Abstract. Ozone (O_3), an important and ubiquitous trace gas, protects lives from harm of solar ultraviolet (UV) radiation in the stratosphere but is toxic to living organisms in the troposphere. Additionally, tropospheric O_3 is a key oxidant, and source of other oxidants (e.g, OH and NO_3 radicals) for various volatile organic compounds (VOC). Recently, highly oxygenated organic molecules (HOM) were identified as a new compound group formed from oxidation of many VOC, making up a significant

5　source of secondary organic aerosol (SOA). The pathways forming HOM from VOC involve autoxidation of peroxy radicals (RO_2), formed ubiquitously in many VOC oxidation reactions. The main sink for RO_2 is bimolecular reactions with other radicals, HO_2, NO or other RO_2, and this largely determines the structure of the end products. Organic nitrates form solely from RO_2 + NO reactions while accretion products ("dimers") solely from RO_2 + RO_2 reactions. The RO_2 + NO reaction also converts NO into NO_2, making it a net source for O_3 through NO_2 photolysis.

10　There is a highly nonlinear relationship between O_3, NO_x, and VOC. Understanding the O_3 formation sensitivity to changes in VOC and NO_x is crucial for making optimal mitigation policies to control O_3 concentrations. However, determining the specific O_3 formation regimes (either VOC-limited or NO_x-limited) remains challenging in diverse environmental conditions. In this work we assessed whether HOM measurements can function as a real-time indicator for the O_3 formation sensitivity based on the hypothesis that HOM compositions can describe the relative importance of NO as a terminator for RO_2. Given the

15　fast formation and short lifetimes of the low-volatile HOM (timescale of minutes), they describe the instantaneous chemical regime of the atmosphere. In this work, we conducted a series of monoterpene oxidation experiments in our chamber while varying the concentrations of NO_x and VOC under different NO_2 photolysis rates. We also measured the relative concentrations of HOM of different types (dimers, nitrate-containing monomers, and non-nitrate monomers) and used ratios between these to estimate the O_3 formation sensitivity. We find that for this simple system, the O_3 sensitivity could be described very well

20　based on the HOM measurements. Future work will focus on determining to what extent this approach can be applied in more complex atmospheric environments. Ambient measurements of HOM have become increasingly common during the last decade, and therefore we expect that there already are a large amount groups with available data for testing this approach.

1 Introduction

Ozone (O_3), as a key trace gas in the atmosphere, directly and indirectly affects human lives, and it plays diametrically opposed
roles in the troposphere ("bad" ozone) and stratosphere ("good" ozone) (Sandermann, 1996; Staehelin et al., 2001; Seviour, 2022). The formation and depletion of O_3 has been investigated over the past decades (Chapman, 1930; Crutzen, 1970, 1971; Stolarski and Cicerone, 1974; Tiao et al., 1975; Dodge, 1977). Atmospheric O_3 is almost entirely produced through the reaction between atomic oxygen (O^3P) and molecular oxygen (O_2) (Wang et al., 2017). In the stratosphere, the O^3P source is O_2 photolysis with ultraviolet (UV) wavelengths below 240 nm (Chapman, 1930). Stratospheric O_3, which constitutes approximately 90% of Earth's atmospheric O_3, plays a crucial role in absorbing UV radiation in the UVB band (280-315 nm), protecting organisms on the ground from the harm of UV radiation (Gruijl and Leun, 2000; Seinfeld and Pandis, 2016). Although certain man-made substances, such as chlorofluorocarbons, were found to be responsible for significant depletion of stratospheric O_3, the implementation of the 1987 Montreal Protocol and its subsequent amendments has contributed to the recovery of the stratospheric O_3 layer (Seinfeld and Pandis, 2016; Chipperfield et al., 2017).

In the troposphere, in addition to its role as a greenhouse gas (Ehhalt et al., 2001), O_3 serves as a secondary air pollutant due to its detrimental impacts and indirect emissions (Seinfeld and Pandis, 2016; Nuvolone et al., 2018). Not only is it toxic, but it also participates in chemical reactions that lead to the formation of other harmful molecules (Nuvolone et al., 2018). In contrast to stratospheric O_3, in the troposphere, the source of O^3P is NO_2 photolysis at wavelengths less than 420 nm (Madronich et al., 1983). However, the net formation of tropospheric O_3 occurs through chemical reactions involving nitrogen oxides ($NO_x = NO + NO_2$) and various volatile organic compounds (VOC) in the presence of UV light (Lelieveld and Dentener, 2000). In an ideal "clean" system without any VOC, once O_3 is formed, it readily converts NO back to NO_2 by reacting with NO, resulting in a null cycle as shown below (also illustrated as "NO_x cycle" in Fig A1):

$$NO_2 + hv \xrightarrow{O_2} NO + O_3 \qquad\qquad \text{R1}$$

$$O_3 + NO \rightarrow NO_2 + O_2 \qquad\qquad \text{R2}$$

When VOC are present, they will be oxidized to form peroxy radicals (RO_2) by atmospheric oxidants, such as O_3 and OH (Atkinson and Arey, 2003):

$$VOC + oxidant \xrightarrow{O_2} RO_2 \qquad\qquad \text{R3}$$

The RO_2 radicals can thus replace O_3 in converting NO into NO_2 (R4a). Some fraction of RO_2 + NO reactions will also lead to the formation of organic nitrates, $RONO_2$ (R4b) (Atkinson and Arey, 2003):

$$RO_2 + NO \rightarrow RO + NO_2 \qquad\qquad \text{R4a}$$

$$\rightarrow RONO_2 \qquad\qquad \text{R4b}$$

In summary, the presence of RO_2 radicals, supplied by VOC, can perturb the "NO_x cycle", leading to the net increase of O_3 (Fig. A1). As one of the most characteristic features of the photochemical smog episodes in many cities (Tiao et al., 1975; Tang
et al., 1995; Dickerson et al., 1997), this O_3 formation process (R1-R4a, Fig A1), known as O_3-NO_x-VOC sensitivity or O_3

55 formation sensitivity, has been investigated since the last century (Haagen-Smit et al., 1953; Kinosian, 1982). The Empirical

Kinetic Modeling Approach (EKMA) curve, namely O_3 isopleths, was proposed by Dodge (1977) and has been widely used to

visually study the O_3 formation sensitivity (Liu and Shi, 2021). The O_3 isopleths reveal a highly nonlinear response of O_3 to its

precursors, demonstrating that the impact on O_3 formation by reducing or increasing either VOC or NO_x does not consistently

exhibit the same behavior (Meyer Jr et al., 1977; Harris et al., 1982; Sillman et al., 1990). The outcome is dependent on the

60 relative concentrations of VOC (as a surrogate for RO_2) and NO_x, leading to the division of the formation area into NO_x-limited

and VOC-limited regimes (Sillman, 1999; Melkonyan and Kuttler, 2012). In the NO_x-limited regime, the concentration of O_3

generally increases with an increase in NO_x, while its response to changes in VOC remains relatively small. This is because the

supply of RO_2 species from VOC is abundant and R4a is limited by NO (the "NO_x cycle" is saturated in Fig. A1). Conversely,

in the VOC-limited regime, an increase in VOC concentration generally leads to an increase in O_3, whereas an increase in

65 NO_x may even result in a decrease in O_3 levels. This is because NO_x is in excess compared to RO_2. Moreover, very high

levels of NO_x can directly titrate O_3 (Sillman, 1999) or consume OH radicals (Atkinson et al., 2004), thereby reducing the

supply of RO_2 species (R3) and promoting the reaction R2, which results in a decrease in the O_3 concentration. These effects

were demonstrated by the amplified O_3 pollution in cities during the COVID-19 lockdown, when NO_x emissions dropped

dramatically (Sicard et al., 2020).

