6 **Abstract**

7 During the 2020 austral summer, the pristine atmosphere of the southwest Indian Ocean
8 (SWIO) basin experienced significant perturbations. This study examines the variability of
9 aerosols and carbon monoxide (CO) over this remote oceanic region and investigates the
10 underlying processes in the upper troposphere – lower stratosphere (UT-LS). Aerosol profiles
11 in January and February 2020 revealed a multi-layer structure in the tropical UT-LS. Numerical
12 models (FLEXPART and MIMOSA) indicated that the lower stratospheric aerosol content was
13 influenced by the intense and persistent stratospheric aerosol layer generated during the 2019-
14 20 extreme Australian bushfire events. A portion of this layer was transported eastward by
15 prevailing easterly winds, leading to increased aerosol extinction profiles over Reunion on
16 January 27th and 28th. Analysis of advected potential vorticity revealed isentropic transport of
17 air masses containing Australian biomass burning aerosols from extra-tropical latitudes to
18 Reunion at the 400 K isentropic level on January 28th. Interestingly, we found that biomass
19 burning (BB) activity in eastern Africa, though weak during this season, significantly
20 influenced (up to 90%) the vertical distribution of CO and aerosols in the upper troposphere
21 over the SWIO basin. Ground-based observations at Reunion confirmed the simultaneous
22 presence of African and Australian aerosol layers. This study provides the first evidence of
23 African BB emissions impacting CO and aerosol distribution in the upper troposphere over the
24 SWIO basin during the convective season.

25 **1. Introduction**

26 Significant amounts of aerosols and trace gases, such as carbon monoxide (CO), are released
27 into the atmosphere during biomass burning (BB) events in the Southern Hemisphere,
28 particularly in Southern America and Southern Africa from July to November (Bencherif et al.,
29 2020; Garstang et al., 1996; Holanda et al., 2020). These activities disrupt the vertical
30 distribution of gases and aerosols, potentially reaching the stratosphere (Andreae and Merlet,
31 2001; Héron et al., 2020). Under specific meteorological conditions, pyro-convection events
32 can directly inject soot and smoke into the stratosphere (Dowdy and Pepler, 2018; Fromm et
33 al., 2010). The radiative impact of these particles and gases depends on their abundance, vertical
34 distribution, and residence time, influencing their dispersion (Darbyshire et al., 2018; Morgan

1 et al., 2019). Transported over long distances, these aerosols and gases can affect the
2 composition of traditionally aerosol-free regions.

3 The southwest Indian Ocean (SWIO) basin stands out as one of the Earth's pristine regions
4 where aerosol concentration is predominantly governed by sea salts (Dufлот et al., 2022).
5 Characterized by a wet season (December to April) and a dry season (May to November), the
6 SWIO region's atmospheric composition during the dry season is significantly influenced by
7 Southern Hemisphere BB activity (Clain et al., 2009; Edwards et al., 2006; Kaufman et al.,
8 2003; Swap et al., 2003). Studies have highlighted the crossing of BB plumes over South Africa
9 during the dry season, with southern African BB emissions primarily reaching the SWIO basin
10 via five identified transportation modes (Edwards et al., 2006; Garstang et al., 1996). Situated
11 in the subtropical southern Indian Ocean at the convergence of air masses from southern Africa,
12 Reunion Island (21.0°S, 55.5°E) provides an ideal location to study the impact of regional
13 transport on atmospheric composition over the SWIO basin. Ozone radiosonde and ground-
14 based lidar observations at Reunion have revealed a significant annual increase in tropospheric
15 ozone during the August-November period, aligned with the BB season in southern Africa and
16 Madagascar (Clain et al., 2009).

17 Additionally, long-range transport of BB plumes from South America can influence the tropical
18 tropospheric composition over the SWIO basin (Dufлот et al., 2010 2022; Zhou et al., 2018).
19 By combining ground-based observations of carbon monoxide (CO) from a Fourier Transform
20 Infrared (FTIR) spectrometer installed at Reunion with FLEXPART model simulations, Dufлот
21 et al. (2010) demonstrated the potential of southern African and southern American BB events
22 to inject substantial amounts of ozone precursors such as CO and aerosols throughout the
23 troposphere over the SWIO basin. This synergy of CO and aerosol observations aids in
24 understanding the influence of BB events on aerosol burden evolution (Bègue et al., 2021;
25 Bencherif et al., 2020; Jones et al., 2001). Recent analysis of Aerosol Optical Depth (AOD)
26 from sun-photometer data at Reunion over 12 years by Dufлот et al. (2022) revealed that BB
27 activity explains 67% of AOD variability, with Southern Africa and southern America
28 contributing 22% and 20%, respectively. Despite Australia's reputation for intense BB events
29 (Fromm et al., 2006; 2010; De Laat et al., 2012), its contribution to observed AOD variability
30 over Reunion is relatively low (4.7%).

31 The Australian BB activity primarily occurs in the northern part of the continent between
32 September and January, although the most severe fires typically occur in southeastern Australia.
33 Extreme fires in this region during the austral summer can lead to pyro-convection events, with
34 a significant impact on the stratosphere at regional and global scales. The unprecedented 2019-

1 20 fire season, known as the "Black Summer," witnessed numerous pyro-convection outbreaks,
2 injecting approximately 0.9 Tg of smoke into the stratosphere (Yu et al., 2021). This smoke
3 mass, containing 2.5% black carbon, induced a 1 K warming in the stratosphere of the Southern
4 Hemisphere mid-latitude for more than 6 months following its injection. The smoke layer was
5 advected by westerly winds, dispersing across all extra-tropical latitudes in the Southern
6 Hemisphere. The optical characteristics of the stratospheric smoke layer were measured by lidar
7 systems in Chile and Argentina, with the smoke layer extending from 9 to over 30 km in height
8 (Ohneiser et al., 2022). The presence of this smoke layer significantly impacted the record-
9 breaking ozone hole over Antarctica in September-November 2020, as reported by Tencé et al.
10 (2022). Despite the extensive research on the impact of Australian fires on the stratospheric
11 composition and circulation over extra-tropical latitudes, relatively little attention has been paid
12 to their influence over tropical/subtropical latitudes.

13 This study aims to document the transport of the Australian smoke layer in the southern
14 subtropics over the Indian Ocean during the January-February period, corresponding to the wet
15 season in the SWIO basin. The intensity of convective activity during this season, with the
16 presence of the Inter-Tropical Convergence Zone (ITCZ) over the entire basin, often leads to
17 tropical depressions reaching the stage of tropical cyclones (Lashkari et al., 2017; Barthe et al.,
18 2021; Neuman et al., 1993). The Regional Specialized Meteorological Centre (RSMC) at
19 Reunion reported the development of 6 tropical cyclones and 4 tropical storms in the SWIO
20 basin during the cyclonic season 2019-20.

