4% of ^{39}Ar release (Fig.
8b). The spectrum then shows a rapid decrease in apparent ages, reaching a semi-plateau age of 492±1.7
510 Ma comprising of 3 steps with nearly 50% of ^{39}Ar release. Towards the higher temperature end of the
experiment, a second semi-plateau comprising ~30% ^{39}Ar release with an age of 495±1.1 Ma is observed.
The terminal heating steps in the experiment (>95% ^{39}Ar release) are not used in the age analyses due to
their low radiogenic argon release contribution (60%-40%) (Fig. A3, Supplement 1). A closure temperature
range of 297°-535°C has been estimated employing Arrhenius plot analyses (Supplement 1). Effects of ^{39}Ar
515 recoil are observed in the initial heating steps of the experiment. No obvious correlation is observed with
Cl/K ratio plot (Supplement 1).

Sample 2746271 is a white-mica separate from non-boudinaged quartz-muscovite vein and has a similar
degassing pattern to the boudinaged quartz-muscovite vein (Fig. 8c). The sample preserves an older age
of 519±6.5 Ma observed in the muscovite sub-spectrum in the first 4% of ^{39}Ar release. The age spectrum
520 remains relatively flat for most part of the experiment and shows a uniform plateau age of 493±0.9 Ma
comprising approximately 70% ^{39}Ar release. No obvious correlation is observed with Cl/K ratio plot (Fig.
A4, Supplement 1).

525 Arrhenius plot analyses (Supplement 1) demonstrates the presence of multiple age domains within the
samples at Kanmantoo Mine area. In the host schist, the c. 506 Ma age domain corresponds to an activation
energy of 47 kcal/mol. The c. 492 Ma and c. 495 Ma age domain in the mica from boudinaged vein
correspond to activation energies of c. 53 kcal/mol and 154 kcal/mol, respectively. The c. 493 Ma age
domain from the non-boudinaged vein has contributions from multiple domains of varied retentivity as per
the Arrhenius plot with activation energies varying from 52 kcal/mol to 91 kcal/mol, however, a single plateau
530 age is observed in the age spectrum and does not reflect any age variation corresponding to changing
activation energies. Effects of ^{39}Ar recoil are observed in the initial heating steps of the experiment in this
sample.

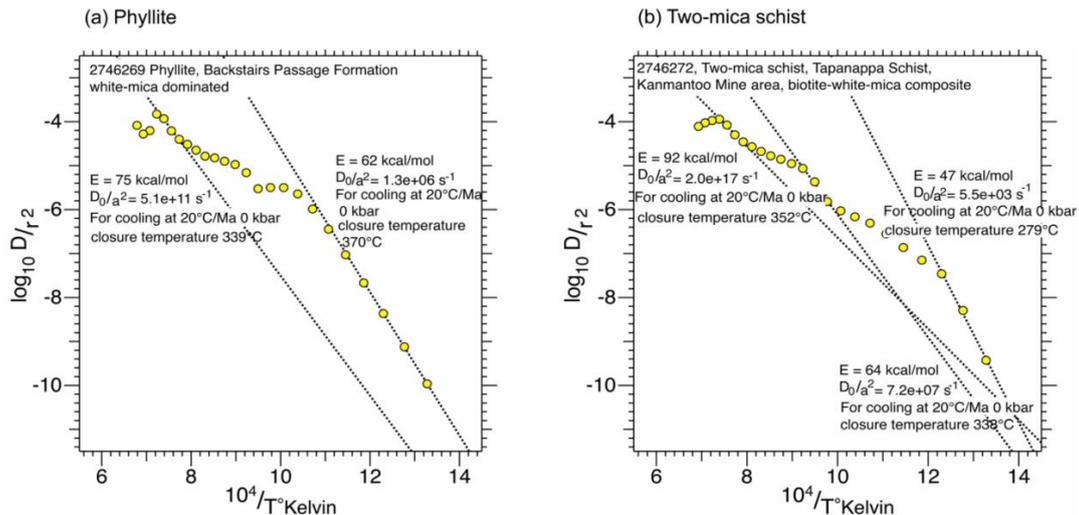

Tapanappa Formation

535 **Figure 8.** Age spectra of (a) host biotite-schist, (b) Boudinaged quartz-muscovite vein and (c) non-boudinaged quartz-muscovite vein.

