## 32 33 **Abstract**

34 The sulfur cycle plays a key role in atmospheric air quality, climate, and ecosystems, such as  
35 pollution, radiative forcing, new particle formation, and acid rain. In this study, we compare the  
36 spatial and temporal distribution of four sulfur-containing species, dimethyl sulfide (DMS),  
37 sulfur dioxide (SO<sub>2</sub>), particulate methanesulfonate (MSA), and particulate sulfate (SO<sub>4</sub>), that  
38 were measured during the airborne NASA Atmospheric Tomography (ATom) mission and  
39 simulated by five AeroCom-III models to analyze the budget of sulfur cycle from the models.  
40 This study focuses on remote regions over the Pacific, Atlantic, and Southern Oceans from near  
41 the ocean surface to ~12-km altitude range, and covers all four seasons. These regions provide us  
42 with highly heterogeneous natural and anthropogenic source environments, which is not usually  
43 the case for traditional continental studies. We examine the vertical and seasonal variations of  
44 these sulfur species over tropical, mid-, and high-latitude regions in both hemispheres. We  
45 identify their origins from anthropogenic versus natural sources with sensitivity studies by  
46 applying tagged tracers in GEOS model linking to emission types of anthropogenic, biomass  
47 burning, volcanic, and oceanic emissions. Our work presents the first assessment of AeroCom  
48 sulfur study using ATom measurements, providing directions for improving sulfate simulations,  
49 which remain the largest uncertainty in radiative forcing estimates in aerosol climate models. In  
50 general, the differences among model results can be greater than one-order of magnitude.  
51 Comparing with observations, simulated SO<sub>2</sub> is generally low while SO<sub>4</sub> is high. Using

52 interactive oxidant calculation is insufficient to account for model sulfate bias. There are much  
53 larger DMS concentrations simulated close to the sea surface than observed, indicating that the  
54 DMS emissions may be too high from all models. The parameterization of converting DMS  
55 seawater concentrations into DMS emission fluxes needs to be revisited. Anthropogenic  
56 emissions are the dominant source (40-60% of the total amount) for atmospheric sulfate  
57 simulated at locations and times along the ATom flight tracks at almost every altitude, followed  
58 by volcanic emissions (18-32%) and oceanic sources (16-32%). Similar source contributions can  
59 also be derived at broad ocean basin and monthly scales, indicating that any reductions of  
60 anthropogenic sulfur emissions would have global impacts in modern times.

61

## 62 **1. Introduction**

63 Atmospheric sulfur species have wide-ranging environmental and health impacts. About two-  
64 third of sulfur emissions come from anthropogenic activities (Chin et al., 2000); therefore,  
65 considerable efforts have been made to reduce these sulfur emissions. For example, acid rain  
66 occurs when sulfur dioxide (SO<sub>2</sub>) is oxidized to form sulfuric acid and particulate sulfate (SO<sub>4</sub>),  
67 which fall to the ground with the rain (Bian et al., 1993; Grennfelt et al., 2020) and can devastate  
68 aquatic ecosystems (Josephson et al., 2014; McDonnell et al., 2021). Through the competing  
69 neutralization reaction of SO<sub>4</sub> and nitrate with NH<sub>3</sub> and other alkaline species, SO<sub>4</sub> affects  
70 strongly both particulate nitrate formation (Bian et al., 2017) and aerosol pH (Huang et al., 2020;  
71 Nault et al., 2021). Sulfate is a key component of particulate matter (PM), which degrades air  
72 quality (Dong et al., 2018; Tan et al., 2018) and directly reflects the sun's rays (Moch et al.,  
73 2022; Myhre et al., 2013). Due to its highly hygroscopic nature, sulfate aerosol affects cloud  
74 physics (Boucher et al., 2013; Breen et al., 2021; Seinfeld et al., 2016) and thus indirectly  
75 radiative forcing (Penner et al., 2016; Wang et al., 2021) through aerosol-cloud interactions. The  
76 contribution of aerosols to atmospheric clouds and energy budget remains the largest uncertainty  
77 in climate models (Gryspeerd et al., 2023; Jia et al., 2021, 2022; Klein et al., 2013; Malavelle et  
78 al., 2017). Sulfate is important primarily because the atmospheric sulfate component itself  
79 contributes to radiation forcing (RF) almost as much as all other major non-natural aerosol  
80 components, as concluded from 16 AeroCom model results (Myhre et al., 2013). More  
81 importantly, uncertainty in sulfate simulations in current climate models is a major contributor to  
82 biases in aerosol optical depth (AOD, Fig. 3 in Gliß et al., 2021) and RF (Fig. 7 in Myhre et al.,  
83 2013).

84

85 Unlike other major atmospheric aerosols, a significant fraction (i.e., roughly a quarter) of sulfate  
86 in the atmosphere comes from marine biological emissions (Chin et al., 1996). The impact of  
87 oceanic sulfate is particularly pronounced on marine shallow clouds, which are characterized by  
88 low droplet number concentrations and weak updraft velocities (Rissman et al., 2004). Sulfur  
89 research has also focused on the tropical upper troposphere (TUT), where the growth of new  
90 aerosol particles and homogeneous nucleation involving sulfuric acid is at a maximum  
91 (Williamson et al., 2019), and where deep convective transport allows a small portion of the  
92 sources to reach the lower stratosphere. The resulting sulfate aerosols in the stratosphere can  
93 persist for years (Holton et al., 1995). Unfortunately, the observations in the TUT region and  
94 above are sparse. Acquiring atmospheric composition and its chemical/physical properties over  
95 remote oceans is challenging, although satellites can often provide total column constraints of  
96 aerosol optical depth.

97

98 The NASA Earth Venture Suborbital (EVS-2) Atmospheric Tomography (ATom) airborne  
99 mission provided abundant measurements of gases and aerosols over the world's oceans (Hodzic  
100 et al., 2020; Thompson et al., 2021). In particular, a suite of instruments integrated on the NASA  
101 Douglas DC-8 jetliner (hereafter DC-8) made measurements of many important sulfur species  
102 including dimethyl sulfide (DMS), SO<sub>2</sub>, particulate methanesulfonate (MSA) and SO<sub>4</sub> over the  
103 Pacific and Atlantic Oceans in both hemispheres and the Southern Ocean in all four seasons.  
104 This comprehensive sulfur dataset provides us with unprecedented opportunities to assess sulfur  
105 source, transport, chemistry, deposition, and particle activation and growth represented in the  
106 global aerosol models, and to estimate the extent of anthropogenic influence on remote oceanic  
107 atmospheric composition and cloud properties.

108  
109 This study has two specific scientific goals. First, we explore the vertical and seasonal variation  
110 of sulfur species (i.e., DMS, SO<sub>2</sub>, MSA, and SO<sub>4</sub>) using ATom measurements and simulations  
111 from five global models that participated in the AeroCom-ATom model experiments. AeroCom  
112 is an international initiative of scientists aiming at the advancement of the understanding of the  
113 global aerosol and its impact on climate (<https://aerocom.met.no/>). Here we focus on remote  
114 regions over the Pacific, Atlantic, and Southern Oceans, from near the surface to an altitude of  
115 about 12 km, covering all four seasons. Second, we determine whether the produced SO<sub>4</sub>  
116 originated from anthropogenic or natural sources by using tagged tracers associated with  
117 emission types.

118  
119 Our work is the first study to use ATom measurements for comparison with the AeroCom  
120 models, focusing on all sulfur species simulated in current aerosol climate models. This work  
121 extends previous efforts using ATom measurements to evaluate the organic carbon (Hodzic et  
122 al., 2020) and black carbon (Katich et al., 2018) of AeroCom models, as well as individual  
123 models focusing on new particle formation in the tropics (Williamson et al., 2019), fine aerosol  
124 lifetime (Gao et al., 2022), aerosol vertical transport (Yu et al., 2019), sea salt (Bian et al.,  
125 2019), smoke (Schill et al., 2020), mineral dust (Froyd et al., 2022), and DMS chemistry (Fung  
126 et al., 2022). Furthermore, to our knowledge, there are no studies that systematically investigate  
127 the changes and sources of all major sulfur species in the ocean. Our study aims not only to  
128 reveal sulfur variability based on multiple measurements and model simulations, but also to tease  
129 out the underlying processes behind the variability through a comprehensive analysis of  
130 simulated sulfur species in aerosol climate models.