21 The study is structured as follows: Section 2 outlines the observations and the model employed
22 to investigate aerosol layer transport. Section 3 reviews the formation and transport of the
23 Australian aerosol layer across the Southern Hemisphere. Section 4 analyzes the impact of the
24 Australian BB plume on aerosol and CO variability over the SWIO basin. Section 5 discusses
25 the influence of convective activity on aerosol smoke layer transport over the SWIO basin.
26 Finally, Section 6 provides a summary and future perspectives of the study.

27 **2. Instrumentation and Model description**

28 **2.1 Aerosols data sets**

29 The aerosol datasets used in this study resulted mainly from two ground-based observations
30 sites from the Network for the Detection of Atmospheric Composition Change (NDACC,
31 www.ndacc.org) network as well as a suite of spaceborne sensors products.

32 **2.1.1 Lauder ground-based lidar**

1 Measurements of aerosol optical properties at Lauder (45.0°S; 169.7°E) have been performed
2 using lidars since 1992. The lidar system, detailed by Sakai et al. (2016), utilizes a Nd:YAG
3 laser beam at 532 nm with linear polarization. The lidar detects Rayleigh-Mie backscattering at
4 532 nm with parallel and perpendicular components. Extinction and backscatter coefficients
5 were derived using the methodology outlined by Fernald et al. (1984), incorporating an aerosol
6 extinction-to-backscatter ratio, known as the lidar ratio (LR). LR values for January-May 2020
7 are 88 sr and 60 sr for altitudes above and below 23 km, respectively, determined through signal
8 attenuation methodology described by Uchino et al. (1983) and Young (1995). Aerosol
9 depolarization was computed from the backscatter ratio and the total linear volume
10 depolarization ratio (Sakai et al., 2003), calculated as the ratio of perpendicular to parallel
11 components of the backscattered signal at 532 nm. To analyze aerosol variability attributed to
12 Australian fires, a background profile was defined using measurements taken during periods
13 without significant atmospheric disturbances, such as volcanic eruptions or pyro-convection
14 outbreaks. In this study, the background extinction profile at Lauder was constructed from
15 measurements made between 1997 and 2004.

16 **2.1.2 Reunion Island ground-based lidars**

17 The Atmospheric Physics Observatory of La Réunion (OPAR) serves as a permanent station
18 for long term atmospheric observations (Baray et al., 2013). Two lidar systems operating the
19 Maïdo Observatory, situated at 2200 m above mean sea level (AMSL), retrieve ozone and
20 aerosol profiles in the UV (355 nm) and visible (532 nm) parts of the light spectrum. These
21 systems, LiO3T (532 nm) and LiO3S (355 nm), are described by Baray et al. (2006). Extending
22 from approximately 15 km to the middle stratosphere (~35 km), these lidars provide high-
23 resolution aerosol optical property measurements (extinction, backscatter ratio) with a vertical
24 resolution of 15 m. By employing two distinct wavelengths, the Reunion lidar profiles facilitate
25 the assessment of the Angström exponent of aerosols between 355 nm and 532 nm, providing
26 insight into the aerosol's extinction behavior and microphysical properties, particularly particle
27 size. A small Angström exponent typically indicates a coarse mode driving the aerosol's optical
28 properties. Further details on the Angström exponent, aerosol size, and their relative error
29 concerning extinction properties are elaborated in Baron et al. (2023) and its supplementary
30 information. The inversion process in this study utilized the Klett method (Klett, 1985),
31 assuming a lidar ratio of 60 sr, typical of aged biomass burning (BB) aerosols (Müller et al.,
32 2007). Nine lidar profiles recorded during the January-March 2020 period were employed, with
33 the background extinction profile at Reunion constructed from measurements taken between

1 2017 and 2019, excluding the perturbation induced by the Calbuco eruption in April 2015
2 (Bègue et al., 2017).

3 **2.1.3 CALIOP**

4 Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) is a nadir pointing lidar orbiting
5 the Earth onboard the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation
6 (CALIPSO) satellite since 2006. CALIOP operates at two wavelengths (532 and 1064 nm) and
7 measures total attenuated backscatter vertical profiles with altitude-varying vertical (30–300 m)
8 and horizontal (300–5000 m) resolution. In the present study, we used CALIOP product version
9 3.3 level 1B which includes calibrated attenuated backscatter along with collocated
10 meteorological information provided by the National Aeronautics and Space Administration
11 Global Modeling and Assimilation Office (GMAO). These data undergo postprocessing using
12 a treatment described and validated by Vernier et al. (2009). Scattering Ratio (SR) profiles used
13 for the detection of the smoke plume are calculated following the methodology described by
14 Khaykin et al. (2018). Initially, the collocated GMAO data correct the backscatter profiles of
15 molecular attenuation and ozone absorption. Subsequently, the SR was calculated as the ratio
16 of total and molecular backscatter coefficients, with the latter derived from GMAO air density.
17 SR profiles were recalibrated at 36-39 km, following the methodology given by Vernier et al.
18 (2009). Data with depolarization larger than 30 % were discarded to the treatment in order to
19 avoid aliasing cirrus clouds above the thermal tropopause. CALIOP data were obtained from
20 the ACDISC data archive (<ftp://acdisc.gsfc.nasa.gov>) hosted by NASA Goddard Space Flight
21 Center.

22 **2.1.4 OMPS-LP**

23 The Ozone Mapper and Profiler Suite Limb profiler (OMPS-LP) has been operational on the
24 Suomi National Polar Partnership (NPP) satellite platform since October 2011. In this study,
25 we utilized aerosol extinction profiles from the NASA OMPS data product version 2.0 (Taha
26 et al., 2021). These profiles were retrieved from the limb scattering solar radiation
27 measurements at wavelengths of 510, 600, 675, 745, 869, and 997 nm, chosen to minimize the
28 impact of gaseous absorption. Aerosol extinction measurements are provided from 10 to 40
29 km altitude on a 1 km vertical grid, resulting in near-global coverage every 3-4 days. The OMPS
30 data were employed to investigate the global transport of aerosol BB plumes and their influence
31 on the aerosol variability over Reunion. Following the recommendation of Taha et al. (2021),
32 we used aerosol extinction measurements at 745 nm. The background extinction profile was
33 constructed using measurements obtained from 2012 to 2014 and from 2016 to 2018, excluding

1 periods affected by the Calbuco eruption (Bègue et al., 2015). The OMPS data are downloaded
2 from: <https://ozoneaq.gsfc.nasa.gov/>.