70 To mitigate the uncertainties associated with photochemical models and efficiently determine the O_3 formation sensitivity,

various photochemical indicators have been utilized since the last century. (Wang et al., 2017; Liu and Shi, 2021). For example,

the O_3 production efficiency (OPE = $\frac{\Delta O_3}{\Delta NO_z}$) is defined as the number of O_3 molecules produced per molecule of NO_x before

the NO_x is oxidized to more stable products, i.e., NO_z species (Trainer et al., 1993; Wang et al., 2017). Smaller values of OPE

indicate the inefficiency of the "NO_x cycle" (Fig. A1), suggesting that the supply of RO_2 from VOC becomes the limiting factor.

75 As a result, the photochemical system tends to be VOC-limited. Conversely, when OPE values are higher, the system tends to

be NO_x-limited. Additionally, several modifications had been made to the OPE indicator to account for different situations,

such as replacing ΔO_3 with ΔO_x (O_x=O_3+NO_2) (Kleinman et al., 2002) and replacing ΔNO_z with ΔNO_y (NO_y=NO_z+NO_x)

(Wang et al., 2006). Other chemical species have also been utilized as photochemical indicators, including the ratio of H_2O_2

to HNO_3 (Hammer et al., 2002). High values of $\frac{H_2O_2}{HNO_3}$ indicate high potential for cross-reactions of two HO_2 radicals, which

80 is associated with high $\frac{VOC}{NO_x}$ and thus indicative of the NO_x-limited regime. For a more widespread application, space-based

$\frac{HCHO}{NO_2}$ measurements from global O_3 monitoring satellites have been introduced as an indicator (Martin et al., 2004), based on

the fact that levels of HCHO and NO_2 in the tropospheric column are closely linked to VOC and NO_x emissions, respectively.

However, all these indicators are not inherently linked to the O_3 formation process, and the corresponding threshold values

depend on environmental conditions (Liu and Shi, 2021). This makes it challenging to universally apply these indicators.

85 During the past decade, highly oxygenated organic molecules (HOM) have been recognized as a new group of VOC oxi-

dation products, particularly important for the formation of secondary organic aerosol (SOA) due to their fast formation and

low volatilities (Ehn et al., 2014; Bianchi et al., 2019). Aerosols play a significant role in both impacting human health ad-

versely (Kelly and Fussell, 2015) and influencing climate (Boucher et al., 2013). Formed in the atmosphere-mimicking gas

phase and containing six or more oxygen atoms (Bianchi et al., 2019), HOM are produced via RO_2 autoxidation which rapidly

90   increases their oxygen content through intramolecular H atom abstractions followed by O_2 additions (Crounse et al., 2013; Ehn et al., 2014). Eventually, these highly oxygenated RO_2 will generally be terminated similarly as other RO_2, such as through bimolecular reactions with NO_x, RO_2 or HO_2 radicals (i.e., R4, R5 and R6).

$$RO_2 + RO_2 \rightarrow ROOR + O_2 \hspace{6cm} \text{R5a}$$
$$\rightarrow ROH + RC{=}O + O_2 \hspace{5cm} \text{R5b}$$
95   $$RO_2 + HO_2 \rightarrow ROOH + O_2 \hspace{5.5cm} \text{R6a}$$
$$\rightarrow RC{=}O + H_2O + O_2 \hspace{5cm} \text{R6b}$$

The O_3 formation precursors, namely NO_x and VOC, thus are intrinsically connected also to HOM formation through RO_2 chemistry. As such, if the daytime HOM distribution is dominated by organic nitrates, it suggests that the majority of RO_2 are

100   being terminated by reactions with NO (R4), thus contributing to O_3 formation. On the other hand, if we observe large amounts of HOM dimers or non-nitrate monomers, formed from $RO_2 + RO_2/HO_2$ (R5 and R6), there must be a large fraction of RO_2 that do not contribute to the O_3 formation process, suggesting that increased NO_x would also lead to more O_3. In other words, ratios of different types of HOM can function as another indicator for determining the sensitivity of O_3 formation. The situation is complicated by several factors, including challenges in identifying which HOM might have formed from RO_2 termination

105   by RO_2 or HO_2, or by knowing if a HOM is a monomeric product of a larger VOC precursor or a dimeric product from smaller VOC. Still, if HOM could be used even as a qualitative indicator for O_3 formation, one particular benefit would be that they would serve as a real-time indicator. This is because both the formation (through autoxidation) and loss (through condensation onto aerosol particles) of HOM take place on timescales of minutes or less.

In this study, our objective is to assess the viability of using the ratio of HOM dimers or non-nitrate monomers to HOM

110   organic nitrates as an indicator of O_3 formation sensitivity. We conducted a series of experiments in an atmosphere simulation chamber (Riva et al., 2019a), focusing on the ozonolysis of α-pinene, the most abundantly emitted monoterpene (Pathak et al., 2007). By varying the concentrations of O_3 formation precursors NO_x and α-pinene, as well as the NO_2 photolysis rate, we explored the shift between NO_x-limited and VOC-limited regimes in the chemical system. We employed mass spectrometers and gas monitors to measure HOM products, α-pinene, O_3, and NO_x. We also developed a simple 0-D box model to simulate

115   the concentrations of O_3 and its precursors in the chamber under different conditions. Finally, by analyzing both experimental and model outcomes, we evaluated the potential of the HOM ratios as indicators of O_3 formation sensitivity (either VOC-limited or NO_x-limited) in this system.

2 Methods

2.1 Experiments

120 The experiments were conducted in the COALA chamber, as presented by Riva et al. (2019a). The cuboid chamber is made of fluorinated ethylene propylene (FEP) and has a volume of 2 m^3 with a volume to surface area ratio of 0.2. The chamber was run in "steady-state mode" (Peräkylä et al., 2020; Krechmer et al., 2020), meaning there was a continuous flow of air and reagents (O_3, NO_2, α-pinene) through the chamber. The total flow was around 55 L min^{-1}, giving an average residence time of approximately 36 minutes ($\tau = \frac{2000 \text{ L}}{55 \text{ L min}^{-1}} \approx 36 \text{ min}$). Each stage, where the experimental conditions remain unchanged,

125 lasted at least 1.5 hours, which is approximately three times the residence time, allowing the chamber to reach a pseudo steady state, as confirmed by the time series obtained during the experiments (e.g., Fig. 4).

Table 1. Experimental conditions. Each experiment consisted of 3-9 "stages" that corresponded to a specific time period during which the inputs remain constant. The parameter that was varied included input O_3, α-pinene, or NO_x concentrations, as well as NO_2 photolysis rate (J_{NO_2}). These variations are indicated in the table by multiple values or ranges in a given cell. Experiment numbers (No.) and number of total stages per experiment are shown in the first two columns.

		Input			
Experiment *No.*	Number of stages	J_{NO_2} (s^{-1})	O_3 (ppb)	α-pinene (ppb)	NO_x range (ppb)
1.	7	1.85×10^{-3}	10.5	30/60	0 - 21.5
2.	8	1.85×10^{-3}	15	15/45/60	0 - 21.5
3.	9	1.85×10^{-3}	22.5	10/45/60	0 - 35.2
4.	9	1.15×10^{-3}	15.5	15/45/60	0 - 44.5
5.	9	0.35×10^{-3}	15.5	15/45/60	0 - 44.5
6.	3	1.85×10^{-3}	10/15.5/22.5	60	44.5
7.	8	1.85×10^{-3}	10	30/45/60	0 - 21.5

The details of the conducted experiments are provided in Table 1. The UV LED lights (wavelength $\sim$ 400 nm, manufactured by LEDlightmake Inc., Shenzhen, China) (Zhao et al., 2023a) used for photolyzing NO_2 were kept on throughout each experiment, while the input concentrations of the precursors NO_2, O_3 and α-pinene were varied across experiments and stages to

130 map out a wide range of different conditions. The photolysis rate was varied by using varying numbers of LED light strips (1, 3, or 5). Experiments without VOC addition (no. Z1-Z5, Table A1) were used to evaluate the photolysis rates (given in Table 1) for each number of light strips. We acknowledge that using alkene ozonolysis for this type of study is not ideal as O_3 also reacts with the VOC, making the determination of actual O_3 formation more complicated. The choice of this system was partly due to our chamber not having a good light source for producing OH radicals, thus limiting us to O_3 oxidation, and partly because

135 the HOM spectra from this system has been studied in great detail, making the interpretation of the HOM easier.