131  
132 The structure of this paper is as follows. Section 2 describes the ATom measurements and the  
133 AeroCom models used in this study. Section 3 presents the ATom-AeroCom sulfur comparison  
134 from different perspectives, namely the overall comparison in Sect. 3.1, the vertical profiles in  
135 Sect. 3.2, and the regional and seasonal analysis in Sect. 3.3. The sulfur budget analysis is given  
136 in Sect. 4. We further present investigations of source origins for aerosol SO<sub>4</sub> along flight tracks  
137 and over oceans in Sect. 5. Finally, we summarize our findings in Sect. 6.

## 138 139 **2. Data**

### 140 **2.1 ATom measurements**

141 ATom was a NASA-funded Earth Venture Suborbital project designed to study the effects of air  
142 pollution on chemically reactive gases, aerosols, and greenhouse gases in the remote atmosphere.  
143 ATom deployed a large suite of gas and aerosol measurement instruments on the NASA DC-8

144 aircraft for systematic sampling, covering an extended region of the globe from 85°N to 85°S  
145 over the Pacific and Atlantic Oceans, with vertical profiles from near-surface to near-tropopause  
146 (i.e., 0.2-12 km, Thompson et al., 2021). Four ATom deployments (ATom-1 to -4) were  
147 executed over each of the four seasons from 2016 to 2018, and their flight paths are shown in  
148 Fig. 1. The extensive aerosol and gas measurements made during ATom include inorganic and  
149 organic aerosols, precursor gases, particle size distributions and particle composition. Table 1  
150 lists the instruments for ATom sulfur species observations used in this study including the  
151 relevant sampling details needed for the model comparison.

152  
153 We use SO<sub>4</sub> and MSA that had been measured by two instruments, the University of Colorado  
154 Aerodyne high-resolution time-of-flight aerosol mass spectrometer (AMS, Canagaratna et al.,  
155 2007; Guo et al., 2021), and the NOAA Particle Analysis by Laser Mass Spectrometry (PALMS,  
156 Froyd et al., 2019). The latter makes *in situ* measurements of the chemical composition of  
157 individual aerosol particles. Furthermore, AMS measured submicron aerosols while PALMS  
158 provided mass mixing ratio and size distribution up to 3 μm in dry diameter (Brock et al., 2019).  
159 It is worth noting that AMS data were independently processed and reported at both 1-s and 60-s  
160 time resolutions by instrument PI (Jimenez et al., 2019). The detection limit varied with different  
161 averaging time resolutions, and they were provided directly for each sampling point in AMS  
162 datasets. Some negative measurements were also presented in AMS datasets, and this is normal  
163 for measurements of very low concentrations in the presence of instrumental noise. The AMS  
164 data at 60-s resolution is recommended owing to more robust peak fitting at low concentrations  
165 (Hodzic et al., 2020). Given the complex data overlays (i.e., starting, ending, and frequency)  
166 reported from multiple instruments, the ATom team also provide a 10-s merged dataset to  
167 facilitate users' applications. In this study, we evaluate data reported in different time  
168 resolutions, using AMS as an example, to ensure the quality of merged data that are exclusively  
169 used as the primary dataset in this work.

170  
171 Two instruments were used for SO<sub>2</sub> measurements: the California Institute of Technology  
172 Chemical Ionization Mass Spectrometer (CIMS) and the NOAA Laser Induced Fluorescence  
173 (LIF) (Table 1). The CIMS uses CF<sub>3</sub>O<sup>-</sup> as a reagent ion which reacts with SO<sub>2</sub> via fluoride ion  
174 transfer chemistry. The product ion is detected by a compact time-of-flight mass spectrometer  
175 (CToF). The precision of the CIMS SO<sub>2</sub> measurement decreases with increasing water vapor  
176 concentration (Eger et al., 2019; Huey et al., 2004; Jurkat et al., 2016; Rickly et al., 2021),  
177 making it challenging to measure SO<sub>2</sub> in remote ocean regions. In these regions, the ambient  
178 water vapor may be sufficiently high that the CIMS SO<sub>2</sub> precision at 1-s resolution (~130 parts  
179 per trillion by volume, pptv) is insufficient for measuring ambient SO<sub>2</sub> value there (<100 pptv).  
180 To address this shortcoming, the ATom science team added a new instrument, the NOAA LIF, to  
181 the ATom-4 payload. The NOAA LIF instrument uses red-shifted laser-induced fluorescence to  
182 detect SO<sub>2</sub> at very low ppt levels (Rickly et al., 2021; Rollins et al., 2016). Both instruments  
183 report negative values and the detection limit of the LIF instrument is about 2 pptv.

184  
185 DMS was measured during ATom by two instruments, the University of California, Irvine  
186 Whole Air Sampler (WAS), and the NCAR Trace Organic Gas Analyzer (TOGA). The WAS  
187 reported DMS for all four ATom deployments, while the TOGA reported data for ATom-2 to -4  
188 and not for ATom-1 due to possible issues associated with the TOGA inlet (the inlet was  
189 changed for ATom-2 to -4). Both instruments have comparable detection limit (1 pptv) and

190 accuracy (~15%). However, the sampling time interval of WAS (variable but ~180s) was longer  
191 than TOGA (~120s).

192

## 193 **2.2 AeroCom models**

194 Five global aerosol models participated in an AeroCom-ATom model experiment  
195 (<https://wiki.met.no/aerocom/phase3-experiments>): CAM-ATRAS, E3SM, GEOS, IMPACT,  
196 and OsloCTM3. The experiment required all participating models to (1) conduct three-year-  
197 simulations of 2016-2018 (i.e., covering the whole ATom observation period); (2) use or nudge  
198 meteorological data for the simulation period; and (3) use the same pre-defined emission fields  
199 for precursor gases and aerosol tracers. The suggested emissions are the Coupled Model  
200 Intercomparison Project Phase 6 Community Emissions Data System (CEDS, Hoesly et al.,  
201 2018) for anthropogenic source, daily biomass burning emission (such as The Global Fire  
202 Assimilation System, GFAS), a dataset based on satellite volcanic SO<sub>2</sub> observations from the  
203 OMI instrument on the Aura satellite (Carn et al., 2016, 2017) for outgassing and eruptive  
204 volcanic emission, and DMS concentration in sea surface from Lana et al. (2011). Wind-driven  
205 emissions, such as dust and sea salt, are calculated online by each model. Table 2 summarizes  
206 the detailed model characteristics and input datasets relevant to this study. It is worth noting that  
207 CEDS specifies anthropogenic emissions from various sectors, including emissions from  
208 shipping. The version of CEDS used in this work has emissions up to 2014 and all models use  
209 2014 emission for ATom periods. Furthermore, unlike other models that use CEDS emissions,  
210 the anthropogenic emissions of OsloCTM3 are obtained following Shared Socioeconomic  
211 Pathways (SSP) under Representative Concentration Pathway (RCP) scenario with medium  
212 radiative forcing by the end of the century (SSP245, Fricko et al., 2017), and the emissions are  
213 interpolated to 2016 and 2017. Following the experimental protocol, all models provided results  
214 for all AToms except for OsloCTM3 that omitted data in ATom-4. Unlike traditional AeroCom  
215 experiments that used gridded daily/monthly averaged data, modelers are required to interpolate  
216 model results along flight track every 10 s (see more discussion in Sect. 3.1) using three-  
217 dimensional high frequency (e.g., hourly or even less depending on the models' time step) data  
218 to facilitate the comparison. It is worth noting that the models do not have any actual information  
219 at 10-s time resolution, given their time steps are at least 10× greater and their spatial resolutions  
220 are coarse. However, the interpolation methodology suggested here provides the best model  
221 information at their current configuration to compare with aircraft measurements.