3 Additionally, we utilized aerosol absorbing index (AAI) data from OMPS to characterize the
4 transport of the aerosol BB plume. The AAI enables the detection of absorbing aerosols by
5 quantifying the spectral difference between specific pairs of UV wavelengths. Positive AAI
6 values indicate the presence of UV-absorbing aerosols such as dust and smoke, while negative
7 values suggest non-absorbing aerosols. Values close to zero typically correspond to the
8 presence of clouds. The AAI data used in this work are available on the NASA Earth Data
9 platform: <https://earthdata.nasa.gov/earth-observation-data>

10 **2.2 CO and water vapor measurements**

11 **2.2.1 FTIR**

12 Ground-based Fourier Transform Infrared (FTIR) spectrometers enable the retrieval of total
13 columns and volume mixing ratio profiles of trace gases like CO with high accuracy and
14 precision (Clerbaux et al., 2008; Vigouroux et al., 2015; Zhou et al., 2019). In the present study,
15 FTIR observations from Lauder and Reunion conducted as part of the framework of the
16 NDACC and Total Carbon Column Observing Network (TCCON) networks respectively, are
17 utilized. The FTIR systems and data retrieval methods are extensively described by de Mazière
18 et al. (2018) and Wunch et al. (2015).

19 At Lauder, CO measurements have been made since the early 1990s using a Bruker high-
20 resolution spectrometer over a wide spectral range (around 600–4500 cm^{-1}). The CO dataset
21 used in this study aligns with that used by Bègue et al., (2021) and Kloss et al., (2019),
22 providing details on spectral measurements, CO retrieval strategy, and derived CO column
23 abundances..CO total columns and volume mixing ratio profiles for the Lauder site, spanning
24 a 48-layer atmosphere (0.37–100 km asl), were obtained from the NDACC website
25 (<http://www.ndacc.org>).

26 At Reunion, FTIR measurements have been routinely conducted since 2011 within the TCCON
27 network using a Bruker high-resolution spectrometer. The GGG2014 code (Wunch et al., 2015)
28 was employed to simultaneously retrieve CO and O₂ total columns. The column-averaged dry-
29 air mole fraction of CO was then determined as the ratio between the retrieved CO total columns
30 and the total columns of dry air, leveraging the O₂ total columns provided by TCCON. CO
31 abundance data for Reunion were sourced from the TCCON database (<https://tccondata.org>).
32 For this study, the background evolution of CO is established using measurements obtained
33 between 2015 and 2018 (De Mazière et al., 2017).

34 **2.2.2 IASI**

1 The Infrared Atmospheric Sounding Interferometer (IASI) utilizes a Fourier Transform
2 spectrometer to measure chemical species like CO (Clerbaux et al., 2009; Coheur et al., 2009).
3 Operating aboard the three Metop satellites, IASI retrieves CO total and partial columns occurs
4 in near real-time from the nadir radiances measured by the instrument in the thermal infrared
5 covering wavelengths from 6.62 to 15.5 μm . This enables the generation of global distributions
6 for both day and night measurements, covering the troposphere and lower stratosphere. The
7 Fast-Optimal Retrievals on Layers for IASI (FORLI-CO, Hurtmans et al., 2012) was employed
8 to retrieve total and partial CO columns, while also flagging data contaminated by clouds. For
9 this study, CO columns from IASI instruments on Metop-A (operating since 2006) and Metop-
10 B (operating since 2012) are utilized. The IASI products used in this study can be accessed
11 through the AERIS platform: <https://iasi.aeris-data.fr/CO>.

12 **2.2.3 MLS**

13 The Microwave Limb Sounder (MLS) on board the Aura satellite has been conducting vertical
14 profile measurements of various trace gases in the UT-LS since 2004 (Waters et al., 2006). For
15 this study, CO and water vapor observations (version 5) from January 2017 to January 2020
16 were utilized, covering a global domain spanning between 10°S and 25°S in latitude and 30°E
17 and 60°E in longitude. All MLS version 5 retrieval quality flags (quality, status, convergence,
18 and precision) were meticulously followed for all analyses (Livesey et al., 2022). The
19 recommended pressure levels for science applications with CO and water vapor MLS data range
20 from 0.0215 to 215 hPa ([Version 5.0x Level 2 and 3 data quality and description document](#),
21 nasa.gov). The CO and water vapor profiles from MLS were obtained from the Atmospheric
22 Composition Data and Information Services Center (ACDISC) archive
23 (<ftp://acdisc.gsfc.nasa.gov>) hosted by the NASA Goddard Space Flight Center.

24 **2.3 Numerical Modelling**

25 **2.3.1 FLEXPART Model**

26 The Lagrangian transport and diffusion model FLEXPART version 10.4 is utilized in this study
27 to simulate the long-range transport of atmospheric tracers (Pisso et al., 2019; Stohl et al., 2005).
28 This version of FLEXPART incorporates improvements in various aspects, including
29 microphysical and chemical parameterizations (Pisso et al., 2019). Source identification was
30 achieved by releasing particles from a receptor location and simulating backward trajectories
31 (Seibert and Franck, 2004). Model calculations rely on ERA5 reanalysis meteorological
32 observations from ECMWF, extracted at 3-hourly intervals with a horizontal resolution of 0.5°
33 $\times 0.5^\circ$ and a vertical resolution of 137 hybrid model levels (Hersbach et al., 2020).

34

1 The model simulations involved aerosol (Black Carbon-BC and Organic Carbon-OC) and CO
2 tracers, considering removal mechanisms such as dry and wet deposition for aerosols and OH
3 reactions for CO. The parametrization (default values for the scavenging coefficient and the
4 nucleation efficiency and size) for the BC was found in the paper of Grythe et al. (2017) and
5 the chemical parameterization for CO was in default in FLEXPART data but can be found in
6 the reference kinetics database IUPAC (Atkinson et al., 2006). Each simulation consists of
7 20,000 particles released over Reunion daily, at altitudes between 15 and 19 km every 0.5 km,
8 and traces them backward in time over one month. Simulations of backward trajectories over
9 long periods (1-2 months) have been explored in previous studies (Aliaga et al., 2021; Eckhardt
10 et al., 2017; Xu et al., 2021). The simulations included turbulence parameterization and
11 convection activation (Forster et al.; 2007).