All the input reactants, as well as the HOM products, were continuously measured online using instruments described below. The identified HOM species in this study were categorized into three groups: 1) "HOM monomers" (HOM$_{Mono}$), C$_8$-C$_{10}$ compounds without any nitrogen atoms; 2) "HOM organic nitrates" (HOM$_{ON}$), C$_8$-C$_{10}$ compounds with one nitrogen atom; and 3) "HOM dimers" (HOM$_{Di}$), C$_{18}$-C$_{20}$ compounds without any nitrogen atoms.

2.2 Instrumentation

2.2.1 Mass spectrometers

A nitrate-adduct Chemical Ionization Mass Spectrometer (NO$_3$-CIMS, Tofwerk AG/Aerodyne Research, Inc.) was used for online measurements of HOM with high selectivity (Jokinen et al., 2012; Ehn et al., 2014; Riva et al., 2019b). A large sheath flow of 20 L min^{-1} (to minimize wall losses) carries nitric acid (HNO$_3$) across X-rays, producing nitrate ions (NO$_3^-$). Then, in an electric field, NO$_3^-$ are guided towards a 10 L min^{-1} sample flow, ionizing targeted HOM molecules by clustering with them. (Kürten et al., 2014). Finally, the charged sample molecules are directed through a critical orifice and into an Atmospheric Pressure Interface Time-of-Flight Mass Spectrometer (APi-TOF), where they are detected based on mass-to-charge ratios (m/z) (Junninen et al., 2010). The NO$_3$-CIMS was equipped with a standard TOF (HTOF), having a mass resolution of 5000 at m/z 188 Th. The concentrations of HOM were converted from their normalized signals (i.e., the ratio of HOM-containing ions to reagent ions) by multiplying with a calibration factor (C), which takes different efficiencies into account (Jokinen et al., 2012; Bianchi et al., 2019):

$$[HOM] = C \cdot \frac{HOM(NO_3^-)}{\sum_{i=0}^{2}(HNO_3)_i(NO_3^-)} \tag{1}$$

Calibrating with sulfuric acid (Kürten et al., 2012), we determined C to be 1.56×10^9 cm^{-3} ($\pm 50\%$) based on a flow-tube model (He et al., 2023). However, in this study, the accuracy of C is less important since the normalized signals of HOM were sufficient for relative comparisons.

A Proton Transfer Reaction Time-of-Flight mass spectrometer (PTR-TOF 8000, Ionicon Analytik GmbH), designed for online measurements of VOC (Jordan et al., 2009), was utilized in our study specifically for the detection of α-pinene. The PTR is an ionization method where water molecules (H$_2$O) are ionized in a hollow cathode discharge, resulting in the formation of hydronium ions (H$_3$O$^+$) (Hansel et al., 1995). Then, as proton donors, H$_3$O$^+$ are directed into a drift tube, where trace organic compounds are ionized by proton transfer process with proton affinity as the key parameter (Hansel et al., 1995; Graus et al., 2010). After a differentially pumped ion transfer unit, the charged molecules enter a TOF, where collisions are negligible under a low pressure of $\sim 10^{-6}$ mbar with a high vacuum (Graus et al., 2010). The inlet flow was 1 L min^{-1} with 0.1 L min^{-1} being sampled into the ion drift tube. Further details regarding the calibration and settings of the PTR can be found in Zhao et al. (2023b), and the calibration factor for α-pinene (detected as C$_{10}$H$_{17}^+$ at m/z 137 Th) was $\sim$104 ppb^{-1} after normalization by primary ion isotope H$_3{}^{18}$O$^+$ (at 21 Th). The analysis of raw data from the NO$_3$-CIMS and PTR-TOF was conducted using the MATLAB-based set of programs called tofTools (version 611) (Junninen et al., 2010).

2.2.2 Gas monitors

The concentrations of NO_x and O_3 were measured by gas monitors. A photometric O_3 analyzer - model 400 (Teledyne API) was used to detect O_3 in the chamber. The amount of O_3 determines how much of a 254 nm UV light signal is absorbed in the

170 sample cell. The absorption difference between the intact sample air and the O_3-removed air, achieved by a switching valve periodically, enables the determination of the stable O_3 concentrations.

As for NO_x, a NO-NO_2 analyzer - model T200UP (Teledyne API) was utilized. With a high-efficiency photolytic converter, NO_2 is transformed to NO with minimal interference from other gases. Using the chemiluminescence detection principle, NO is measured by reacting with O_3, yielding light in direct proportion to the amount of NO (Archer et al., 1995). In this way, both

175 sampled NO and total NO_x can be measured, without and with using the photolytic converter, respectively. This enables the determination of the NO_2 concentration in the sample by subtraction.

2.3 Box model

As O_3 was both injected and produced in the chamber, and sinks included reactions with NO and VOC as well as flush out, we constructed a simple 0-D box model (12 reactions, 9 species, Table A2) to mimic the main reactions and to generate O_3 isopleth

180 diagrams. These isopleths were then used to determine sensitivity regimes for O_3 formation. Reaction rates were adapted from the NIST Chemical Kinetics Database (https://kinetics.nist.gov/kinetics/index.jsp). The model did not include closed-shell HOM products and all peroxy radicals were treated as a single term (i.e., "RO_2"). The box model was first employed to determine NO_2 photolysis rates under different numbers of UV lights in the zero-VOC experiments (Table A1), where only O_3 and NO_2 were used as input species. The high agreement between model and observation (detailed results are shown in section

185 3.1 and 3.3) showed that the model was adequate for simulating the targeted reactions in our chamber.

3 Results and discussions

3.1 NO$_2$ photolysis rate determination

Figure 1 illustrates an example of a zero-VOC experiment, while Table A1 provides a comprehensive list of all zero-VOC experiments conducted. Using the box model, NO$_2$ photolysis rates (J$_{NO_2}$) were fitted to accurately simulate the gas concen-

190 trations, namely O$_3$ and NO$_x$, at each stage of the experiment. With a NO$_2$ photolysis rate of 1.85×10^{-3} s^{-1} with 5 UV lights, the modeled gas concentrations agreed extremely well with measured values (Fig. 1). Similar agreement was observed for different inputs of O$_3$ and NO$_2$ (Fig. A2 and A3), indicating the robustness of both model and fitted J$_{NO_2}$. Furthermore, employing the same procedure, the photolysis rates with 3 and 1 UV lights were determined to be 1.15×10^{-3} s^{-1} and 0.35×10^{-3} s^{-1}, respectively (Fig. A4 and A5).
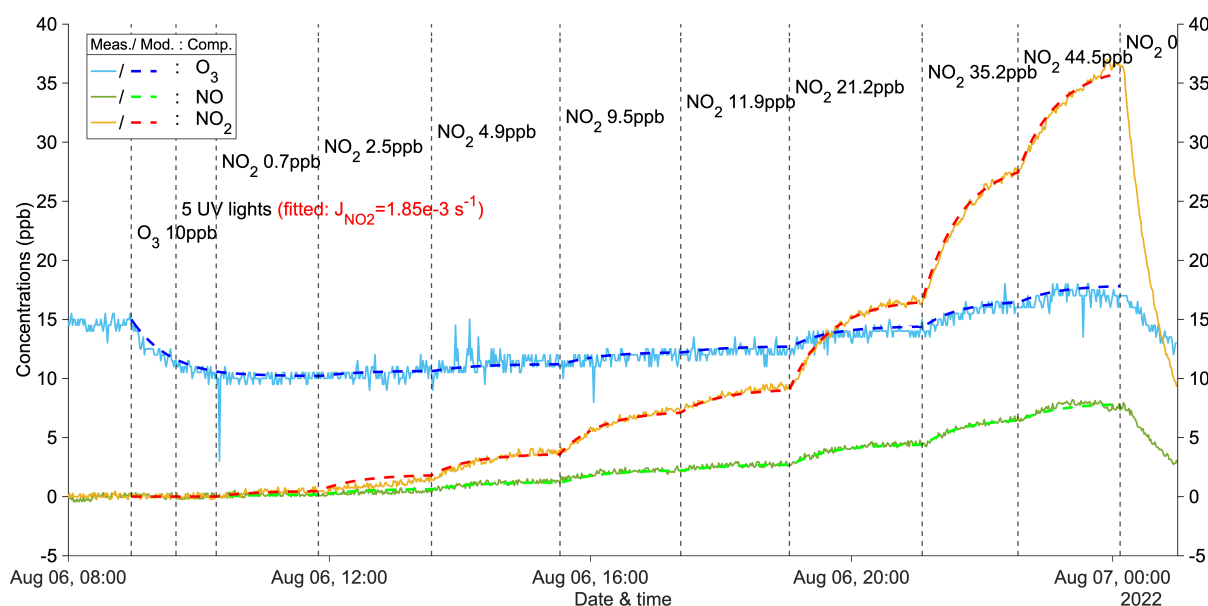