222

223 The AeroCom-ATom experiment also designed three sensitivity simulations by tracking gas and  
224 aerosol emissions to anthropogenic, biomass burning, and volcanic sources to attribute the origin  
225 of sulfur sources on sulfur simulations over remote oceans. These experiments were conducted  
226 with the Goddard Earth Observing System (GEOS) model. The setup of the GEOS model  
227 followed the experiment protocol generally, but GEOS used its own daily biomass burning  
228 emissions that were derived from the Quick Fire Emissions Dataset (QFED) developed based on  
229 MODIS fire radiative power and calculated in near real-time at 0.1° resolution (Darmenov and  
230 da Silva, 2015; Pan et al., 2020). Emissions from biogenic sources were calculated using the  
231 Model for Emissions of Gases and Aerosols from Nature (MEGAN) embedded in the GEOS  
232 model.

233

## 234 **2.3 Tag-tracer study in GEOS**

235 Tag trackers or tags are tied to sources of selected emission types and/or emission locations.  
236 Such tag isolates plume from certain activities and is a powerful tool to help understand source  
237 attribution or diagnose model performance at the process level. The mechanism behind this  
238 technique is that each specific aerosol component in GEOS GOCART is modeled independently  
239 of the other components, and the contribution of each emission type to the total aerosol mass is  
240 not disturbed by the other emission types. Therefore, additional aerosol tracers can be easily  
241 "tagged" to capture emission type (e.g., anthropogenic, biomass burning, etc.) and location  
242 (local, regional or global scale). Tags can be multi-instantiated and computed simultaneously  
243 with their baseline counterparts, thereby increasing the computational efficiency of scientific  
244 research.

246 Tag-tracer technique in GEOS has been widely used in aerosol and gas studies (Bian et al., 2021;  
247 Nielsen et al., 2017; Strode et al., 2018) and in supporting various aircraft field campaigns such  
248 as Arctic Research of the Composition of the Troposphere from Aircraft and Satellites  
249 (ARCTAS) and ATom. Such techniques are also adopted in other models such as GEOS-Chem  
250 model (Fisher et al., 2017; Ikeda et al., 2017; Lin et al., 2020) and Community Earth System  
251 Model (CESM, Butler et al., 2018).

253 Four tags linked to emission types of anthropogenic, biomass burning, volcanic, and marine  
254 emissions were used in GEOS model to identify anthropogenic versus natural sources of sulfate,  
255 and the results are discussed in Sect. 5.

### 257 **3. ATom-AeroCom comparisons of sulfur species**

258 This section presents a comparison of sulfur species between ATom measurements and  
259 AeroCom model simulations. The consistency and diversity of data across remote regimes, both  
260 horizontally and vertically, help us understand the effects of emissions, transport, and chemical  
261 transformations, and shed light on improving the processes in models to best represent the ATom  
262 observations.

#### 264 **3.1 Overall comparison**

265 The overall performance of SO<sub>4</sub> PDF distribution observed from the AMS and PALMS  
266 instruments and simulated by five AeroCom models for four ATom deployments is presented in  
267 Fig. 2. Also shown in Fig. 2 are the corresponding various percentiles, namely, 0<sup>th</sup> (minimum),  
268 25<sup>th</sup>, 50<sup>th</sup> (median), 75<sup>th</sup>, and 100<sup>th</sup> (maximum), and the mean for statistical analyses. The ATom  
269 team provided a 10-s merged dataset deliberately by integrating data from various instruments to  
270 a unified temporal resolution. We use this 10-s merged data where observations above detection  
271 limit (DL) throughout the main text unless otherwise stated. When multiple instruments  
272 measured the target field, only points where all instrument measured above DL values were  
273 included in analysis, as AMS 10-s in red and PALMS 10-s in grey in Fig. 2. All model results  
274 were sampled mimicking flight observations (see Sect. 2.2), and only data with measurements  
275 available were used in comparison. This approach ensures that model evaluation is based on  
276 high-quality measurements. It is worth noting that the given statistical values in this method  
277 represent more regions having high tracer concentration or mixing ratio. In the supplementary  
278 material, we further give a model-observation comparison for all available measurement data  
279 including negatives.

280

281 The mean of PALMS SO<sub>4</sub> is generally about 10-50% higher than AMS SO<sub>4</sub> across four ATom  
282 deployments. This performance may be attributed, at least in part, to the fact that the sample size  
283 range of PALMS (~3 μm) is larger than that of AMS (~0.75 μm), as mentioned in Sect. 2.1.  
284 However, the difference between the two observations is much smaller than the difference  
285 between observation and model. Clearly, the differences in simulated SO<sub>4</sub> among models are  
286 high and can easily exceed several orders of magnitude. Most observed and simulated SO<sub>4</sub>  
287 exhibit highest probability density around SO<sub>4</sub> values of 10-100 ng sm<sup>-3</sup>. With the exception of  
288 GEOS and CAM-ATRAS, the model SO<sub>4</sub> PDFs show higher tails beyond 100 ng sm<sup>-3</sup>, which  
289 explain the higher median and mean SO<sub>4</sub> simulated by the models. Statistical analysis performed  
290 on selected percentiles (box-and-whisker panels in Fig. 2) indicates that multi-model SO<sub>4</sub>  
291 medians are about 3.7 (ATom-1), 2.2 (ATom-2), 1.9 (ATom-3), and 1.2 (ATom-4) times higher  
292 than observed. In general, nearly all measurements and models indicate that SO<sub>4</sub> concentrations  
293 on a global ocean basis are highest during the Northern Hemisphere (NH) spring season (ATom-  
294 4). Similar analysis was also performed on all (e.g., both positive and negative) measurement  
295 data (Fig. S2), the median/mean values of observations are naturally smaller than those in Fig. 2  
296 by 8-20%, but the PDF distributions are almost identical between the two treatments.  
297

298 Figure 3 shows the PDF distribution and statistics for SO<sub>2</sub>. All observed and simulated data were  
299 reprocessed by including points above the detection limit (2 pptv) only. Both instruments (CIMS  
300 and LIF) were deployed during ATom-4. Despite CIMS being less precise than LIF (Rollins et  
301 al., 2016), both instruments agreed within 95% and CIMS measured SO<sub>2</sub> concentrations were  
302 consistently 3-7% lower than LIF measurements. This difference is within the combined  
303 uncertainties of the two measurements, but it suggests a systematic calibration difference that is  
304 currently unresolved (Rickly et al., 2021). Meanwhile, the width of CIMS SO<sub>2</sub> PDF (measured at  
305 half-height) is narrower in ATom-4 than ATom-3, because of improved measurement precision  
306 in ATom-4. The CIMS resolution was improved in ATom-4, which enables a better separation of  
307 SO<sub>2</sub> and formate-H<sub>2</sub>O. The CIMS SO<sub>2</sub> PDF in ATom-4 is around 10 pptv and is more consistent  
308 with LIF measurements and model simulations. In contrast, the distribution of SO<sub>2</sub> measured by  
309 CIMS during ATom-1 to -3 is spread much wider than the models. Throughout ATom periods,  
310 models, especially E3SM, GEOS, and OsloCTM3, show higher peak heights and narrower peak  
311 widths. Statistics indicate lower model SO<sub>2</sub> medians than observed (box-and-whisker in Fig. 3),  
312 especially during ATom-1. However, the model means are comparable or even higher than those  
313 observed, indicating that the models simulate unobserved episode events. Consequently, the  
314 simulated mean/median ratio is higher than the observed value. Among the four ATom  
315 deployments, ATom-4 has much better model observation consistency. Figure S3 presents the  
316 corresponding analysis, including the measured negative values. Compared to Fig. 3, the  
317 observed median and mean values drop substantially (up to 50%), but the model statistics change  
318 relatively small.