The Arrhenius plot for the host phyllite and biotite schist in this study is presented in Fig. 9. Both samples have distinct age domains with varied retentivities expressed in terms of their activation energies and closure temperatures estimated for a moderate cooling rate of 20°C/Ma. Assuming a simplified spherical geometry for the minerals, Arrhenius plot analyses (Fig. 9) estimated closure temperatures of 370°-339°C for the phyllite, and 279°-352°C for the two-mica schist. Table 3 summarizes geochronology data obtained in this study.

540

545 **Figure 9.** Arrhenius plots for (a) phyllite from Backstairs Passage Formation unit, and (b) two-mica schist from Tapanappa Formation. The plot employs FAP principle of Forster and Lister (2010) to estimate activation energies (E) and closure temperature(s) (T_c).

Sample	Lithology	Stratigraphic unit	Mineral analysed	Interpreted age(s) (Ma) $\pm 2\sigma$ error	Age type	Interpretation	Estimated closure temperature window (Tc)
2746268	Micaceous quartz vein	Backstairs Passage Formation	white mica	476 \pm 2.3	sub-plateau	max. intrusion age	313-329°C

				468±1.4	sub-plateau	min. intrusion age	
2746269	Phyllite	Backstairs Passage Formation	biotite-white mica composite	484±1.1	sub-plateau	max. age of S _{cren} formation or min. age of S _{diff} formation	339-370°C
				481±1.5	sub-plateau		
2746270	Boudinaged quartz-muscovite vein	Tapanappa Formation	white mica	531±3.6	upper limit	Relict older/inherited age	297-535°C
				495±1.1	sub-plateau	min. formation age of boudinaged vein effect of younger undeformed vein	
				492±1.7	sub-plateau		
2746271	Non-boudinaged quartz-muscovite vein	Tapanappa Formation	white mica	519±6.5	upper limit	Relict older/inherited age	283-455°C
				493±0.9	plateau age	Min. formation age of non-boudinaged vein	
2746272	Two-mica schist	Tapanappa Formation	biotite-white mica composite	506±2.3	upper limit	Older age component	279-352°C
				498±1.6	intermediate ages	Ages similar to intrusives in the region. Reflects intrusion of boudinaged quartz-muscovite vein	
				496±1.7			
				488±1.6	intermediate limit	max. age of retrogression and garnet growth (inferred)	

Table 3. Summary of geochronology results from this study

550 6 Discussion

6.1 What have we dated? Cooling ages vs. deformation/growth ages

One of the key arguments presented while interpreting argon data is deciding whether the ages are cooling ages or if they represent important geological events experienced by the unit in question. Often, this is debated and sometimes it is difficult to present a simple answer.

The Ar-systematics in a mineral are affected by various parameters including and not limited to pressure, ambient temperature, closure temperatures, rate of cooling and composition of a mineral. In general, age spectra with more than one plateau age are often considered 'mineral mixtures', and are interpreted to have preserved information on the timing of different geological episodes of cooling and/or deformation, sometimes referred to as 'rim' and 'core' domains in a mineral preserving varied ages for simple understanding. The rims are usually considered as zones of partial argon loss mantling a core that is essentially closed and/or is more retentive of argon. When a mineral cools, the retentivity begins to increase and the age thus recorded by the mineral depends on its cooling rate and mineral composition among many factors. Ar-closure during rapid cooling occurs at a higher temperature than that for slow cooling and thus, the age preserved is likely to be in close agreement with the true age of the event dated (Lister and Baldwin, 1996). Similarly, a sample held at a higher ambient temperature for geologically significant periods of time would most likely preserve age(s) that may not have any geological significance due to loss of Ar by diffusion. This is sometimes true for plateaus, where well-defined plateaus are considered a characteristic of fast cooling whereas low apparent ages in the initial part of the age spectrum are characteristic of slow

575 cooling and a staircase morphology represents diffusive Ar-loss. The age spectrum profiles then generated would reflect the nature of cooling and would record different T-t histories (Lister and Baldwin, 1996). The more pronounced staircase nature of the spectrum in the initial parts of the experiment are indicative of slower cooling leading to more diffusive loss of argon and thus preservation of ages which are fair to be interpreted as 'cooling ages'.