Figure 1. A zero-VOC experiment (Z1) for determining the photolysis rate of NO$_2$. Measured (abbreviated as Meas.) and modeled (abbreviated as Mod.) concentrations of different compounds (abbreviated as Comp.) are shown in solid and dashed lines respectively. Dashed vertical lines indicate specific time points of operations, with corresponding labels for each operation. Note that the operation labels show input information (input NO$_2$ = measured NO$_2$ + NO).

195 3.2 HOM determination

A steady-state spectrum (experiment no. 2) obtained from the NO$_3$-CIMS (Fig. 2) illustrates the identified closed-shell HOM products, including HOM$_{Mono}$ (light green), HOM$_{ON}$ (blue), and HOM$_{Di}$ (dark green). Table 2 provides the formulas of all the selected HOM species. Figure A6 displays the steady-state spectra of all stages, with the corresponding input information

described in Fig. 4a. As expected, with the injection of more NO_2, the signals of HOM_{ON} increased, while those of HOM_{Mono}
200 and HOM_{Di} decreased considerably (stage (2) - (5) in Fig. A6). This observation is consistent with the dominance of the RO_2
+ NO reaction over the RO_2 cross-reactions at a few ppb of NO_x (Yan et al., 2016, 2020). After the addition of more α-pinene,
all signals showed a noticeable rise (stage (6) - (7) in Fig. A6) due to the increased supply of RO_2 species.
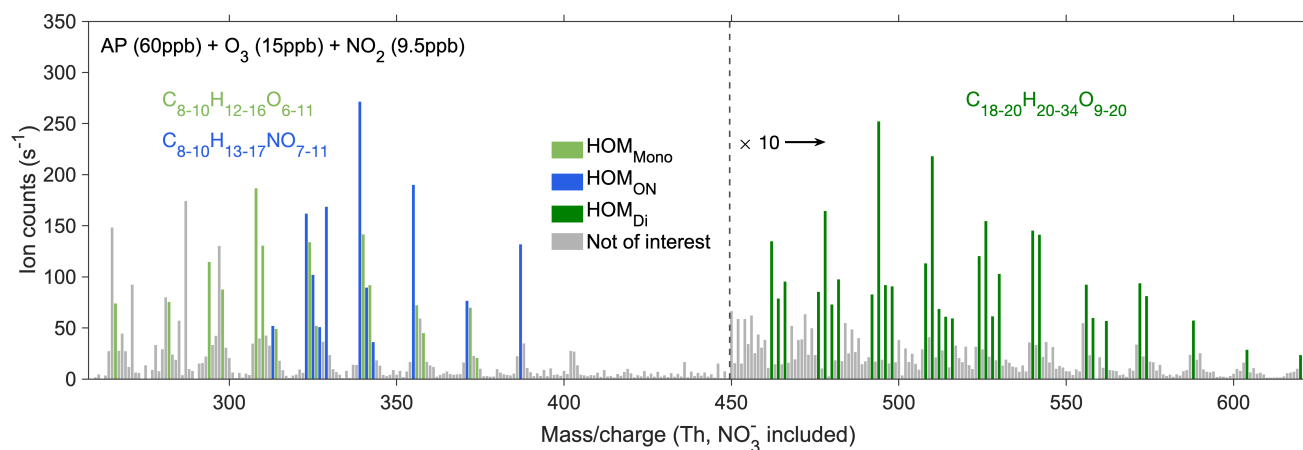

Figure 2. The steady-state spectrum (15 min average) at the stage (7) of experiment no. 2 from the NO_3-CIMS. The spectrum was corrected
by subtracting the corresponding background signals. Light green bars show HOM_{Mono}, dark green ones show HOM_{Di}, blue ones show
HOM_{ON} while grey ones show peaks not of interest. The peaks not of interest either exhibited relatively low signals, represented radicals,
contained too small a number of carbon/oxygen atoms, or had uncertain mass-to-charge ratios. The peaks larger than 450 Th are multiplied
by 10.

Table 2. Identified HOM closed-shell species based on the experiment no. 2 The reagent ion NO_3^- is excluded.

Monomers	Dimers	
$C_8H_{12}O_x$ (x=6-9)	$C_{18}H_{22}O_x$ (x=17-20)	$C_{19}H_{32}O_x$ (x=10-13)
$C_{10}H_{14}O_x$ (x=7-11)	$C_{18}H_{24}O_x$ (x=12,14,16,17)	$C_{20}H_{20}O_{15}$
$C_{10}H_{16}O_x$ (x=6-11)	$C_{18}H_{26}O_x$ (x=11-14)	$C_{20}H_{30}O_x$ (x=10-18)
Organic nitrates	$C_{18}H_{26}O_x$ (x=11-14)	$C_{20}H_{32}O_x$ (x=9,11-15)
$C_8H_{13}NO_x$ (x=8,9)	$C_{18}H_{30}O_{13}$	$C_{20}H_{34}O_x$ (x=11,12)
$C_9H_{15}NO_x$ (x=8,9)	$C_{19}H_{26}O_x$ (x=10-19)	
$C_{10}H_{15}NO_x$ (x=7-11)	$C_{19}H_{28}O_x$ (x=9-16)	
$C_{10}H_{17}NO_x$ (x=7,8)	$C_{19}H_{30}O_x$ (x=9-13)	

Our experiments showed that HOM organic nitrates with fewer than 9 oxygen atoms ($HOM_{ON,O\leq8}$) exhibited the slowest
decay at the end of the experiment (Fig. 3). This can be explained by the evaporation of these semi-volatile $HOM_{ON,O\leq8}$
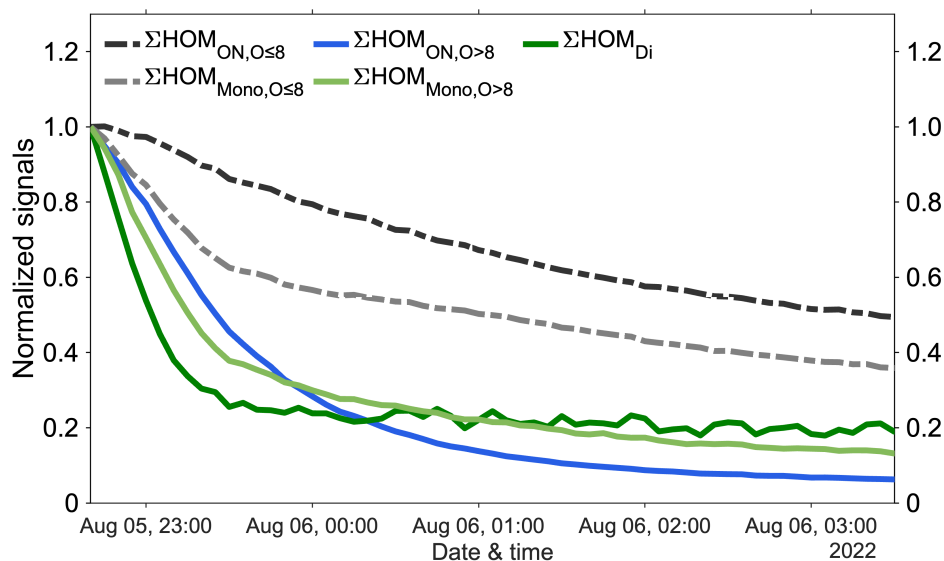