319  
320 Atmospheric DMS observations are scarce, especially on a global scale. Thus, DMS  
321 measurements by the two instruments (WAS and TOGA) during the four ATom deployments  
322 provide an unprecedented opportunity to investigate biological DMS over global remote oceans  
323 and evaluate model DMS simulations on spatial and temporal distributions. By excluding points  
324 with measured values below detection limit (i.e., 1 pptv), the overall DMS comparison in Fig. 4  
325 indicates TOGA has higher data peaks and probability densities when DMS ranges from 3-10  
326 pptv. However, this does not appear to be consistent with the lower median and mean values of

327 TOGA, indicating a higher tail in the WAS DMS PDF. Likewise, although the peak of WAS  
328 DMS PDF is significantly higher than all models from 3-10 pptv (~5-20 pptv for ATom-3), the  
329 median and mean of the WAS DMS are lower, suggesting an even higher tail in model DMS  
330 PDF. Overall, there is a big gap between the WAS and TOGA DMS measurements, and both are  
331 surprisingly low compared to the models. Statistical analysis performed on selected percentiles  
332 (the box-and-whisker) indicates that multi-model DMS medians are about 4.9 (ATom-1), 8.6  
333 (ATom-2), 6.6 (ATom-3), and 7.7 (ATom-4) times higher than observed, while model GEOS has  
334 a better performance (i.e., 1.2, 2.7, 2.3, and 2.8 correspondingly). Even though the model DMS  
335 median is mostly higher than the observed value, the degree of overestimation is not as serious as  
336 the mean value that can be more than tenfold, indicating a few points are simulated with  
337 extraordinarily high DMS values. Based on what we know about DMS sources and sinks, these  
338 very large simulated DMS appear most commonly in the boundary layer (BL). Indeed it is  
339 confirmed in Fig 5 by looking at the ratios of DMS median values between model simulations  
340 and observations. The analyses are performed on four vertical ranges (e.g., the entire vertical  
341 column, the BL 0-1.5 km, the low-middle free troposphere 1.5-6 km, and the upper troposphere  
342 6-12 km). The last column “MMM/MOM” refers to multi-model median to multi-observation  
343 median. The high ratio stems mostly from the BL, above which the consistency is much better.  
344 Meanwhile, the PDF distribution and statistics of the models agree better with the WAS  
345 measurement than with the TOGA measurement. We should also acknowledge that this is a very  
346 limited set of observations we used here, and that there are some longer-term DMS observations  
347 near the surface that were used as input for the parameterization of DMS emissions. More DMS  
348 observations near the ocean surface are needed to make a confident comparison.

349

### 350 **3.2 Vertical profiles**

351 Vertical profiles of ATom-1 to -4 for observed and modeled SO<sub>4</sub>, SO<sub>2</sub>, DMS, and MSA are  
352 shown in Figs. 6-9, respectively, for five latitude bands (from the north to the south) and for both  
353 the Pacific and Atlantic Ocean basins. Again, the profiles include equal amounts of data for each  
354 measurement and model result. In other words, all comparisons show only available points  
355 where the two observed values (i.e., AMS vs. PALMS for SO<sub>4</sub> and MSA, CIMS vs. LIF for  
356 SO<sub>2</sub>, and TOGA vs. WAS for DMS) are greater than their detection limits, and where the model  
357 values are extracted.

358

359 The average and range of sulfur tracers for ATom-1 to -4 are shown in Figs. 6-9 and their  
360 corresponding details in each ATom are further given in Figs. S5-8. As shown in Fig. 6, the SO<sub>4</sub>  
361 measured by the two instruments are close to each other and lie generally within the span of  
362 modelled SO<sub>4</sub> throughout the ATom periods. The spread of modeled SO<sub>4</sub> concentrations is large,  
363 easily exceeding an order of magnitude, especially in the upper troposphere. Despite the need for  
364 improvements, the models are generally able to capture the shape of the SO<sub>4</sub> profile.

365 Specifically, CAM-ATRAS and GEOS have good SO<sub>4</sub> vertical gradients over the tropical and  
366 NH oceans, but their SO<sub>4</sub> values are too low compared to measurements over the Southern  
367 Hemisphere (SH) free troposphere. The SO<sub>4</sub> of IMPACT and OsloCTM3 decreases too slowly  
368 with altitude, as shown by their overestimated SO<sub>4</sub> values at high altitudes globally. E3SM  
369 performed SO<sub>4</sub> simulations among other models. However, the performance of these models’  
370 SO<sub>4</sub> vertical profiles cannot simply be explained by the way the oxidant is applied, because  
371 among the five models, CAM-ATRAS, IMPACT, and OsloCTM3 used interactive oxidant  
372 calculations, while E3SM and GEOS used archived oxidant data (Table 2). The complexity of

373 the chemistry deserves more attention. Of the five models, OsloCTM3 and GEOS participated in  
374 the multi-model OH assessment (Nicely et al., 2000) and OsloCTM3 had a shorter methane  
375 lifetime (relative to OH) than GEOS.

376

377 Figure 7 shows generally lower modeled SO<sub>2</sub> volume mixing ratios compared to the CIMS  
378 observations for most altitudes and latitude bins. The spread among modeled SO<sub>2</sub> values exceeds  
379 an order of magnitude around the measured SO<sub>2</sub>. SO<sub>2</sub> is better simulated by model IMPACT in  
380 the NH and by models CAM-ATRAS and OsloCTM3 in the SH than other AeroCom models.  
381 The tropical Pacific appears to be an interesting region, with all models except GEOS failing to  
382 capture observed local SO<sub>2</sub> sources. Basically, the observed SO<sub>2</sub> is high at the surface, falls  
383 rapidly in the BL, and then gradually decreases above the BL, except for ATom-1, during which  
384 a second peak appears just above the BL (see Fig. S6 for the details of ATom-1 to -4 separately).  
385 These observations indicate a strong local source for SO<sub>2</sub> in all seasons and a transport source in  
386 the low free-troposphere NH summer (ATom-1). Like observations, the model GEOS provides a  
387 local source for SO<sub>2</sub> at the surface, but it misses the plume above the BL in ATom-1, and its  
388 vertical SO<sub>2</sub> convection is consistently too weak. Since only one flight was in ATom-1, more  
389 observations are needed to confirm whether GEOS has been failing to catch the plume there  
390 during the NH summer. All other models show lower SO<sub>2</sub> at the surface than in the lower free  
391 troposphere, which is inconsistent with the observed profiles. Figure S6 also shows an excellent  
392 agreement of SO<sub>2</sub> profiles measured by the CIMS and LIF during ATom-4 and models agree  
393 with measurements better in ATom-4 as well.

394

395 DMS measurements fill in another piece of the puzzle for the atmospheric sulfur budget. As  
396 shown in Fig. 8, all five AeroCom models generally overestimate DMS in the BL, particularly  
397 for models CAM-ATRAS and OsloCTM3. This large bias close to the surface requires us to  
398 revisit the DMS emissions employed in our models. Of the five models, DMS emissions of  
399 E3SM, and IMPACT are derived directly from climate emission inventories, while the DMS  
400 emission of the other three models are parameterized using monthly climatological DMS  
401 concentrations in sea water and surface meteorologies (e.g. surface wind and temperature, see  
402 details in Table 3). Specifically, the parameterization used to convert DMS seawater  
403 concentrations into DMS emission fluxes was using Nightingale et al. (2000) in CAM-ATRAS  
404 and OsloCTM3 and Liss and Merlivat (1986) in GEOS. The three models used two inventories  
405 of monthly DMS seawater concentrations, Lana et al. (2011) for CAM-ATRAS and GEOS, and  
406 Kettle and Andreae (2000) for OsloCTM3. It is worth noting that even the latest climatological  
407 database by Lana et al. (2011) was constructed by compiling measurements before 2000, so the  
408 potential long-term change of DMS emission caused by environment change could be missed  
409 (Barford, 2013). Also, although the data used by Lana et al. (2011) is large (i.e., ~47,000  
410 seawater concentration measurements), interpolation and extrapolation techniques were still  
411 necessary in creating a global monthly climatological DMS emission. Gali et al. (2018) reported  
412 updated oceanic DMS levels on a global scale using remote sensing satellite data. However,  
413 much effort is still needed to accurately establish global rates of change in order to create global  
414 DMS emissions for climate modeling. This parameterization of air-sea exchange is important  
415 because CAM-ATRAS and OsloCTM3, using the same parameterization but different DMS  
416 seawater concentrations, reported close emissions in Sect. 4. On the other hand, the DMS  
417 emissions of CAM-ATRAS are almost twice as high as those of GEOS. This difference in

418 emissions results from different parameterizations in the two models, since both models read the  
419 same DMS seawater concentration.