12 Model outputs were distributed over a regular vertical grid from ground level to 25 km in
13 altitude. These outputs were used to assess the residence time of the BB aerosols and CO, as
14 well as their contributions to the variability of aerosol optical properties and CO over the SWIO
15 basin. Discussions were based on emission sensitivity analysis from backward simulations. The
16 residence time of particles was integrated over the entire atmospheric column and latitude to
17 create averaged maps and longitudinal cross-sections, providing insights into the geographical
18 and vertical dispersion of BB aerosols.

19 The BB contributions to the vertical distribution of CO and the aerosol optical properties were
20 calculated by combining the potential emission sensitivity (PES) with an emission inventory,
21 as explained in Stohl et al. (2003). PES represents FLEXPART particles injected at the
22 layer/altitude of emissions. Pyro-convection was not considered in the model. BB aerosol and
23 CO mass concentration profiles were obtained by summing all output grid points. For BB
24 emissions, a layer between 0 and 3 km was used for Africa and between 9 and 16 km for
25 Australian fires.

26 The Global Fire Assimilation System (GFAS) version 1.2 emission (Kaiser et al., 2012) and the
27 Global Air Pollutant Emissions - EDGAR v6.1 emission inventory
28 (<http://edgar.jrc.ec.europa.eu>) for CO were utilized. These emissions represent total CO
29 emissions from anthropogenic activities, excluding large scale BB. Multiplying the CO
30 emission flux from this inventory by the FLEXPART emission sensitivity for a layer between
31 0 and 1 km provides the contribution of anthropogenic sources to total CO abundance. Finally,
32 aerosol mass concentration profiles are converted into extinction profiles using the Mie
33 scattering model, considering spherical particles with a density of 2 g.cm^{-3} and a refractive
34 index of $2.0 + 0.64i$ for optically absorbing aerosols.

2.3.2 MIMOSA Model

The Modèle Isentropique de transport Mésoéchelle de l'Ozone Stratosphérique par Advection (MIMOSA) model is a potential vorticity (PV) advection model designed to run on isentropic surfaces with a resolution of $0.3^\circ \times 0.3^\circ$ (Hauchecorne et al., 2002). Its advection scheme is semi-Lagrangian with a time step of 1 h and is driven by ERA5 reanalysis meteorological observations. The model can be continuously run to track the evolution of PV filaments over several months. The accuracy of the MIMOSA model has been evaluated and validated in previous studies. Hauchecorne et al. (2002) assessed its accuracy, and it was validated against airborne lidar ozone measurements using a correlation between PV and ozone, as ozone behaves as a quasi-conserved chemical tracer on timescales of a week or so within most of the lower stratosphere (Heese et al., 2001). Moreover, the MIMOSA model can be used to determine the origin of air masses influencing a given site, similar to an isentropic Lagrangian trajectory model. This capability has been demonstrated in various studies (Bencherif et al., 2011; Hauchecorne et al., 2002; Portafaix et al., 2003; Bègue et al., 2017).

3. Formation of an intense stratospheric BB plume over Australia

Figure 1 shows the AAI obtained from OMPS on board CALIOP over New-Zealand on 1st January. Following the strongest outbreak during New Year's Eve, a wide plume of BB aerosol with large values of AAI (higher than 12) is transported toward the Tasman Sea on 1st January 2020 (Fig. 1a). The CALIOP attenuated SR profiles are calculated along the CALIOP track (blue line in Fig. 1a) crossing the absorbing aerosol plume above New-Zealand. CALIOP observations reveal a broad region of high values (ranging from 10 to 25) between 36° S and 46° S centered at 16.5 km altitude (Fig. 1b).

Figure 2a illustrates the daily extinction profiles at 532 nm derived from lidar measurements over Lauder (New-Zealand) between 1st December 2019 and 1st April 2020. Note that a strong convective activity prevented lidar operations between mid-December 2019 and the 1st January 2020. Figure 2a reveals high values in the extinction (from $3 \times 10^{-3} \text{ km}^{-1}$ to $9 \times 10^{-3} \text{ km}^{-1}$) in the stratosphere over Lauder starting in mid-January 2020, one order of magnitude above the typical stratospheric aerosol background (Sakai et al., 2016). The vertical extent of the plume increased significantly between mid-January and 1st April 2020 with an aerosol layer spanning from 11.5 to 20 km. The ascent of BB aerosol could be due to adiabatic heating effect (De Laat et al., 2012). A statistically significant increase of sAOD (between 15 and 30 km) is observed in January 2020 (2.5 times higher than background value) and still visible in April 2020 with same amplitude (Fig. 2b).

1 The same observation can be made for the carbon monoxide in the UTLS over New-Zealand,
2 as shown in Figure 3 with the observations made by the FTIR at Lauder. Prior to the convective
3 period, the maximum of CO mixing ratio (120-130 ppbv) is observed in the troposphere (Fig.
4 3a). An increase of CO mixing ratio in the lower stratosphere is visible from mid-December
5 2019 with the maximum (50-90 ppbv) observed in the UT-LS (9-13 km). The partial column
6 of CO (between 9 and 30 km), calculated from FTIR, reaches its maximum values (~33 %
7 higher than background value) in January 2020 and slightly decreases in April 2020 (~24%
8 higher than background value) (Fig. 3b). Above the lower stratosphere, the CO mixing ratio
9 decreases significantly due to photochemical reactions which are more efficient with altitude
10 (Brasseur and Solomon, 2005).

11 Our works suggest that the injection of CO and absorbent aerosols ends up de-correlated in
12 altitude given their different properties. In order to extend the discussion, the spatial dispersion
13 of the Australian BB plume in the Southern Hemisphere will be discussed in the next section.

14 **4. Transport of the Australian BB plume over the SWIO basin**

15 **4.1 Aerosol and CO variability over a subtropical site: Reunion**

16 Figure 4 shows time-averaged maps for AOD from OMPS and CO partial column (9-30 km)
17 from IASI observation. The transport of the aerosol (with values ranging from 6×10^{-3} to $1 \times$
18 10^{-2} km^{-1}) and CO (with values ranging from 6 to $8 \times 10^{17} \text{ molecules. cm}^{-2}$) plume over the
19 Southern Pacific occurred mainly within the 18°S – 60°S latitudinal band. One can observe an
20 aerosol band (with values ranging from 5×10^{-3} to $9 \times 10^{-3} \text{ km}^{-1}$) across the Southern
21 Hemisphere between 40°S and 60°S during the 9-16th January 2020 period (Figure 4a). The
22 Australian aerosol plume has already circled the Southern Hemisphere during the first two
23 weeks of January 2020. The same conclusion cannot be made for CO from space-borne
24 observations (Figure 4b). One can observe weak values of CO (less than $5 \times 10^{17} \text{ molecule.cm}^{-2}$)
25 over southern Atlantic and without a real link with the large plume observed over southern
26 Pacific (Fig. 4b).