9

Figure 3. The normalized signal decay of HOM_{ON}, HOM_{Mono}, and HOM_{Di} after experiment no. 2 ended. All signals were normalized first to primary ions and then to the signals at the moment when experiment no. 2 ended. $\sum HOM_{ON,O>8}$ (sum of HOM_{ON} species with more than 8 oxygen atoms) are in solid blue lines, $\sum HOM_{ON,O\leq8}$ are in dashed black lines, $\sum HOM_{Mono,O>8}$ are in solid light green lines, $\sum HOM_{Mono,O\leq8}$ are in dashed grey lines while $\sum HOM_{Di}$ are in solid dark green lines.

compounds from chamber walls even after the gas phase production had stopped. Despite showing a faster decay compared to $HOM_{ON,O\leq8}$, non-nitrate HOM monomers with fewer than 9 oxygen atoms ($HOM_{Mono,O\leq8}$) also showed overall slow decays (Fig. 3). As a result, prior to subsequent experiments, the concentration levels of $HOM_{ON,O\leq8}$ and $HOM_{Mono,O\leq8}$ remained high, obscuring actual concentration changes following the addition of NO_x. In contrast, $HOM_{ON,O>8}$, $HOM_{Mono,O>8}$ and HOM_{Di} experienced fast decays, reaching a low and stable level (≤0.2) within a few hours after the experiment (Fig. 3). Despite the higher normalized background level of HOM_{Di} due to their lower concentrations, this stable level allowed for accurate background subtraction in subsequent experiments, enabling measurements of true changes in concentration. Therefore, to ensure the accuracy of our results, we excluded the less oxygenated and more volatile HOM species, specifically $HOM_{ON,O\leq8}$ and $HOM_{Mono,O\leq8}$. Consequently, the indicating ratio used in this study is defined as the ratio between the sum of HOM_{Di} or $HOM_{Mono,O>8}$ and the sum of $HOM_{ON,O>8}$, represented as $\frac{\sum HOM_{Di}}{\sum HOM_{ON,O>8}}$ (Indicating Ratio 1, abbreviated as IR1) or $\frac{\sum HOM_{Mono,O>8}}{\sum HOM_{ON,O>8}}$ (IR2).

3.3 Indicating ratios

In this section, we detail the conducted experiments. Experiment no. 2, is depicted in Fig. 4, while the other experiments are shown in Fig. A7-A12. Variation of NO_2 and α-pinene input concentrations lead to changes in both indicating ratios (IR1 and

IR2) that correspond with changes in O_3 concentrations (Fig. 4), suggesting a possible sensitivity of O_3 formation. From stage
(1) to (5), injection of more NO_2 led to increased formation of $HOM_{ON,O>8}$, while production of HOM_{Di} and $HOM_{Mono,O>8}$
was suppressed. As a result, the indicating ratios decreased. Additionally, the concentration of O_3 increased during this period,
but the rate of increase decreased with higher NO_2 inputs. This trend suggests a gradual shift from a NO_x-limited regime to
a more VOC-limited regime in the system. For example, during stage (5) with 9.5 ppb NO_2, the O_3 concentration remained
relatively constant. This observation indicates the system may have shifted to the VOC-limited regime. Next, when additional
α-pinene was introduced ($\sim$ 45 ppb during stage (6)), a significant increase in O_3 concentration was again observed, consistent
with the system being in the VOC-limited regime during stage (5). However, after injection of $\sim$ 60 ppb α-pinene during stage
(7), the O_3 concentration reached a plateau, indicating that the system had shifted back to the NO_x-limited regime. Moreover,
during these two stages, the indicating ratios experienced a substantial increase. In the last stage (8), when additional NO_2 was
injected to reach 21.5 ppb, while input α-pinene concentration remained unchanged, the O_3 concentration increased again, and
the indicating ratios decreased noticeably, confirming that the previous stage was NO_x-limited. However, it should be noted
that the system in this stage might not yet be VOC-limited.

Other experiments with 5 UV lights (Fig. A7, A8, and A11) also exhibited similar time series patterns as described above.
One noticeable difference is that higher initial O_3 concentrations resulted in less pronounced increases in O_3 during the first
5 stages with varying NO_2 levels. This can be attributed to the reaction O_3 + NO (R2) becoming faster, competing with the
formation of O_3 from the RO_2 + NO reaction (R4a) followed by NO_2 photolysis (R1). As a result, there was a reduced O_3
formation in the presence of higher initial O_3 concentrations due to the scavenging of NO by existing O_3.

Compared to experiment no. 2 (Fig. 4), experiments with fewer lights (but similar initial concentrations; Fig. A9 and A10)
provide insight into the effect of UV light intensities on O_3 formation sensitivity and the consistency of the indicating ratios
under different light intensities. More lights led to more pronounced increase in O_3 concentrations at the same stages because
additional O_3 was produced from NO_2 photolysis. On the other hand, fewer lights resulted in lower NO levels in the system
since NO_2 input was the sole source of NO_x. This led to reduced NO_2 formation from RO_2 + NO reaction (R4a), and subse-
quently less O_3 formation. This aspect is crucial in determining the O_3 sensitivity. In this sense, the presence of fewer lights
implies that higher levels of NO_2 input are required to ensure sufficient NO levels for reaching the VOC-limited regime. This
can be confirmed by the stage where $\sim$ 45 ppb α-pinene was injected (Fig. 4, A9 and A10). During this stage, the O_3 con-
centration showed a significant increase with either 3 or 5 UV lights, indicating that the system had reached the VOC-limited
regime in the previous stage. However, when only 1 UV light was used, the O_3 concentration remained relatively constant,
suggesting that the system with 1 light did not reach the VOC-limited regime. It is worth mentioning that the indicating ratios
exhibited more significant changes when using more lights. This can be attributed to the fact that more lights result in increased
production of O_3 and NO, leading to more drastic changes in HOM distributions and thereby influencing the indicating ratios
to a greater extent.

Using the box model described in section 2.3, the concentrations of O_3 and its precursors were captured well both qual-
itatively and quantitatively (e.g., Fig. 4a). In general, simulated concentrations of O_3 during the steady states differed from
measured values by at most 10%, while differences for NO_x were even smaller. The largest discrepancy in concentrations
Figure 4. Time series of experiment no. 2 with 15 ppb α-pinene and 15 ppb O_3 as initial inputs. 5 UV lights were on during all stages. Three subplots show the time series of different compounds: a) measured (abbreviated as Meas., in solid lines) and modeled (abbreviated as Mod., in dashed lines) concentrations of O_3, NO_x (both shown by left y-axis; the NO concentration is multiplied by 10), and AP (i.e., α-pinene, shown by right y-axis); b) normalized signals of $\sum HOM_{Mono,O>8}$ (sum of non-nitrate HOM monomers with more than 8 oxygen atoms), $\sum HOM_{ON,O>8}$ (sum of HOM organic nitrates with more than 8 oxygen atoms), and $\sum HOM_{Di}$ (sum of HOM dimers); c) IR1 ($\frac{\sum HOM_{Di}}{\sum HOM_{ON,O>8}}$) and IR2 ($\frac{\sum HOM_{Mono,O>8}}{\sum HOM_{ON,O>8}}$). The grey shaded area represents the time period selected for background subtraction before calculating the ratio. Dashed vertical lines indicate specific time points of operations, with the corresponding labels for each operation in the subplot a. The bolded number in parentheses in subplot c corresponds to the number of stages. The steady-state mass spectra obtained by the NO_3-CIMS for each stage is shown in Fig. A6.

($\sim 15\%$) was observed for α-pinene, which can be attributed to the simplifications made in the model. Specifically, the OH
255 concentration will be underestimated if the model did not accurately capture the yields of HO_2, which can be converted into OH via reactions with NO.