580 To illustrate this concept better, the two locations from this study are explained here where $^{40}\text{Ar}/^{39}\text{Ar}$ apparent cooling and/or growth/deformation ages can be differentiated. As an example, the age spectra from the Backstairs Passage Formation (Fig. 7) displays a staircase morphology in the initial 20% of ^{39}Ar release for the host phyllite and the quartz-muscovite vein. Following the formation of fabric (S_{cren} and S_{diff}) in the host phyllite between c. 484-481 Ma, the cross-cutting quartz muscovite vein formed between c. 476-468 Ma after the host phyllite had substantially cooled. The age data for the muscovite from quartz muscovite vein shows the growth of a more-retentive white mica domain at c. 468 Ma (Fig. 7b) as it degasses in the higher temperature part of the experiment subsequent to the degassing of c. 476 Ma domain. Similarly, the c. 481 Ma age domain in the host phyllite is interpreted here as a mica growth/resetting event which is linked to the formation of the younger S_{cren} fabric overprinting the older S_{diff} fabric (Fig. 7a). In summary, the younger age components degassing in the high temperature parts of the heating experiment for the host phyllite and the quartz-muscovite vein are understood here as mineral growth/fabric formation ages and not 'cooling ages'. Moreover, the younger age limits in the samples are identified as minimum age constraints on the deformation and/or intrusion in the region, while the older age components constrain the maximum ages of these geological episodes. Furthermore, no geologically meaningful ages could be identified in the initial the 20% of ^{39}Ar release from both age spectra due to diffusive ^{40}Ar loss.

595 The age spectra for mineral separates from the Kanmantoo Mine area do not display a staircase morphology (Fig. 8) and have well-defined plateaus for sample 2746270 and 2746271. Thus, we interpret these to have cooled rapidly and preserving age(s) closer to or no younger than the true age(s) of the events dated. A sub-spectrum is observed in the first 5% of ^{39}Ar gas release which could be a relict older component. The age spectrum for sample 2746272 (Fig. 8a) shows a steep rise in the initial 10% of ^{39}Ar release, however, no interpretation has been made from this part of the age spectrum.

600 Thus, the interpreted ages for all units in this study are interpreted in context of the timing or duration of geological episodes at particular locations as outlined in Table 4.2 unless specifically outlined as cooling ages.

605

6.2 Timing of Delamerian Orogeny at Kanmantoo Mine area - data interpretation and implications

610 The new $^{40}\text{Ar}/^{39}\text{Ar}$ data from the Kanmantoo Mine area provide constraints on the timing of deformation in this region. However, we recognise that the Delamerian Orogen experienced a complex deformation and metamorphic history and, inferences drawn from this study, on a limited number of samples must necessarily serve as a foundation for further studies and are not intended to define the timing and duration of the Delamerian Orogeny as a whole.

615 The two-mica schist in the Kanmantoo Mine area, sample 2746272, yields an apparent age spectrum (Fig. 8a) that can be interpreted in context of regional and local parameters available. The upper limit of $506\pm 2\text{Ma}$ is interpreted as the likely maximum formation age of schistosity in this unit, however, this fabric may be even older. The age spectrum also records younger ages at c. 498-496 Ma that may reflect the influence of intrusion of the nearby boudinaged quartz-muscovite vein. The boudinaged quartz-muscovite vein itself yields a maximum intrusion age of c. 497 Ma from the muscovite age spectrum (Fig. 8c). This age spectrum also records ages at c. 493 Ma, which may reflect the effects of the later intruded undeformed quartz-muscovite vein. The three samples from this locality therefore appear to define a coherent set of events from schistosity formation by at least $506\pm 2\text{Ma}$, intrusion of an initial phase of quartz-muscovite veining at c. 497 Ma, continued deformation, and finally intrusion of an undeformed quartz-muscovite vein at c. 493 Ma.