27 Figure 5a depicts the evolution of the sAOD at 532 nm calculated between 15 and 30 km from
28 the ground-based lidars and OMPS observations over Reunion from 1st January to 1st March
29 2020. OMPS extinctions are converted to 532 nm using an Angström exponent for the 532–745
30 nm wavelength pair of 1.9, as prescribed by Taha et al. (2021). Reunion witnessed an abrupt
31 increase in the aerosol loading (three times above the typical background) as of 16th January
32 2020 according to satellite observations. The sAOD values observed between 16th January and
33 1st March 2020 are higher than those observed during the passage of the Calbuco plume over

1 Reunion site, which did not exceed 0.013 (Bègue et al., 2017). The increase of sAOD in mid-
2 January coincided with an increase of CO, as shown in Figure 5b based on the use of partial
3 columns (between 9 and 30 km) and CO abundance from IASI and FTIR at the same site and
4 over the same period. The ground-based observations show that the CO abundance observed
5 during this increased phase is on average 20% higher than the values observed during the
6 background period (Fig. 5b). The evolution of sAOD and CO observations in mid-January
7 suggests that Reunion, and its surrounding, have been influenced by the transport of the
8 Australian BB plume.

9 Figure 6 shows aerosol extinction profiles at 355 nm over Reunion for selected days in January
10 or February compared to the January or February background profiles. The two first weeks of
11 January 2020 are representative of the January typical background (shaded area), as illustrated
12 on 13th January 2020 (Fig. 6a). Conversely, the extinction profiles at the end of January 2020
13 (27th and 28th) are marked by a significant increase (4 times higher than the background values)
14 located in the lower stratosphere between 16.8 and 18 km altitude (equivalent to potential
15 temperature levels 380-404 K). On 28th January, the extinction profile exhibits a sudden
16 increase at 17.4 km (~400 K) and quickly decreased afterwards to values observed the previous
17 day (Fig. 6a). The values of extinction (10 to $17 \times 10^{-3} \text{ km}^{-1}$) observed in the lower stratosphere
18 on these two days are of the same order as those observed at Lauder a few days after the pyro-
19 convective event (Fig. 2). In February, the extinction profiles clearly exhibit two significant
20 aerosol layers with the first one located between 16 and 19.5 km (370-440 K) and the second
21 one between 20 and 22.5 km (465-500 K) (Fig. 6b).

22 To further discuss the optical properties of these aerosol layers, the Angström exponent has
23 been calculated between 355 nm and 532 nm from the ground-based lidar measurements (Figs.
24 6c and 6d). In February, the Angström exponent values reveal that the two aerosol layers consist
25 mainly of small aerosol particles (Fig. 6d), consistent with a stratospheric smoke layer (Haarig
26 et al., 2018; Hu et al., 2019; Ohneiser et al., 2021). In January, the profile of Angström exponent
27 exhibits more variability in the UT-LS (Fig. 6c) with values ranging from 0.6 to 1.9, on 27th
28 and 28th January. The wide range of Angström exponent values suggests that the aerosol layer
29 is not homogeneously distributed at this stage and might be interpreted as a mixture of fresh
30 and aged smoke layers (Fig. 6c). Indeed, Müller et al, 2007 showed that ageing of transported
31 smoke translates into a decreasing of the Angström exponent. This may indicate growth and
32 removal processes (e.g., coagulation, condensation, sedimentation) which can modulate the
33 morphology and mixing state of the aerosol layer during its transport (Burton et al., 2015; Hamil
34 et al., 1997).

4.2 Origin of the air masses

To analyze the origin of air masses at Reunion on 27th and 28th January, one-month backward trajectories were calculated using FLEXPART (Aliaga et al., 2021; Eckhardt et al., 2017; Xu et al., 2021). A period of one month was chosen because it refers to the time lapse separating the pyro-convective outbreak event and the day of the measurement at Reunion. The representation of the potential emission sensitivity (PES) from back-trajectories simulations initialized at 18 km originating from Reunion on 27th and 28th January 2020 are presented in Figure 7.

Figures 7A-1 and 7B-1 display the horizontal trajectories, whereas vertical movement is shown in Figures 7A-2 and 7B-2, respectively. The vertical transect of FLEXPART back trajectories in Figure 7A-2 confirms a high probability of air mass contribution from Australia if the fires emissions are directly injected into the stratosphere by convection (black rectangle in the figure), (i.e. layer of 9 to 16 km of injection taken for the PES, see section 2.3.1). According to FLEXPART results, part of the Australian smoke layer is advected zonally by the prevailing easterly winds and is observed over Reunion on 27th and 28th January 2020 at 18 km. The FLEXPART simulations also suggest that Reunion is influenced by eastward transport of air masses. This pathway is clearly visible on 28th January 2020 (Figs. 7B-1 and 7B-2). Air masses from high latitudes seem to cross the subtropical latitudes following a wave shape and reach the SWIO basin by passing over the Cape of Good Hope (Figure 7B-1).

In order to delve further on this eastward transport of air masses over the SWIO basin, the MIMOSA model has been used to produce a continuous evolution of PV fields for the period from 1st to 31st January 2020 for the 400 K isentropic level. The localization of the aerosol plume obtained from OMPS observations at the 400 K \pm 5 K isentropic level are also superimposed (Fig. 8). The 400 K isentropic level is chosen according to the layers observed in the extinction profiles over Reunion between 390 and 404 K isentropic level on 27th and 28th January 2020 (Fig. 6a). Air masses from mid-latitudes (40-60°S) cross the subtropical latitudes (20-40°S) and are advected eastward between South Africa and Madagascar following a wave shape (Fig. 8). Given the Australian BB aerosol are mainly located in the mid-latitudes (Fig. 4a), we can reasonably conclude that the filament reaching the SWIO basin contains aerosol from the Australian BB event. On 27th January, air masses containing aerosol are observed at Madagascar and its surroundings (Fig. 8a). These air masses are advected eastward and reach Reunion on 28th January (Fig. 8b).

Our analysis demonstrated that the Australian BB plume was transported over the SWIO basin following two distinct pathways.

4.3 Contribution of the Australian BB plume on the CO and aerosol variability

Because a significant simultaneous increase of CO and sAOD is observed over Reunion and its surroundings from 16th to 29th January 2020, the investigation will focus on this period. The emission sensitivity from FLEXPART, at the altitude where the emissions are injected is combined with CO and aerosol (BC and OC) emission inventory. The CO emissions due to anthropogenic activity are also taken into account by coupling the FLEXPART model with the EDGAR inventory information. The simulated sAOD compare fairly well with the available satellite observations during the 15-29 January period, and the peak observed on mid-January is acceptably well reproduced. Conversely, the partial column of CO seems less consistent with the observations made by IASI.