Overall, both indicating ratios are promising as indicators of O_3 formation sensitivity. However, in all time series (Fig. 4c, A7c-A12c), IR1 ($\frac{\sum \mathrm{HOM_{Di}}}{\sum \mathrm{HOM_{ON,O>8}}}$) exhibited more pronounced changes compared to IR2 ($\frac{\sum \mathrm{HOM_{Mono,O>8}}}{\sum \mathrm{HOM_{ON,O>8}}}$) as we shifted the O_3 formation regimes. This highlights that IR1 holds better potential for quantitatively indicating O_3 formation sensitivity in the absence of other perturbing factors. The intensity of light (i.e., NO_2 photolysis rate) played a crucial role in determining O_3 sensitivity regimes by controlling the amount of NO. Our box model successfully reproduced the measured values of O_3 and its formation precursors, making it reasonable to extend the model to generate O_3 isopleths under chamber conditions beyond those covered in our experiments. With these we can better elucidate how well the HOM ratios can function as O_3 sensitivity indicators in this system.

3.4 Viability of the indicating ratios

In order to validate the indicating ratio, we generated O_3 isopleths by modeling various combinations of input NO_2 and α-pinene concentrations. The indicating ratios obtained from all steady state stages were scattered on the same coordinate system (IR1: Fig. 5-6 and IR2: Fig. A13-A14). The purpose of varying the injection rates of either NO_x or α-pinene within each experiment (e.g., colored curves in Fig. 5) was to shift the system between the VOC-limited and NO_x-limited regimes. Unlike previous studies that used the concentration of VOC as the x-axis (Kinosian, 1982; Chameides et al., 1992), in this study, the x-axis represented the product of the measured α-pinene and O_3 concentrations. This is because the product reflects the potential for RO_2 formation, which reacts directly with NO to contribute to O_3 accumulation (R1-R4a). In typical EKMA plots the oxidant is primarily thought to be OH, the concentration of which is independent of the VOC concentrations, thus the x-axis would be largely equivalent regardless of whether plotting VOC or VOC times oxidant. In our case, the VOC concentration will directly influence the oxidant (i.e., O_3) concentration through chemical reactions, and therefore we chose to use the current x-axis. The ridge line of the EKMA curves was plotted for each experiment, represented by dotted lines in e.g., Fig. 5b-d. The reason for separating the b-d plots from each other is due to the differences in constant O_3 inputs or NO_2 photolysis rates in each experiment, resulting in distinct O_3 isopleths. For the context of this work, we do not separate a transition regime where O_3 formation is sensitive to both NO_x and VOC, but simply define the VOC- and NO_x-limited regimes based on the ridge line. Farther above the ridge line, the system is more VOC-limited, while farther below the line, the system is more NO_x-limited. It's notable that in the VOC-limited regime, instead of a reduction, the O_3 concentration even increased slowly with the addition of NO_x, primarily due to the photolysis of the input NO_2.

Comparing experimental and model results, the steady state stages of all experiments with 5 UV lights exhibited a consistent pattern for the indicating ratios, allowing qualitative determination of O_3 formation sensitivity (Fig. 5 and A13). Generally, the farther the steady state point is from the ridge line, the darker the coloring (either blue or green). Specifically, when the color is darker blue, it indicates a smaller value of the indicating ratios, suggesting a higher likelihood of the system being in the VOC-limited regime. Conversely, when the color is darker green, it signifies a higher value of the ratios, indicating a higher likelihood of the system being in the NO_x-limited regime. It is worth noting that experiment no. 7 was essentially a duplicate of experiment no. 1, but with additional stages. When comparing the indicating ratios at stages with the same inputs, as shown in Fig. 5d and A13d, it becomes apparent that the values are highly consistent and closely aligned. Moreover, the background
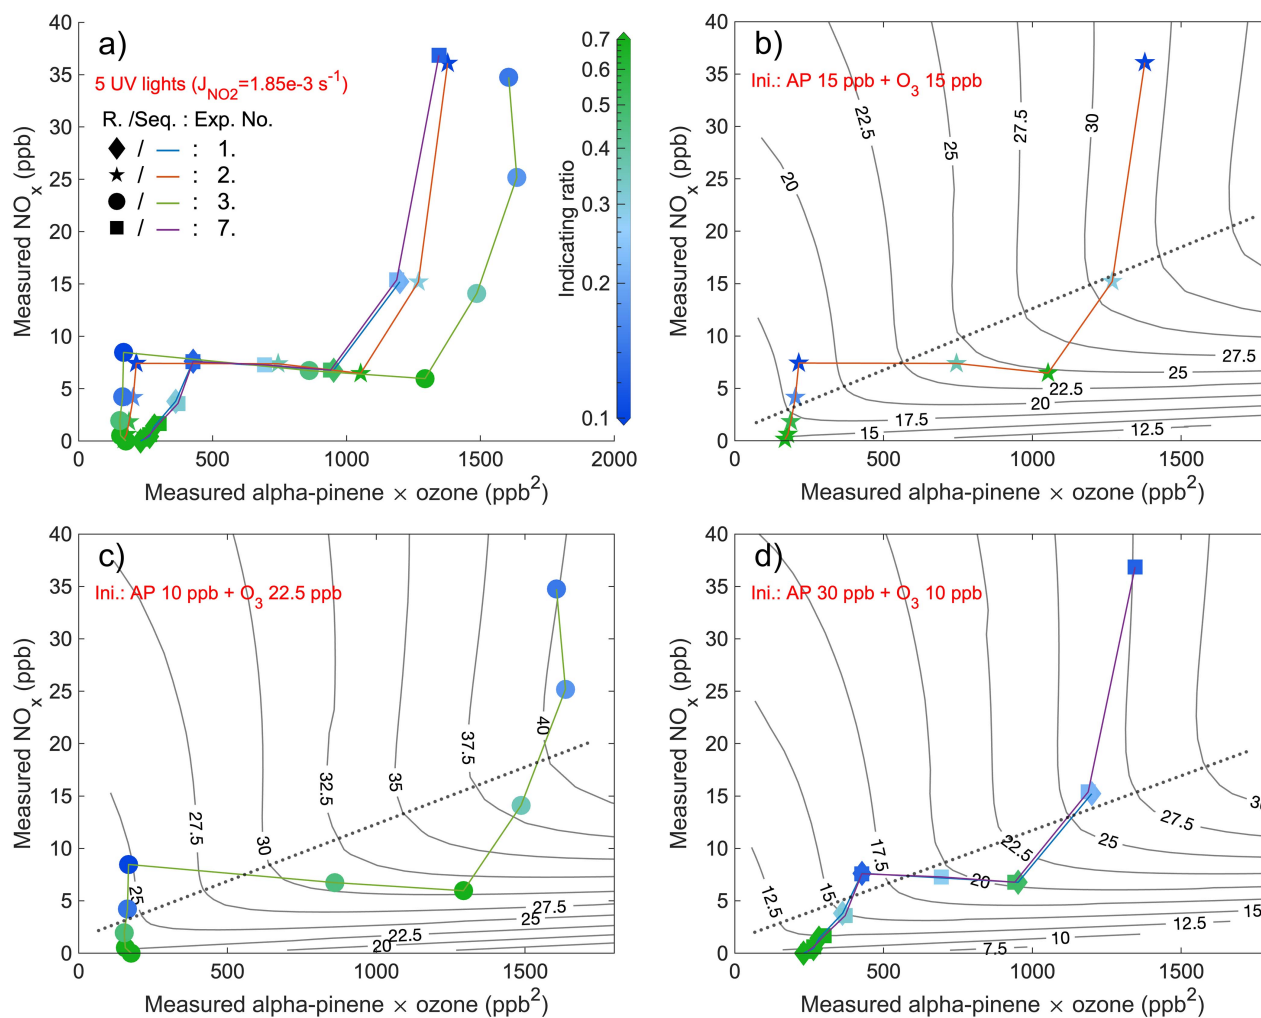