420  
421 Meanwhile, the modeled DMS vertical gradient is generally steeper than the observed one (e.g.,  
422 Fig. 8 A54N-90N), implying slower vertical transport or faster chemical conversion of DMS to  
423 SO<sub>2</sub> in the model. The data collected from the AeroCom models did not provide us with enough  
424 information to obtain the determinants. Currently, GEOS and OsloCTM3 account for two  
425 products from the oxidation of DMS (i.e., SO<sub>2</sub> and MSA) but only GEOS output MSA results.  
426 The other models consider DMS oxidation products only as SO<sub>2</sub>. These chemical processes in  
427 the model may also need to be revisited. Previous studies proposed other chemical reactions for  
428 DMS loss in the atmosphere. For example, halogen chemistry represented 71% of the DMS loss  
429 in the study of Hoffmann et al. (2016). Veres et al. (2020) estimated that about 30% of DMS in  
430 the atmosphere was oxidized to a sulfur compound, hydroperoxymethyl thioformate (HPMTF),  
431 reported only in ATom-4. To this end, the HPMTF serves as a new reservoir of oceanic sulfur  
432 and its life cycle in the atmosphere is unknown. The new finding indicates that important  
433 components of Earth's sulfur cycle are not yet been fully understood and urges us to reassess this  
434 fundamental marine chemical cycle. However, including these chemical DMS losses further  
435 reduces DMS above the surface, making DMS in the models even lower at high altitudes.

436  
437 Of the five models, only GEOS reports MSA (Fig. 9). The GEOS MSA matches observations in  
438 the lower troposphere. In the upper troposphere (UT), the GEOS MSA tends to decrease slowly  
439 or even increase with altitude. These patterns do not agree with observations, and this  
440 inconsistency can be explained at least partially by the MSA phase stages defined in the model  
441 and observations. AMS and PALMS only measure the particle phase of MSA, but GEOS MSA  
442 is the total MSA and is not accurately represented by observations, especially in UT. Yan et al.  
443 (2019) reported that the ratio of MSA to SO<sub>4</sub> can be reduced by 30% when calculations do not  
444 consider methanesulfonic acid in the gas phase (MSAg) at low temperatures.

### 445 446 **3.3 Regional and seasonal analysis**

447 In order to analyze model performance on a regional and seasonal basis, Figs. 10-12 show  
448 histograms of SO<sub>4</sub>, SO<sub>2</sub>, and DMS concentrations as a function of altitude (rows) and latitudinal  
449 band (columns). Only multi-model median is shown here to highlight any common problems in  
450 the models. Further details of each individual model are given in Figs. S9-11 and discussed in  
451 supplementary material. Each model in this study has its anomalous behavior at a specific time  
452 and location. With this knowledge, modelers can further explore the simulation to identify  
453 potential causes of model anomalies.

454  
455 High SO<sub>4</sub> concentration regions vary across seasons (Fig. 10). In the free troposphere (i.e., 1.5 –  
456 12 km), these regions cover the tropics to mid-latitudes in summer and winter (i.e., ATom-1 and  
457 ATom-2) and shift to mid- to high-latitudes in spring and autumn (i.e., ATom-3 and ATom-4).  
458 The most high concentration areas appeared in the SH high-latitudes during ATom-3 (SH spring)  
459 and the NH high-latitudes during ATom-4 (NH spring). Things are a bit more complicated in the  
460 BL, but the tropical atmospheric SO<sub>4</sub> concentration appears to be always elevated, and SO<sub>4</sub>  
461 concentration levels and SO<sub>4</sub> interregional variation are more pronounced in ATom-1 (NH  
462 summer). Among all AToms, the performance of the model SO<sub>4</sub> simulation is best for ATom-4  
463 and worst for ATom-1 (NH summer). Compared to observations, model tends to simulate higher

464 SO<sub>4</sub> concentrations in the free tropospheric atmosphere. Both observations and simulations show  
465 that the SO<sub>4</sub> in the Pacific is higher than that in the Atlantic during the NH high-latitude autumn  
466 (ATom-3) and the NH mid-latitude spring (ATom-4). The differences between observations and  
467 simulations are generally larger in the Atlantic than in the Pacific, particularly in the SH. SO<sub>4</sub>  
468 concentration levels in simulated and observed worlds can differ significantly in certain areas of  
469 each ATom. Differences may be caused by majority models or a few individual models. For  
470 example, in summer and winter, the CAM-ATRAS model gave the highest estimates of  
471 atmospheric SO<sub>4</sub> in the oceanic BL, but the IMPACT and OsloCTM3 models gave the highest  
472 estimates of atmospheric SO<sub>4</sub> in the free troposphere (Fig. S9). All models except the GEOS  
473 model generally overestimate SO<sub>4</sub> in the atmosphere.

474  
475 Atmospheric SO<sub>2</sub> (Fig. 11) is most abundant in the BL of NH mid-latitude Pacific Ocean during  
476 ATom-1 (NH summer) and the tropical Pacific BL during ATom-3 (NH autumn), and this high  
477 SO<sub>2</sub> region extends to the atmosphere above. Areas where free tropospheric SO<sub>2</sub> concentrations  
478 are relatively large do not necessarily follow the example of the BL. For instance, free  
479 troposphere appears to be more polluted than other regions in the NH Pacific during ATom-2  
480 and in the SH mid-latitude Atlantic (A40S-20S) during ATom-4, but not in the BL, implying a  
481 potential source of horizontal transport. The interregional variation of SO<sub>2</sub> in BL is much larger  
482 than in the free troposphere, from which local oceanic sources of SO<sub>2</sub> can be inferred. In terms of  
483 model-observation comparison, model simulated SO<sub>2</sub> in the free troposphere is generally lower,  
484 which is opposite to the case of SO<sub>4</sub>. A rapid SO<sub>2</sub> to SO<sub>4</sub> chemical conversion in models could  
485 be one of reasons. Fig. S10 further shows individual model SO<sub>2</sub> simulation. For example, the  
486 E3SM model gives significantly higher SO<sub>2</sub> compared with the measurements and other models  
487 in BL (Fig. S10). Unlike the case of SO<sub>4</sub>, all models tend to underestimate SO<sub>2</sub> in the free  
488 troposphere, with some exceptions, such as the GEOS model for the mid- to high-latitude North  
489 Pacific winter (ATom-2) and the CAM-ATRAS and IMPACT models for the mid-latitude South  
490 Atlantic autumn (ATom-4).

491  
492 Surface DMS (Fig. 12) is generally higher in the tropics when the ocean is warm and in mid-high  
493 latitudes during springtime (e.g., ATom-3 SH spring and ATom-4 NH spring). A remarkable  
494 pattern of high model DMS values in the BL is revealed throughout the ATom cycle. This  
495 phenomenon also occurs in the free lower troposphere, but not necessarily in the upper  
496 troposphere. The high model DMS in BL can be attributed to (1) too high DMS emission, (2) too  
497 slow DMS chemical loss, and (3) too slow DMS vertical transport from BL to free troposphere.  
498 Additional insight can be obtained by focusing on remote high-latitudes, for example SH high-  
499 latitude (40°S-70°S) Pacific, where land source impacts are limited. Thus, the higher simulated  
500 SO<sub>2</sub> there in the BL in SYom-4 ruled out a chemical cause due to low DMS loss. The extremely  
501 high surface DMS is also not due to the slow vertical transport because simulated DMS is also  
502 high in the layers above the BL. A large model DMS emission is likely responsible for the  
503 simulated high surface DMS. The overestimation of surface DMS multi-model median in Fig. 12  
504 is clearly attributable to the contribution of all models shown in Fig. S11, with the models CAM-  
505 ATRAS and OsloCTM3 being more prominent.