625 The likely maximum formation age of schistosity at c. 506 Ma agrees well with the timing of D_2 Delamerian episode (c. 505 Ma; Foden et al., 2006). Using Arrhenius data (Fig. 9b), the diffusion domains for muscovite

630 within the Tapanappa Schist began closing to argon diffusion at 352°C until final closure at 279°C. Such low closure temperatures could explain the preservation of very minor older age component in the schist. We interpret the interval of c. 4 My between the two veins at c. 497 Ma and c. 493 Ma as a period of continued tectonic activity, possibly a regional fluid flow event. This could likely be a consequence of addition of heat into the crust, possibly due to prevailing extensional tectonics at the time as exemplified by the late-stage A-type granites and mafics in the region. The 493 Ma age marks the termination of deformation at the Kanmantoo Mine area.

635 In summary, the regional deformation fabric at the Kanmantoo Mine formed between c. 506-495 Ma based on the structural relationships and ages obtained from the host schist and quartz-muscovite vein, where the boudinaged vein truncates the two-mica schist no later than c. 495 Ma. Regional tectonics was active until the intrusion of non-boudinaged vein i.e., no later than c. 493 Ma.

640 Microstructure analyses are important in deciphering sequences of tectonic events in a region, principally the ones that have experienced a complex deformation history, and the Kanmantoo Mine area is one such example. Here, garnet growth is the last event to have occurred, justified by its static growth over the primary fabric in the schist (Fig. 6d-h). The presence of altered and pristine garnets hints towards their progressive growth during late syn- to post- Delamerian deformation. We observed the localisation of garnets growing over or near cleavage domains while they rarely grow proximal to the microlithons (quartz-rich domains). During active orogenesis, fluid flow channelization is structurally controlled e.g., more fluid flow in deformed zones/rocks (Oliver, 1996). Along with this, the availability of reactant minerals exerts primary control on fluid-flow and reaction front propagation (Skelton et al., 1995; Kleine, 2015). Thus, growth of garnets is restricted to schistosity (mica-rich domains) due to the availability of 'reactant minerals' for their formation relative to the microlithons. Such a mechanism is then more likely to alter and fracture the garnets in the vicinity of the schistosity relative to those growing in the microlithons. We approximate that garnet formation could relate to the circulation of hot-hydrothermal fluids in the area and associated evolving P-T conditions during retrogressed metamorphic period.

650

655 Flottmann et al., (1996) reported elevated concentration of MnO in the Tapanappa Formation schists, where enrichment is associated with exhalative fluids also evident through high MnO concentration of the garnets in this study (Supplement 4). It is probable that hydrothermal fluids in the area provided the necessary 'ingredients', concomitantly incorporating Mn concentrations from the host schist to form garnets at suitable P-T conditions. Our interpretation of $^{40}\text{Ar}/^{39}\text{Ar}$ data from the host schist estimates the interval of c.493-487Ma as the period of garnet growth. Following this, exhumation of the schists may have destabilised the garnets forming secondary biotite as observed in our microstructures (Fig. 6g-h). This study has not attempted to precisely constrain the timing of garnet formation; therefore, this age estimate is rather relative.

660

Figure 10 is a time-space plot that represents our samples in relation to the established constraints.