Figure 5. Steady state IR1 ($\frac{\sum \mathrm{HOM_{Di}}}{\sum \mathrm{HOM_{ON,O>8}}}$) of experiments from four days with 5 UV lights. X-axis is the multiplication of measured (steady state) α-pinene and O_3 concentrations, while y-axis is the measured (steady state) NO_x. The scatter points (exp. no. 1 (experiment number 1): diamond; exp. no. 2: star; exp. no. 3: round; exp. no. 7: square) are colored by values of IR1 (abbreviated as R. in the figure), and are connected by curves (exp. no. 1: blue; exp. no. 2: orange; exp. no. 3: green; exp. no. 7: purple) showing the sequence (Seq.) of experimental stages. Panel a combines stages of all four days, and the rest three subplots respectively show the stages of experiments with different initial (Ini.) inputs (exp. no. 1 and 7 are in the same panel d due to same initial inputs). EKMA curves (isopleth of O_3 concentrations in ppb), simulated by the box model, are black solid lines, while dotted lines are corresponding ridge lines.

signals of $HOM_{ON,O>8}$, $HOM_{Mono,O>8}$ and HOM_{Di} increased substantially with experiments going on, from 5×10^{-4} - 2×10^{-3} (Fig. A7b) to 4×10^{-3} - 2×10^{-2} (Fig. A11b). However, the accumulating background did not have a significant impact on the
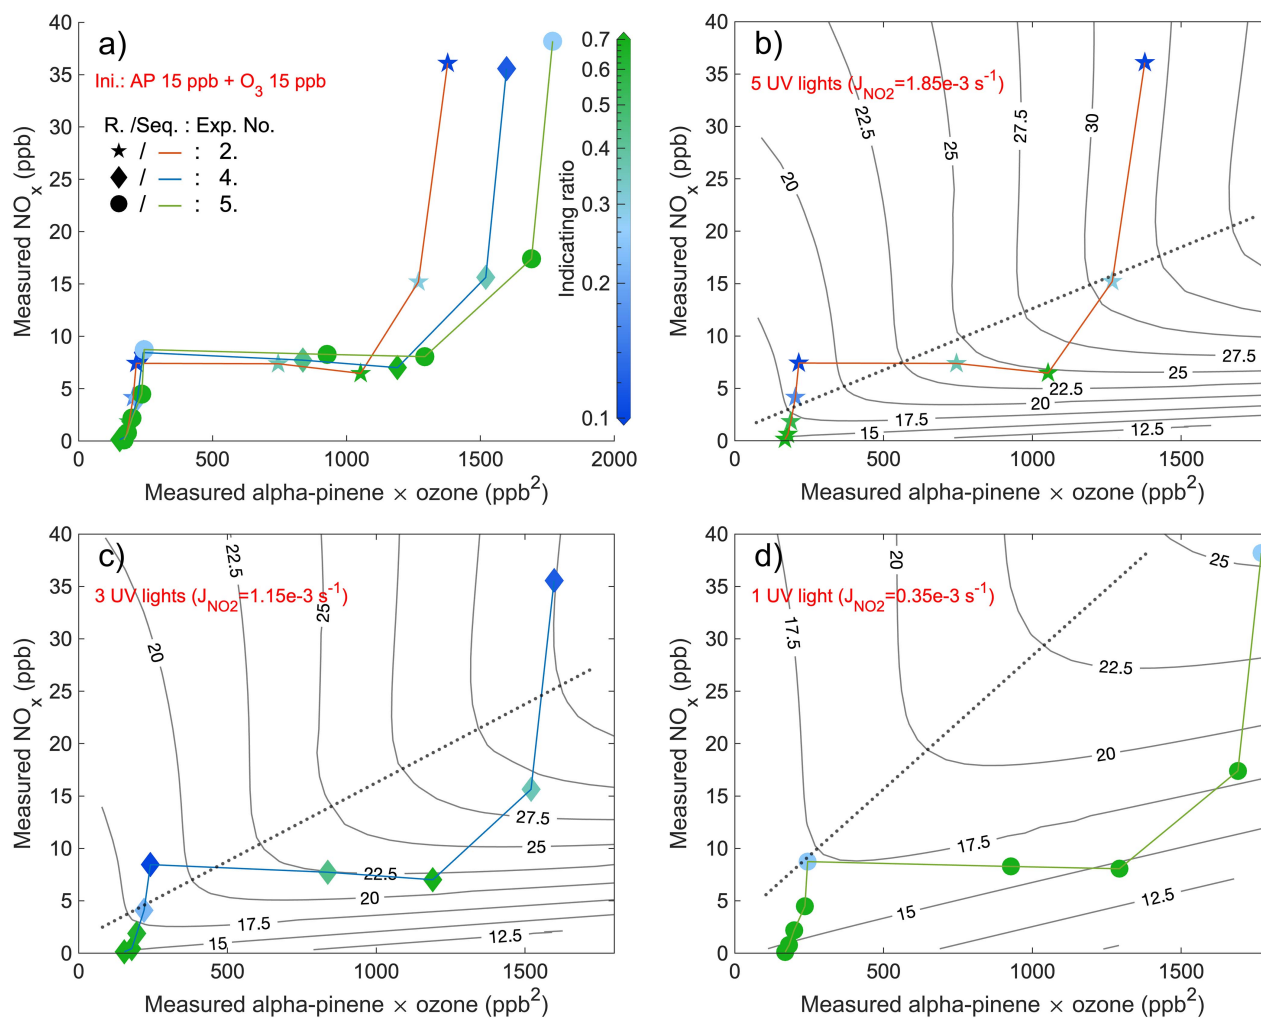

Figure 6. Steady state IR1 ($\frac{\sum \mathrm{HOM_{Di}}}{\sum \mathrm{HOM_{ON,O>8}}}$) of experiments from three days with 5, 3, and 1 UV lights, respectively. X-axis is the multiplication of measured (steady state) α-pinene and O_3 concentrations, while y-axis is the measured (steady state) NO_x. The scatter points (exp. no. 2 (experiment number 2): star; exp. no. 4: diamond; exp. no. 5: round) are colored by values of IR1 (abbreviated as R. in the figure), and are connected by curves (exp. no. 2: orange; exp. no. 4: blue; exp. no. 5: green) showing the sequence (Seq.) of experimental stages. Panel a combines stages of all three days with the same initial (Ini.) inputs, and the rest three subplots respectively show the stages of experiments with different amount of UV lights. EKMA curves by the box model are in black lines and the dotted lines are corresponding ridge lines.

indicating ratios, after the background subtraction (Fig. 5d and A13d). These highlight the remarkable reproducibility of the indicating ratios in our chamber experiments.

295   To investigate the impact of light intensities, a similar comparison was conducted for experiments with the same initial inputs using 5, 3, and 1 UV lights (Fig. 6 and A14). The observed changes in the pattern of the indicating ratios are in line with those

observed in the 5 UV lights experiments described above. The most significant observation is that at lower UV light intensity, the ridge line shifted towards higher NO_x levels at the same potential for RO_2 formation (i.e., the same value of x-axis) (Fig. 6b-d and A14b-d). This finding aligns with the time-series comparison presented in section 3.3, which indicates that at weaker UV

300   intensity, higher input NO_2 is required to generate NO levels sufficient to shift the system towards the VOC-limited regime. When comparing stages with the same conditions except different UV lights, we observed that generally the lower intensity of UV lights corresponded to higher values of the indicating ratios (Fig. 6, A14), showing a higher likelihood of the system being in the NO_x-limited regime. This finding is in agreement with the shift of the ridge line. The correlation between UV intensities, the indicating ratios, and the position of the ridge line reinforces the relationship between the indicating ratios and

305   O_3 formation sensitivity. It suggests that in addition to the relative changes, the absolute values of the indicating ratios are also informative.

The conclusion can be drawn that the indicating ratios can predict the O_3 formation sensitivity, both qualitatively and even quantitatively. More specifically, regardless of the light intensity, IR1/IR2 consistently indicate the VOC-limited regime when below 0.2/0.4, and the NO_x-limited regime when above 0.5/0.7.