#### 506 507 **4. Sulfur budget from AeroCom models**

508 Budget analysis is a simple and basic method that has been widely used to document the  
509 underlying performance of a model. This analysis allows us to evaluate the AeroCom-III sulfur

510 simulations against previous AeroCom-I and -II studies and reserves a record for future model  
511 evaluations. Table 4 summarizes the global sulfur budgets for emissions, wet/dry deposition and  
512 chemistry from the five models. Clearly, the largest source of sulfur (~70 TgS/yr) is SO<sub>2</sub> emitted  
513 directly from anthropogenic (~78%), biomass burning (~2%), and volcanic sources (~20%).  
514 Biogenic DMS (~15-30 TgS) produced and outgassed from decomposition of marine organic  
515 molecules provides the largest natural source of sulfur to the atmosphere. A small amount of SO<sub>4</sub>  
516 (< 3%) is emitted directly from anthropogenic sources.

517  
518 DMS is oxidized in the atmosphere by OH and NO<sub>3</sub> radicals to form SO<sub>2</sub> and MSA. This  
519 biological source of SO<sub>2</sub>, along with SO<sub>2</sub> emitted directly from other sources, reacts with  
520 hydroxyl radicals (OH) in the gas phase and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) and ozone (O<sub>3</sub>) in the  
521 aqueous phase to produce sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) and eventually sulfate particles, which play an  
522 important role in the formation of clouds over the oceans.

523  
524 In the five models, DMS has the shortest global average lifetime (0.6-2.0 days), followed by SO<sub>2</sub>  
525 (1.1-1.8 days), and SO<sub>4</sub> the longest lifetime (3.1-5.6 days). Among them, GEOS has the lowest  
526 global burden and shortest lifetime for all sulfur species. The magnitudes of global burdens and  
527 lifetimes shown here support the model performance shown in Figs. 2-8. For example, models  
528 CAM-ATRAS and OsloCTM3 emit highest DMS, which is consistent with the highest DMS  
529 value (Fig. 4 and S11) and longest lifetime simulated by the two models.

530  
531 The key budget items include DMS emission, SO<sub>2</sub> emission, sulfate source or total deposition  
532 (source and deposition are pretty much the same as expected), lifetime (reversely proportional to  
533 the loss rate), and total atmospheric mass load. From the multi-model mean and standard  
534 deviation, the “diversity” can be calculated. Figure 13 shows the global mean budget items in the  
535 percentage deviation of each model from the multi-model mean, following the same concept  
536 shown in Schulz et al. (2006) and Gliss et al. (2021). It reveals the processes causing model  
537 differences. For example, E3SM and GEOS have approximately the same SO<sub>2</sub> emissions and  
538 total sulfate sources, but the sulfate lifetime is much shorter in GEOS (implying faster removal  
539 rates) thus smaller sulfate burden that is consistent with lower sulfate concentrations in GEOS  
540 than in E3SM. At the same time, the lower total sulfate source in E3SM is compensated by  
541 longer lifetime compared to CAM-ATRAS, resulting in a comparable global burden of SO<sub>4</sub> in  
542 the two models.

543  
544 It is worth pointing out that the much lower atmospheric SO<sub>4</sub> mass loading of the GEOS  
545 simulations is not necessarily related to the poor performance of the GEOS SO<sub>4</sub> simulations, as  
546 revealed by the model-measurement comparison in Figs 2, 6 and S9. Although the multi-model  
547 mean (or median) often represents the best simulation in the modeling domain, common  
548 modeling problems or too small model sample can compromise this effort.

549  
550 To date, there have been no sulfur budget reports focusing on the vast ocean. However, previous  
551 AeroCom studies have reported global sulfate atmospheric loading and its diversity across  
552 multiple AeroCom models using monthly and global mean column loadings. Table 5 summarizes  
553 these studies, including their reported global and annual sulfate multi-model mean (MMM) and  
554 diversity ( $\delta$ ).  $\delta$  is related to the standard deviation (std\_dev) and is defined as  $\delta = \text{std\_dev} /$   
555  $\text{MMM} * 100$  (%). The results of this work are lower than AeroCom-I but higher than AeroCom-

556 II, which may be related to the different target years involved in these studies. One point to note  
557 is that the diversity  $\delta$  of AeroCom-III models has not reduced since AeroCom-I, which was  
558 studied nearly 20 years ago.  
559

## 560 **5. Source origins for aerosol SO<sub>4</sub> along flight track and Ocean basins**

561 In this section, we perform an analysis of source attribution by tagging the sulfur source types  
562 using the GEOS model. This model is the only one that provides tagged data. Our goal is to  
563 understand the sources (anthropogenic, biological, volcanic) of sulfate aerosols in remote regions  
564 and how chemistry, transport, and removal processes determine the vertical distribution of  
565 sulfate aerosols across seasons and ocean locations.  
566

567 Figure 14a presents a quantitative summary of the source attribution of aerosol SO<sub>4</sub> sampled  
568 along the ATom flight tracks. The analysis was performed over four seasons, spanning the  
569 troposphere and three vertical layers (i.e., marine boundary layer, free troposphere and upper  
570 troposphere). Overall, anthropogenic emissions were the dominant source (40–60% of the total)  
571 of simulated tropospheric SO<sub>4</sub> along the ATom flight tracks for almost all altitudes and seasons,  
572 followed by volcanic (18–32%) and oceanic sources (16–32%). Anthropogenic pollution  
573 prevailed over remote oceans most in spring and autumn (ATom-3 and -4). The overall  
574 contributions from volcanic and oceanic sources are comparable during the ATom periods.  
575 Meanwhile, the ocean source contribution has an obvious seasonal variation which is most active  
576 during the SH summer (ATom-2), when marine biochemical activity in the vast Southern Ocean  
577 is the largest. Volcanos show the largest contribution in the NH summer 2016 (ATom-1) during  
578 the four ATom deployments. Given the irregular and character of eruptions, the volcanic  
579 contribution deserves further discussion below.  
580

581 In the vertical direction, SO<sub>4</sub> from anthropogenic emissions contributes more than 50% to the  
582 free to upper troposphere. Even in the marine boundary layer, anthropogenic sources of SO<sub>4</sub> still  
583 account for the largest fraction, except in the SH summer (ATom-2) when oceanic source  
584 became dominant. The relative importance of volcanic and marine sources varies not only  
585 seasonally but also vertically. Oceanic sources understandably make up a significant fraction  
586 (26–42%) of SO<sub>4</sub> in the boundary layer. In the free troposphere, its contribution drops off  
587 sharply, reflecting its local surface source characteristics. On the other hand, SO<sub>4</sub> from  
588 anthropogenic emissions (including shipping emission) expands in the free troposphere,  
589 suggesting that the source originated from distant continental areas. Volcanic SO<sub>4</sub> remains nearly  
590 constant throughout the troposphere, making volcanoes the second largest source there.  
591 Meanwhile, the contribution of others (OTH including biomass burning) to remote ocean SO<sub>4</sub> is  
592 relatively small (< 3%) and will not be discussed further in this study.  
593

594 The sources of SO<sub>4</sub> discussed above are deduced from the location and timing of the ATom  
595 flight path. Conclusions about the total contribution of the ocean needs caution, as there may be  
596 representativeness issues using such narrow-band and instantaneous sampling. There might be a  
597 situation where, for example, volcanoes provide a very large signal but only account for a small  
598 measured area, and in most regions, volcanoes play a very minor role. Whereas oceanic sources  
599 in the marine boundary layer perhaps were the dominant source for a much wider region but the  
600 SO<sub>4</sub> concentration resulting from the DMS was overall a smaller amount compared to other  
601 sources where near a volcanic or anthropogenic source. To address this representation issue, we

602 perform one more analysis with the model data averaged over a wider oceanic region (the shaded  
603 orchid area in Fig. 1) and over a longer period (i.e., monthly mean over ATom periods). Such  
604 source attributions are given in Fig. 14b.