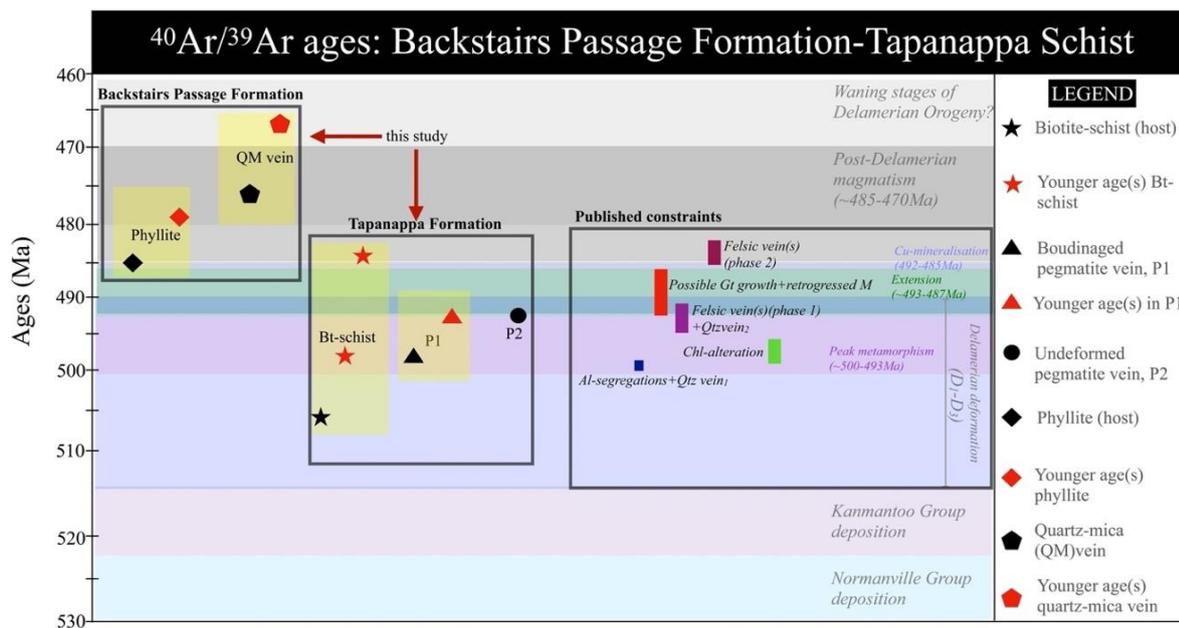

Figure 10. Time-space plot combining major geological episodes and results obtained from this study

The data obtained here has regional implications and agrees well with the established U-Pb, Rb/Sr and Sm-Nd ages reported in Turner et al, 1996; Foden et al., 2006; Foden et al., 2020. In addition to this, new age data with low uncertainty is reported. This paper highlights the complexity of dating and interpreting $^{40}\text{Ar}/^{39}\text{Ar}$ age results of micas from different stratigraphic units. Such age information is crucial for a region where geological episodes have occurred 1-2 My apart. In summary, the evidence of deformation events at Kanmantoo Mine area equate to the regional established D_2 and D_3 events are well observed in our $^{40}\text{Ar}/^{39}\text{Ar}$ age data.

675

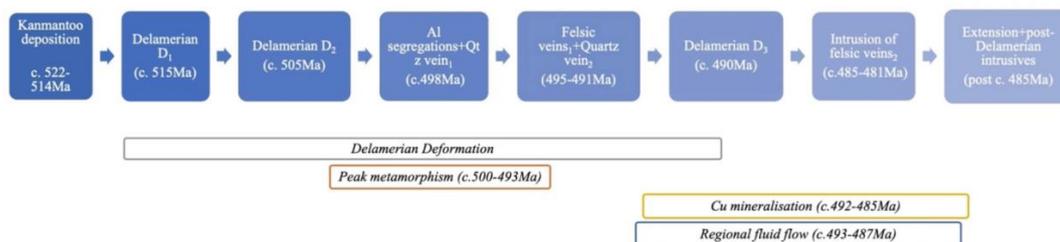

6.3 Timing of regional and local tectonic events

Previous constraints on the timing of geological events that have occurred at the Kanmantoo Mine area lay the foundation for this study, however knowledge gaps remain. We have attempted to fit our results into the established sequence of events. Below is a visual representation of the simplified TSD (Fig. 11) for the Tapanappa Schist, compiling information on local and regional events, geochronology, and microstructural analyses.

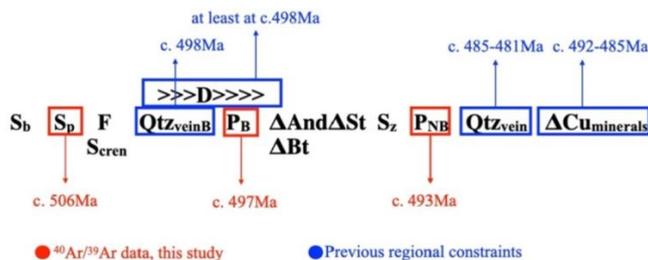

680

6.4 Implications of younger $^{40}\text{Ar}/^{39}\text{Ar}$ ages in the stratigraphically older Backstairs Passage Formation

690

The Backstairs Passage Formation is stratigraphically older than the Tapanappa Formation, yet it has experienced lower grade metamorphism than the overlying Tapanappa Formation. Furthermore, the Backstairs Passage Formation records ages ranging from c. 484-481 Ma in the phyllite (sample 2746269, Fig. 7a), which are younger than the ages recorded in the Tapanappa Formation (sample 2746272, Fig. 8a).