The discrepancies between FLEXPART and observations may be attributable to several possible caveats. One of which can be the lack of the vertical motion induced by pyro-convection in FLEXPART. We tested this issue by applying an injection height in agreement with CALIOP observations (9-16 km, Fig. 1) for the Australian plume (Khaykin et al., 2020). The injection height of the plume plays a key role in its long-range transport (Sofiev et al., 2012). An inappropriate or unrealistic injection height can lead to either a dilution or an overestimation of the plume. The injection height depends on the intensity of the fire, as well as on the meteorological conditions. Another possible explanation in these differences can come from the duration of the backward calculation (1 month) and an underestimation of the emission by GFAS (Brocchi et al., 2018). Using FLEXPART simulations, Brocchi et al. (2018) reveal that an amplification factor of two has been applied to CO emissions from GFAS to obtain comparable similar CO quantities with observations. The other source of difference between the model and the observations stems mainly from whether or not FLEXPART takes several regions into account as a source of pollution. The results shown in the figure 9 target emissions from Australia only. The contribution of other regions is discussed in section 5.

On average, the aerosol emissions from Australia contributed up to 95 % of the sAOD variability over Reunion from 15th to 29th January (Fig. 9a). Conversely, the CO emissions from Australia contribute up to 10% of the enhancement of the partial column of CO from 15th to 29th January (Fig. 9b). Therefore, the transport of the CO plume induced by the Australian sources has not been efficiently transported over the SWIO basin. The variability of CO over the SWIO basin in January is therefore not significantly driven by emissions from Australian fires.

5. Discussion on the influence of the regional sources

1 Fire Radiation Power (FRP) gives quantitative information on combustion rates and its
2 intensity (Fig. 10a). The sparse activity of the African fires in January is clearly illustrated in
3 Figure 11a with moderate values of FRP ranging from 20 to 200 MW.m⁻². These values are ten
4 times lower than those observed over the southeastern Australia between 30th December 2019
5 and 12th January 2020 (Bègue et al., 2021). The off-season African BB activity in January 2020
6 is mainly located over the northwestern (near the Equator) and southeastern side of southern
7 Africa. The most intense values (100-200 MW.m⁻²) are observed over the southeastern side.
8 Despite this sparse activity of BB, the amount of CO injected into the atmosphere is fairly
9 significant (from 5 to 6 × 10¹⁷ molecules.cm⁻²) as shown in figure 10b. The partial column of
10 CO (between 9 and 30 km) over southern Africa from 16th and 29th January is characterized by
11 two regions of high values (higher than 5 × 10¹⁷ molecules.cm⁻², Fig. 10b). The first region
12 stretches between the eastern side of southern Africa and the western side of Madagascar which
13 corresponds to a domain extending between 10°S and 25°S in latitude and 30°E and 45°E in
14 longitude (Fig. 10b). The second region is located on the opposite side, over a domain extending
15 between 10°S and 15°S in latitude and 5°E and 15°E in longitude.
16 The main convective regions presenting negative outgoing longwave radiation anomalies, are
17 located in mainland Africa between 12° S and 25° S and the northern side of the SWIO basin
18 between 16th and 29th January as shown in figure 10c through observation obtained from NCEP.
19 The daily brightness temperature values obtained from MODIS during the same period (not
20 shown) are ranging from 195 to 210 K over the eastern side of southern Africa and the northern
21 tip of Madagascar. These values of brightness temperature can be attributed to deep convection
22 clouds (Héron et al., 2020; Young et al., 2013).
23 On average, the motion of ITCZ over the southern Africa on January is characterized by
24 southward motion from 5°N to 20°S in latitude occurring between 20° E and 35° E in longitude
25 (Fig 10a; Lashkari et al., 2017). A tropical depression formed near the northwestern side of
26 Madagascar between 20th and 22nd January 2020. This tropical depression reached the stage of
27 strong tropical storm on 24th January 2020 and named Diane by the RSMC (Regional
28 Specialized Meteorological Centre) of Reunion. The intensification of the tropical depression
29 into strong tropical storm occurred around the northern tip of Madagascar. Diane passed near
30 Reunion on 25th January 2020 (Fig. 10c). The convective activity over southern Africa and the
31 SWIO basin may hence be due to both ITCZ proximity and Diane activity.
32 To further investigate the convection driven pathway, the vertical cross section of CO and
33 water vapor mixing ratio anomalies calculated from MLS observations between 16th to 29th
34 January 2020 are analyzed (Figs. 11a and 11b). The CO and water vapor mixing ratio anomalies

1 are calculated as a relative difference by considering the monthly background means as the
2 reference values. The calculations are performed over a domain extending between 10°S and
3 25°S in latitude and 30°E and 60°E in longitude (black box in Fig. 10b). This domain includes
4 both the region of deep convection and the first region of high values of CO. The monthly
5 background is calculated from available MLS observations in January between 2017 and 2019.
6 Figure 12a exhibits two regions of high values of CO mixing ratio anomalies (higher than 15%)
7 centered at 37°E and 50°E in longitude at 146 hPa (~15 km) and 100 hPa (~17 km). These
8 regions of CO mixing ratio anomalies are in coincidence with two regions of high values (higher
9 than 20%) of water vapor mixing anomalies (Fig. 11b). This is consistent with the FLEXPART
10 simulations shown in figure 12 which highlight a lift of air masses from the lower troposphere
11 to lower stratosphere between 25°E to 55° E in longitude. The convective activity induced by
12 Diane near Madagascar may have contributed to lift air masses enriched in CO from the lower
13 troposphere.

14 Figure 9 also depicts the evolution of the contribution of the African emission on CO partial
15 columns obtained from satellites observations and simulated by FLEXPART from 15th to 29th
16 January over Reunion. An injection height ranging up to 3 km was chosen for the African fires
17 (Labonne et al., 2007). The Australia contribution on the observed partial column was plotted
18 again (as from figure 9). On average, the CO emissions from Africa contribute up to 90% of
19 the enhancement of the partial column of CO from 15th to 29th January (Fig. 13b). The total
20 Africa and Australia CO contribution reproduce fairly well the observations.

21 Our results suggest that the variability of CO over the SWIO basin can be explained both by
22 the influence of the regional transport from southern Africa, enhanced by convective activity
23 due to the passage of a tropical storm.