605  
606 Qualitative conclusions drawn from source attribution along the flight tracks generally apply to  
607 the ocean basin source attribution, albeit to a slightly different extent. This confirms that  
608 continental man-made sources dominate tropospheric SO<sub>4</sub> even over oceans. There is a clear  
609 seasonal variation in oceanic contribution, which is largest in austral summer (ATom-2)  
610 followed by boreal summer (ATom-1). Concerning volcanic sources, emissions from volcanoes  
611 are of two types. One type is the volcanic degassing emissions that tend to remain nearly  
612 constant throughout the year and are equivalent to about 20% of SO<sub>2</sub> global anthropogenic  
613 emissions. This degassing emission ensures that volcanoes contribute more than 20% to SO<sub>4</sub>  
614 over the oceans. The other type consists in the volcanic eruptions. Due to the irregularity of  
615 volcanic eruptions in terms of different eruption locations, magnitudes, and times, volcanic  
616 eruptions can cause severe fluctuations in SO<sub>4</sub> in the atmosphere. Compared with the source  
617 attribution along the flight trajectory, the volcanic contribution decreased over a larger spatial  
618 and temporal domain (i.e., ocean basin and monthly mean) in the NH winter 2017 by 32%  
619 (ATom-2) and increased in all other three seasons by 14-33%, especially in the NH spring 2018  
620 (ATom-4), when the massive Kilauea eruption in Hawaii began on 3 May 2018. Contrarily, the  
621 anthropogenic contribution increased in the NH winter (ATom-2) by 5% and decreased in other  
622 seasons by 7-21%.

## 623 624 **6. Conclusions**

625 This study investigates sulfur in remote tropospheric regions at global and seasonal scales using  
626 airborne ATom measurements and AeroCom models. The goal is to understand the atmospheric  
627 sulfur cycle over the remote oceans, each model's behavior and the spread of model simulations,  
628 as well as the observation-model discrepancies. Such understanding and comparison with real  
629 observations are crucial to narrow down the uncertainty in model sulfur simulation. Even after  
630 decades of development, models are still struggling to accurately simulate sulfur distributions,  
631 with differences between models often exceeding an order of magnitude. On the other hand, the  
632 agreement between instruments is usually much better. Differences between modeled SO<sub>4</sub> are  
633 particularly large in the tropical upper troposphere, where deep convective transport allows a  
634 small portion of sulfur sources to reach the lower stratosphere where resultant sulfate aerosols  
635 can persist for many years. Compared with observations, simulated SO<sub>2</sub> is generally low while  
636 SO<sub>4</sub> is high. Modeled DMS values are typically an order of magnitude higher than observed  
637 DMS near the surface, pointing to a need to revisit the DMS emission inventories and/or the  
638 biogeochemical modules used to predict DMS emissions. Our work also suggests investigating  
639 three other potential corresponding processes: whether the chemical conversion from SO<sub>2</sub> to SO<sub>4</sub>  
640 is too rapid, whether DMS-generated free tropospheric SO<sub>2</sub> is too low, and whether the vertical  
641 transport of DMS and SO<sub>2</sub> from BL to free troposphere is too low. This further investigation  
642 requires atmospheric oxidant fields and the ability to track SO<sub>2</sub> production and loss using tagged  
643 tracers.

644  
645 We investigate source attribution of SO<sub>4</sub> over remote oceans seasonally and vertically. Sampled  
646 at the location and time of ATom measurements, anthropogenic emissions were the dominant  
647 source (40–60% of the total) of simulated tropospheric SO<sub>4</sub> at almost all heights and seasons,

648 followed by volcanic (18–32%) and oceanic sources (16–32%). These contributions changed to  
649 34–56%, 17–37%, and 19–37% when extended to the broad Pacific and Atlantic during the  
650 months of ATom deployment. This survey confirms that anthropogenic sources dominate  
651 tropospheric SO<sub>4</sub> even over oceans. Given that we find DMS source to be overestimated in the  
652 models, the anthropogenic sources overall are a larger portion of the budget, and biogenic is  
653 likely smaller than volcanic. Volcanic degassing throughout the year contributes about 20%, and  
654 this proportion is increased by explosive eruptions that vary in location and timing. The oceanic  
655 contribution has obvious seasonal variation, the largest in the Southern Hemisphere summer,  
656 followed by the Northern Hemisphere summer.

657  
658 It is understood that anthropogenic sulfur emissions currently offset a significant portion of  
659 greenhouse gas warming, but they are rapidly declining through emissions controls. As these  
660 anthropogenic emissions decrease, natural sources of sulfur, particularly bio-derived sulfur  
661 compounds discharged from the world's oceans, will increase their relative contribution.  
662 Therefore, more efforts are needed to understand the sulfur cycle in remote environments. On the  
663 other hand, our study is the first asserting that anthropogenic emissions remain a major source of  
664 sulfate aerosols generated over remote oceans during the ATom deployment periods, suggesting  
665 that any limitation of anthropogenic sulfur emissions would have modern global implications.

666  
667 Even after two decades of development, the diversity of sulfate simulations from AeroCom-I to  
668 AeroCom-III has not decreased. However, accurate sulfate simulation in current climate models  
669 is crucial to reduce radiative forcing biases. Several potential directions for improving sulfur  
670 simulations are suggested above. More importantly, apart from the shortcomings of individual  
671 models, all modelers should focus on the calculation of the air-sea exchange flux formula, as it  
672 plays a key role in determining DMS emissions. Modelers also need to study DMS and SO<sub>2</sub>  
673 vertical transport as well as SO<sub>4</sub> wet deposition during long-distance transport, as model biases  
674 are greatest at high altitudes. One suggestion to modelers is that the use of online oxidant fields  
675 is insufficient to explain the model sulfate bias, as there was no systematic bias in the sulfate  
676 simulations between the models using interactive oxidants and the models using archival  
677 oxidants in this study. The complexity of chemistry deserves more attention.

679 *Code availability.* The GEOS Earth System Model source code and the instructions for model build are available  
680 at <https://github.com/GEOS-ESM/GEOSgcm/> (Last accessed: 28 August 2023).

681  
682 *Data availability.* The AeroCom model outputs needed to reproduce the results described in this paper are  
683 publicly available for download at <https://acd-ext.gsfc.nasa.gov/anonftp/acd/tropo/bian/ATom-AeroCom-Sulfur/>.  
684 The ATom data was obtained from their ESPO Data Archive: <https://espo.nasa.gov/atom/content/ATom>, last  
685 accessed: 28 August 2022.

686  
687 *Author contributions.*

688 BH and MC conceptualized ATom-AeroCom experiment. BH performed analysis and wrote the manuscript. BH,  
689 PRC, MLi, MTL, RBS, HM, JEP, HW, KZ, and JZ provided AeroCom model results and ECA, KF, RSH, JJ, PCJ,  
690 MLa, BAN, AWR, GS, and LX contributed to ATom measurements. All authors contributed to the editing of the  
691 manuscript.