695

The relationship between metamorphic grade, stratigraphic level and argon ages can be explained in two ways:

700

1. Based on Arrhenius plot analyses (Fig. 9), the host schist and phyllite have similar closure temperature ranges for the biotite-white mica composites dated in this study. As Tapanappa Formation overlies the Backstairs Passage Formation, its early exhumation relative to the underlying Backstairs Passage Formation could explain the older Ar-ages preserved in the Tapanappa Formation. The Ar-diffusion systematics would have closed to diffusion earlier in the schist than in the underlying phyllite. Also, the higher ambient temperatures experienced by the phyllite would have kept it as an 'open-system' to argon diffusion for longer periods than the overlying schist.
2. The proximity of the Tapanappa Formation (schist) to the metamorphic core of the Delamerian Orogen at Reedy Creek than the Backstairs Passage Formation (phyllite) could explain the difference in the argon ages. The schist would have been affected earlier by the migmatization event (c. 514 Ma, U-Pb zircon age Rathjen Gneiss as the source intrusive for migmatization; Drexel and Preiss, 1995) hence recording older ages than the phyllite which was away from the metamorphic core. The dissipated heat from the migmatization event would have reached the schist first and affected the phyllite later leading to mineral growth first in the schist (older ages) and later in the phyllite (younger ages).

715

The age range of c. 484-481 Ma observed in the Backstairs Passage Formation can be interpreted in two ways. The first way is to understand the S_{diff} fabric to have formed at least by c. 484 Ma followed by S_{cren} which formed at least by c. 481 Ma. The other interpretation is to consider the c. 484-481 Ma interval to bracket S_{cren} fabric formation only. Following this, the micaceous vein (sample 2746268) must have intruded the host after c. 476 Ma, with the age range in this sample from c. 476-468 Ma being younger than the youngest age of the mica from the phyllite host (c. 481 Ma).

720

In summary, S_{cren} had developed by c. 481 Ma and the cross-cutting quartz-muscovite vein intruded the phyllite between c. 476-468 Ma. The regional deformation affected the phyllite at Backstairs Passage Formation 10 My later than the Tapanappa Formation at the Kanmantoo Mine area. Deformation affecting

725

755 The younger ages of c. 484-481 Ma observed in the stratigraphically older Backstairs Passage Formation record the timing of fabric formation in this unit with two possible interpretations- either the main foliation formed at c. 484 Ma followed by crenulations forming at c. 481 Ma or the interval of c. 484-481 Ma brackets the formation of crenulation cleavage formation only. The micaceous quartz vein intruded the phyllite between c. 476-468Ma. The ages c. 484-468 Ma are younger than the conventional main interval of Delamerian deformation (c. 514-490 Ma) and are the new findings from this study.

760 These younger ages observed from the Backstairs Passage Formation within the Kanmantoo Group are suggestive of protracted periods of Delamerian deformation and its differentiated nature (effects not observed in the Tapanappa Formation) extending to as young as c. 468 Ma, in contrast to previous studies that have interpreted deformation to have ceased by c. 490 Ma.

765 **Competing interests.** The author has declared that there are no competing interests.

770 **Acknowledgements.** Mr. Shane Paxton is thanked for his guidance with mineral separation and sample preparation training. Dr. Arun Ojha is thanked for his assistance with insightful discussions and proof-reading of the manuscript. Dr. Anthony Reid and Dr. Geoff Fraser are thanked for their help with insightful discussions regarding the age data.

775 **Financial support.** This research forms part of a PhD project undertaken by the contact author from 2019-2023 and has been supported by the Mineral Exploration Cooperative Research Centre whose activities are funded by the Australian Government's Cooperative Research Centre Program. All samples were financially supported by the AuScope National Argon Map and the ANU Argon Lab.