24 **6. Summary and Conclusion**

25 The complex aerosol and CO variabilities over the SWIO basin during the 2020 austral summer
26 have been investigated. The meteorological context and the extensive fires over southeastern
27 Australia were favorable for triggering pyro-convective events between 29th December 2019
28 and 12th January 2020. These pyro-convective events led to a massive injection of combustion
29 products in the stratosphere. The ground-based and space-borne lidars revealed the presence of
30 an intense stratospheric aerosol layer over the southeastern Australia region. Over the Lauder
31 site in New-Zealand, this smoke layer was detected into the stratosphere (centered at 16 km)
32 until April and beyond. The analysis of the spatial and temporal dispersion of the Australian
33 BB plume highlighted its quick transport circling the entire Southern Hemisphere in less than

1 two weeks. Furthermore, the satellite observations revealed that the transport of the Australian
2 smoke layer was mainly bounded within an extra-tropical latitudinal band.
3 Nevertheless, the numerical models clearly showed the influence of the Australian smoke layer
4 on the variability of aerosol over the SWIO basin. Over Reunion, the aerosol extinction profiles
5 exhibited a significant increase in the lower stratosphere during the end of January. The
6 MIMOSA simulations highlighted the isentropic transport of the Australian BB aerosol from
7 extra-tropical latitudes to Reunion at 400 K isentropic level, on 28th January. As a consequence,
8 the corresponding aerosol extinction profile exhibited a sudden increase by drawing a structure
9 similar to a laminae at the 400 K isentropic level. The aerosol extinction profiles also exhibited
10 a moderate increase in the upper troposphere.
11 According to our simulations, the CO variability over the SWIO cannot be explained by the
12 Australian Black Summer. Rather, the CO in the UT-LS is likely driven by African BB
13 emissions during the convective season. The analysis of satellite observations and FLEXPART
14 simulations suggests that, because of the convective activity, air masses enriched in CO have
15 been lifted from the lower troposphere to the lower stratosphere. Air masses from Africa
16 contributed up to 90% of the partial column (between 9 and 30 km) of CO variability over
17 Reunion and its surroundings. The simulations show that the modulation of the CO and aerosol
18 extinction in the upper troposphere and the lower stratosphere over Reunion was driven by the
19 transport of air masses from both Africa and Australia, respectively.

20 **Acknowledgements**

21 Data used in this publication were obtained from NDACC network and are available through
22 its website (<http://www.ndacc.org/>). The work of S. Khaykin has been supported by the Agence
23 Nationale de la Recherche PyroStrat project (21-CE01- 335 0007-01). IASI was developed and
24 built under the responsibility of the “Centre National d’Etudes Spatiales” (CNES, France) and
25 flown on board the MetOp satellites as part of the EUMETSAT Polar System. The authors
26 thank the AERIS infrastructure (<https://iasi.aeris-data.fr/>) for providing access to the IASI data,
27 the National Aeronautical and Space Administration (NASA) for providing CALIOP data,
28 MLS and MODIS fire products. We would especially like to thank the staff of the team working
29 on the lidar systems at the Maïdo observatory. The French Research Infrastructure ACTRIS-
30 FR, CNES are also acknowledged for their support in the upgrade and operation of the Maïdo
31 observatory lidars. Lauder observations are funded by the New-Zealand Government's Strategic
32 Science Investment Fund (SSIF), administered by the Ministry of Business, Innovation and
33 Employment (MBIE). The TCCON site at Réunion Island has been operated by the Royal
34 Belgian Institute for Space Aeronomy with financial support since 2014 by the EU project

1 ICOS-Inwire, the ministerial decree for ICOS (FR/35/IC1 to FR/35/C6), ESFRI-FED ICOS-
2 BE project and local activities supported by LACy/UMR8105 and by OSU-R/UMS3365 –
3 Université de La Réunion. The lidar measurements at Lauder are supported by funding from
4 GOSAT series project.

5 **Data availability**

6 The data used for this study are available and open access by request to scientist mentioned or
7 through the link hereafter: Lidar measurements (tetsu@mri-jma.go.jp, [nelson.begue@univ-](mailto:nelson.begue@univ-reunion.fr)
8 [reunion.fr](mailto:nelson.begue@univ-reunion.fr)), FTIR measurements from TCCON network (mahesh.sha@aeronomie.be); Lauder
9 FTIR data available on the NDACC public access database ([https://www-](https://www-air.larc.nasa.gov/missions/ndacc/data.html)
10 [air.larc.nasa.gov/missions/ndacc/data.html](https://www-air.larc.nasa.gov/missions/ndacc/data.html)); The satellite observations and emission inventory
11 used are available on-line from the sources as stated in the manuscript. The FLEXPART and
12 MIMOSA codes are available on the FLEXPART (<https://www.flexpart.eu/>) and AERIS
13 website (<http://espri.aeris-data.fr/>), respectively.

FIGURES

6 **Figure 1:** (a) Map of Aerosol Absorbing Index obtained from OMPS observations and (b)
7 scattering ratio profiles at 532 nm obtained from CALIOP observations on 1st January 2020.
8 The orbit overpass of CALIOP is indicated by the blue curve, while the blue square corresponds
9 to the Lauder site in plot (a). The black dashed line in (b) corresponds to the 380 K isentropic
10 level calculated from CALIOP observations.

11

a)

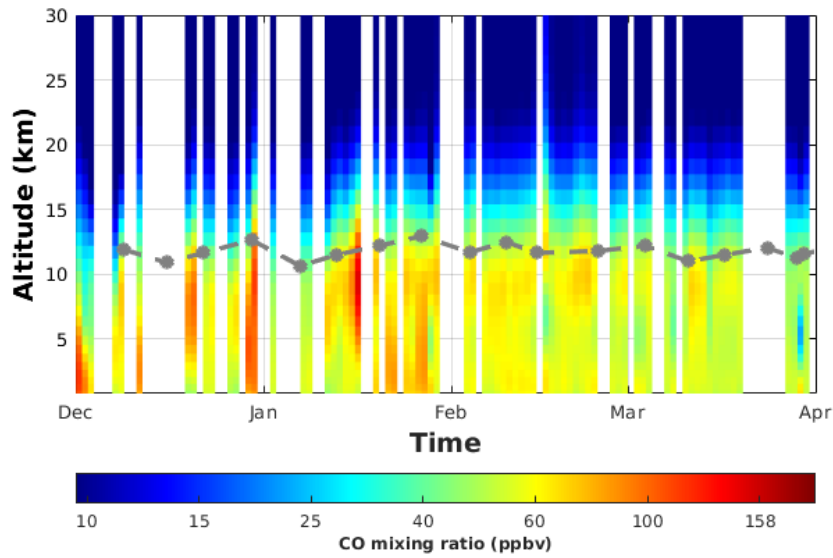

b)