310   **3.5   Implication and further improvements**

Our chamber study (section 3.4) confirmed the significant role of the indicating ratios in determining O_3 formation sensitivity, both qualitatively and quantitatively. However, in the real atmosphere, the conditions will vary significantly more than in our simple system. Most importantly, the amount of different precursor VOC will be vastly greater, and in reactions with OH, the distribution of different types of RO_2 radicals will also be far more complex. As an example, in a rural setting there can be

315   a wide variety of small VOC (C1-C4), isoprene (C5), aromatics (C6-C9) and monoterpenes (C10) that all produce significant amounts of RO_2. Consequently, from these molecules, dimers can form with any carbon number between 2 and 20, while monomers can have carbon numbers between 1 and 10. In addition, both VOC and oxidant concentrations as well as radiation and meteorological patterns will vary over time. This means that it will be difficult to find universal compounds to include in the HOM_{Di}, HOM_{Mono} and HOM_{ON} groups used to calculate the indicating ratios for a given site and a given time. For

320   example, it is likely that there will be few environments where C10-RO_2 from monoterpenes would be efficiently reacting with each other during daytime, meaning that the C20 dimers used here are unlikely to be usable. It remains to be seen whether the HOM_{Mono}-to-HOM_{ON} ratio can be used for C10 compounds in areas with high monoterpene emissions. Nevertheless, conceptually the link between HOM formation pathways and O_3 formation should hold, and it may be possible to determine suitable compound groups for various sites. Our study focused exclusively on α-pinene, but the intrinsic connection between

325   the indicating ratios we proposed and O_3 formation (Fig. A1) is not limited to this specific VOC. Further laboratory and ambient studies are necessary to investigate additional VOC of interest and expand our understanding of the indicating ratios' applicability and generalizability in predicting O_3 formation sensitivity under various atmospheric conditions. In addition, at the extremes, ranging from clear formation of dimeric species to complete lack of dimeric species with abundant organic HOM nitrates, this can be considered a strong qualitative indicator being in a NO_x- or VOC-limited regime, respectively.

4 Conclusions

Both O_3 and HOM are of significant interest, given their impacts from small-scale personal health to large-scale global climate. Due to the intrinsic connection between the formation mechanisms of O_3 and HOM, we suggest new indicators, denoted as $\frac{\sum \mathrm{HOM_{Di}}}{\sum \mathrm{HOM_{ON,O>8}}}$ and $\frac{\sum \mathrm{HOM_{Mono,O>8}}}{\sum \mathrm{HOM_{ON,O>8}}}$, for determining O_3 formation regimes based on the distribution of HOM. One main improvement of using HOM-based indicating ratios compared to those suggested earlier would be the short lifetimes of HOM, which means that these new indicators would be real-time indicators of the formation regime. To assess the viability of the indicating ratios, a series of chamber experiments were carried out using a NO_3-CIMS, a PTR-TOF, and O_3/NO_x monitors. As expected, an increase in NO_x inputs led to an increase in HOM_{ON} and a decrease in HOM_{Di}, HOM_{Mono} and the indicating ratios. Conversely, an increase in α-pinene resulted in a rise in the indicating ratios. Furthermore, when adding enough of one of the O_3 formation precursors (either NO_x or α-pinene), the rate of increase in O_3 concentration slowed down or even stopped. This indicates that the system was shifting to or had already reached the other limited regime.

With a box model, which closely reproduced the measured concentrations of O_3 and its precursors, O_3 isopleths were obtained for different concentrations of NO_x and α-pinene. After drawing ridge lines of the isopleths, it was observed that the indicating ratios provide a qualitative prediction of the O_3 formation regimes: lower values of the ratios indicate a greater likelihood of the system being located in the VOC-limited regime, and vice versa. With less intense UV light ($\lambda \approx 400$ nm), a higher amount of NO_2 was required to shift the system towards the VOC-limited regime. This can be attributed to a decrease in the formation of NO from NO_2 photolysis. Nevertheless, the absolute values of the indicating ratios exhibited a consistent behavior across different intensities of UV light, suggesting that these absolute values are highly valuable for analyzing O_3 formation sensitivity.

The main objective of this study was to evaluate the concept of using HOM distributions in indicating O_3 formation sensitivity. Based on our outcomes, we can conclude that the ratio of HOM dimers or non-nitrate monomers to HOM organic nitrates (i.e., $\frac{\sum \mathrm{HOM_{Di}}}{\sum \mathrm{HOM_{ON,O>8}}}$ or $\frac{\sum \mathrm{HOM_{Mono,O>8}}}{\sum \mathrm{HOM_{ON,O>8}}}$) has the capability to indicate O_3 formation sensitivity, even quantitatively, in this simple system of monoterpene ozonolysis. An indicating ratio of this kind would aid in better control of O_3 pollution and have the potential to be incorporated as a useful parameter in global models for analyzing O_3 formation sensitivity under diverse environmental conditions.

Nevertheless, future studies will need to assess whether this approach is feasible to be applied in real-world conditions where the chemistry is far more complex. The variability of VOC precursors alone will greatly perturb the ideal situation observed in our chamber. Still, we posit that environments with high monoterpene emissions will also produce abundant C10-RO_2 concentrations, and the comparison of the highly oxygenated monomeric termination products (i.e., nitrates vs non-nitrates) can provide an indication of the relative RO_2 termination pathways. Further studies, both ambient observation as well as chamber experiments involving multiple VOC and oxidants, will be necessary to determine the potential of HOM-based indicators for O_3 formation.

Panel a combines stages of all three days with the same initial (Ini.) inputs, and the rest three subplots respectively show the stages of experiments with different amount of UV lights. EKMA curves by the box model are in black lines and the dotted lines are corresponding ridge lines.

Table A1. Zero-VOC experiment conditions. Experiment numbers (No.) and number of total stages are shown in the first two columns. Input information include the number and NO_2 photolysis rates (J_{NO_2}) of UV lights ($\lambda \approx 400$ nm) and concentrations of O_3, α-pinene, and NO_x.

Experiment *No.*	Number of stages	Input			
		Number of lights	J_{NO_2} (s^{-1})	O_3 (ppb)	NO_x range (ppb)
Z1./Z2./Z3.	9/7/7	5	1.85×10^{-3}	10/15.5/22.5	0.7 - 44.5
Z4.	8	3	1.15×10^{-3}	15	0.7 - 44.5
Z5.	7	1	0.35×10^{-3}	15.5	0.7 - 44.5

The figures are shown....

Table A2. Chemical reactions and their reaction rate coefficients used for the box model. Note that RO_2 represent all kinds of peroxy radicals, thus there are huge uncertainties regarding reaction rates. This model is only meant for simulating concentrations of O_3 and its precursors.

Chemical reactions	Reaction rate coefficients [a]
1. $NO_2 + hv \xrightarrow{O_2} NO + O_3$	$0.35/1.15/1.85 \times 10^{-3}$
2. $O_3 + NO \rightarrow NO_2 + O_2$	1.8×10^{-14}
3. $\alpha-pinene + O_3 \xrightarrow{O_2} RO_2 + OH$	8.7×10^{-17}
4. $\alpha-pinene + OH \xrightarrow{O_2} RO_2$	5.5×10^{-11}
5. $RO_2 + NO \rightarrow RO + NO_2$	1×10^{-11}
6. $RO_2 + RO_2 \rightarrow 2RO + O_2$	8×10^{-13}
7. $RO + O_2 \rightarrow HO_2$	Instantaneous
8. $NO + OH \rightarrow HNO_2$	4×10^{-11}
9. $NO + OH \xrightarrow{O_2} HO_2 + NO_2$	1.2×10^{-13}
10. $NO_2 + OH \rightarrow HNO_3$	4×10^{-11}
11. $HO_2 + NO \rightarrow OH + NO_2$	1×10^{-11}
12. $HO_2 + NO_2 \rightarrow HO_2NO_2$	3×10^{-14}
13. $HO_2 + HO_2/RO_2 \rightarrow peroxides$	2×10^{-11}

[a] Except the NO_2 photolysis rates (s^{-1}), all the other reaction rates (cm$^3 \cdot$s^{-1}) are adapted from NIST (National Institute of Standards and Technology) Chemical Kinetics Database (more information see https://kinetics.nist.gov/kinetics/index.jsp).