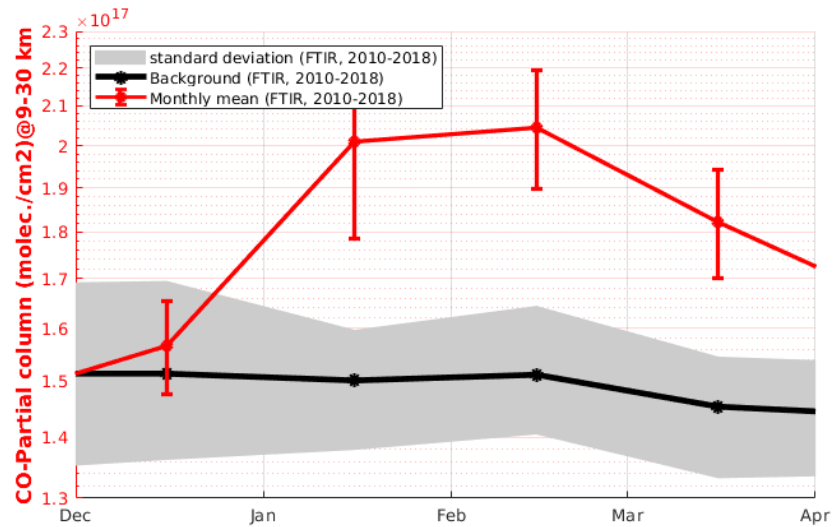

1 **Figure 2:** Time series of (a) daily profiles of aerosol extinction and (b) monthly mean of
 2 stratospheric AOD (sAOD between 15 and 30 km) at 532 nm obtained from lidar observations
 3 between 1st December 2019 and 1st April 2020. In order to screen non-aerosol contributors (such
 4 as clouds) to the extinction measurements, a mask based on the method reported by Nicolae et
 5 al. (2013), which includes consideration of plausible aerosols properties, was used. Specifically,
 6 we only kept profile parts with positive depolarization values, and Angström exponent ranges
 7 from 0.1 to 4. The grey line indicates the tropopause height obtained from radiosonde
 8 measurements. The background evolution of aerosol data and the associated standard deviation
 9 are given in black lines and grey areas, respectively.

10

a)

b)

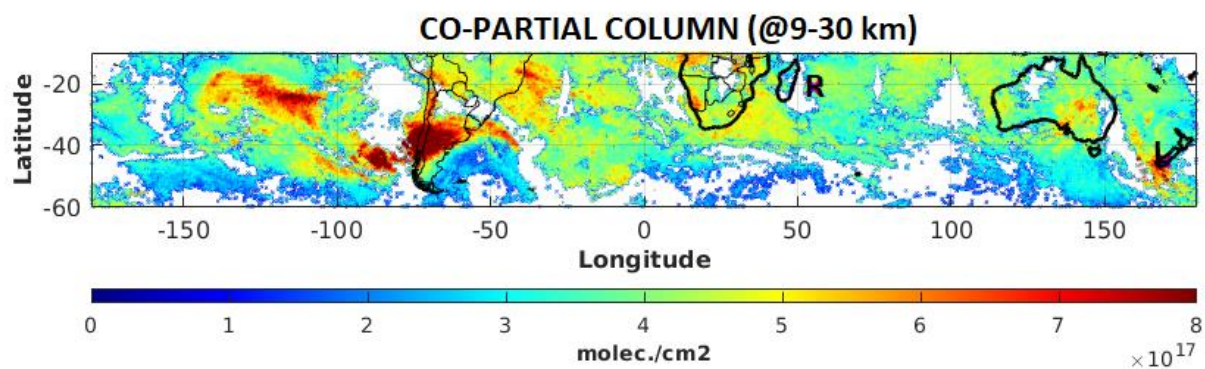

2 **Figure 3:** Time series of (a) daily profiles of CO mixing ratio and (b) monthly mean of partial
 3 column of CO (between 9 and 30 km) obtained from FTIR at Lauder between 1st December
 4 2019 and 1st April 2020. The background evolution of the partial column of CO and the
 5 associated standard deviation are given in black lines and grey areas, respectively. .

b)

3 **Figure 4:** Time-averaged map (from 9th to 16th January 2020) of (a) sAOD (between 15 and 30
4 km at 532 nm) obtained from OMPS observations (b) partial column of CO (averaged between
5 9 and 30 km) obtained from IASI observations. The location of Reunion and Lauder sites are
6 indicated by R and L respectively.

7

a)

b)

2 **Figure 5:** Daily mean evolution of aerosol (a) and CO (b) abundances obtained from ground-
 3 based and satellite observations at Reunion between 1st January and 1st March 2020. Partial
 4 column (molecule.cm⁻²) and abundance (ppb) of CO obtained from IASI (blue line) and FTIR
 5 (red line) respectively are given in the lower panel (b), while sAOD obtained from OMPS (red
 6 line) and Lidar (blue and green dots) are given in the upper panel (a). The black and dashed
 7 lines correspond to monthly mean and the associated standard deviation calculated during the
 8 background period.

1 **Figure 6:** Aerosol extinction (at 355 nm) (a, b) and Angström exponent (355-532 nm) (c, d)
 2 obtained from lidar observations at Reunion in the months January and February 2020. The
 3 tropopause height is indicated by the orange horizontal lines.

3 **Figure 7:** FLEXPART 30-day back trajectories initialized from Reunion (black cross) at 18 km
 4 on 27th January 2020 (A-1-2) and 28th January 2020 (B-1-2). A-1 and B-1 correspond to an
 5 integration of the trajectory positions over the whole altitude range. A-2 and B-2 are the vertical
 6 view integrated over the whole latitude range of the back trajectories A-1 and B-1. The black
 7 rectangle represented the injection height of the biomass burning aerosols.

2 **Figure 9:** a) Daily evolution of sAOD (calculated between 15 and 30 km at 532 nm) obtained
3 from OMPS-LP (red line), lidar (blue dots) and simulated by FLEXPART (orange line) over
4 Reunion from 15th to 29th January 2020. b) Daily evolution of partial column (calculated
5 between 9 and 30 km) of CO observed by IASI (red line) and simulated by FLEXPART (orange
6 line) over Reunion from 15th to 29th January 2020. The CO evolution is simulated by
7 FLEXPART considering only the CO emission (including BB and anthropogenic activity) from
8 Australian emission. The simulated sAOD are calculated in considering only the aerosol
9 emission (BC and OC) from Australian emission.