692  
693 *Competing interests.*

694 At least one of the co-authors is a member of the editorial board of Atmospheric Chemistry and Physics.

695

696 *Acknowledgements.*

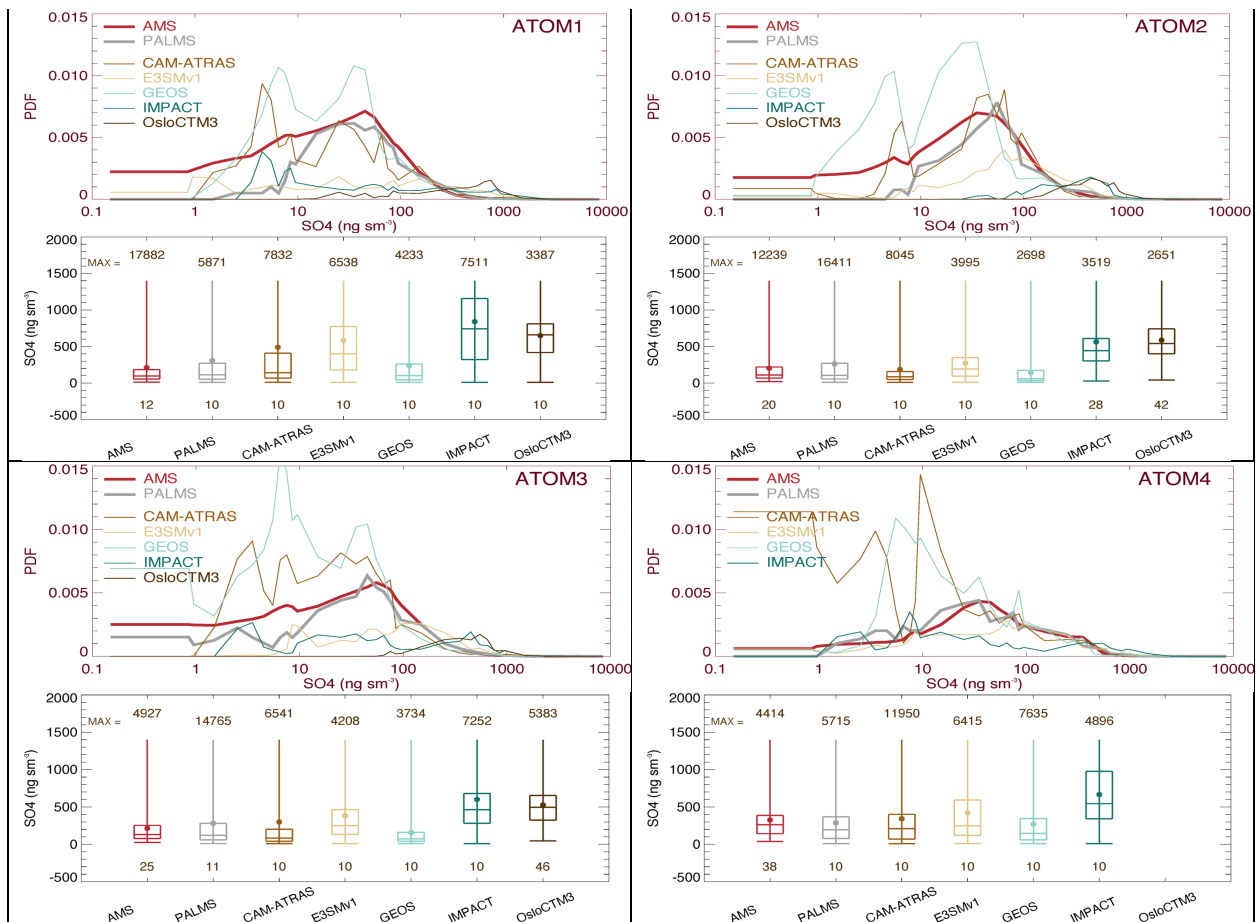

Figure 2. SO<sub>4</sub> probability density functions (PDF) and its statistical values shown by box-and-whisker for the four ATom deployments. All data (AMS in red, PALMS in grey, and five model simulations in other colors) are sampled at 10-s points. Statistical values are calculated when measured values are above the detection limit (DL). Statistical values include the range of the data from minimum to maximum, the three levels of the 25<sup>th</sup>, 50<sup>th</sup> (median), and 75<sup>th</sup> percentiles in the box, and the filled circle for the mean.

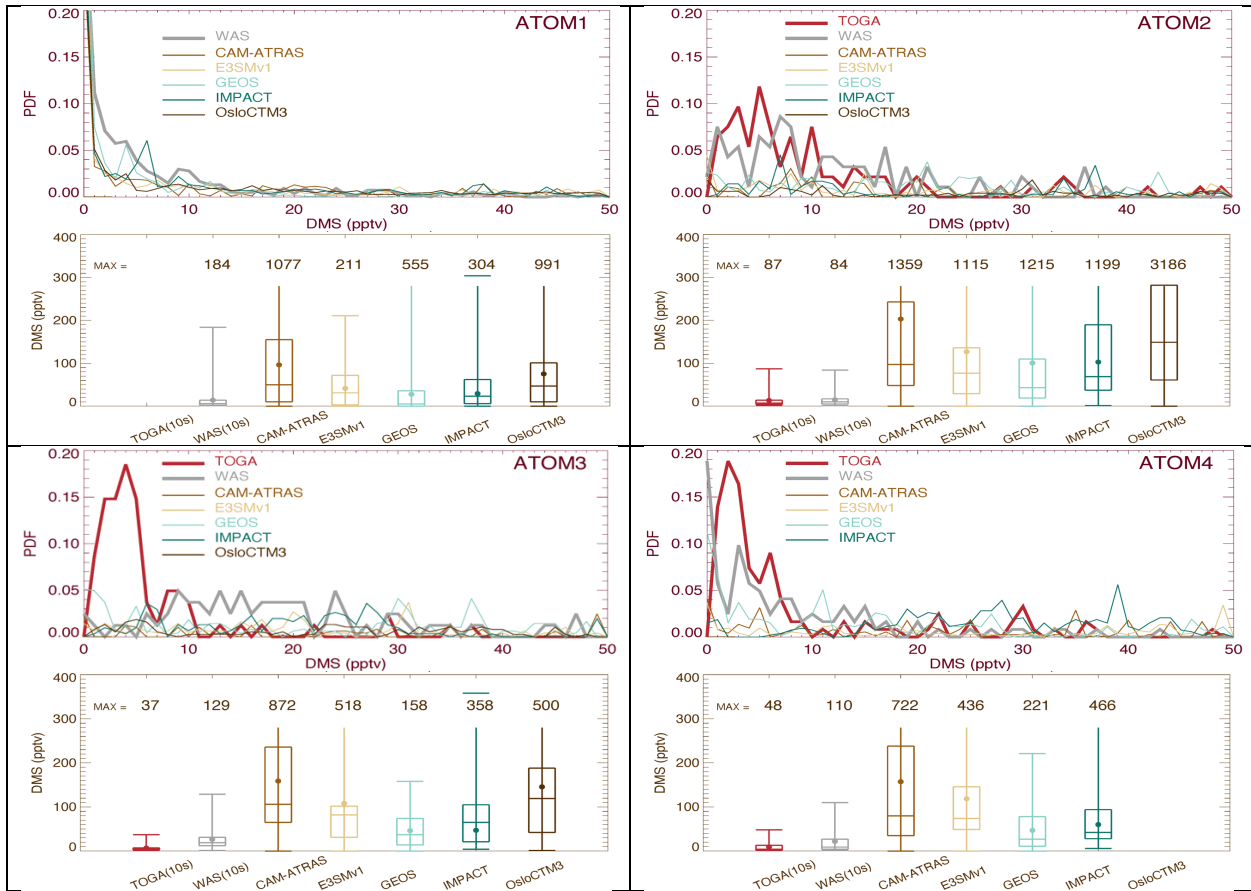

Figure 4. Similar to Fig. 2 but for DMS for ATom-1 to -4. The original data reported by TOGA (e.g., 35-s) and by WAS (e.g., ~60-s) have also been converted to 10-s frequency. Data included in PDF and statistical analysis are on 10-s points where DMS measured by both TOGA and WAS are above DL (i.e., 1 pptv).

1293

Figure 5. Ratio of DMS median values between model simulation and observation for four ATom deployments. Ratio analyses are performed on four vertical ranges as shown in four colors (see legend in ATom-1). The last column “MMM/MOM” refers to multi-model median to multi-observation median.

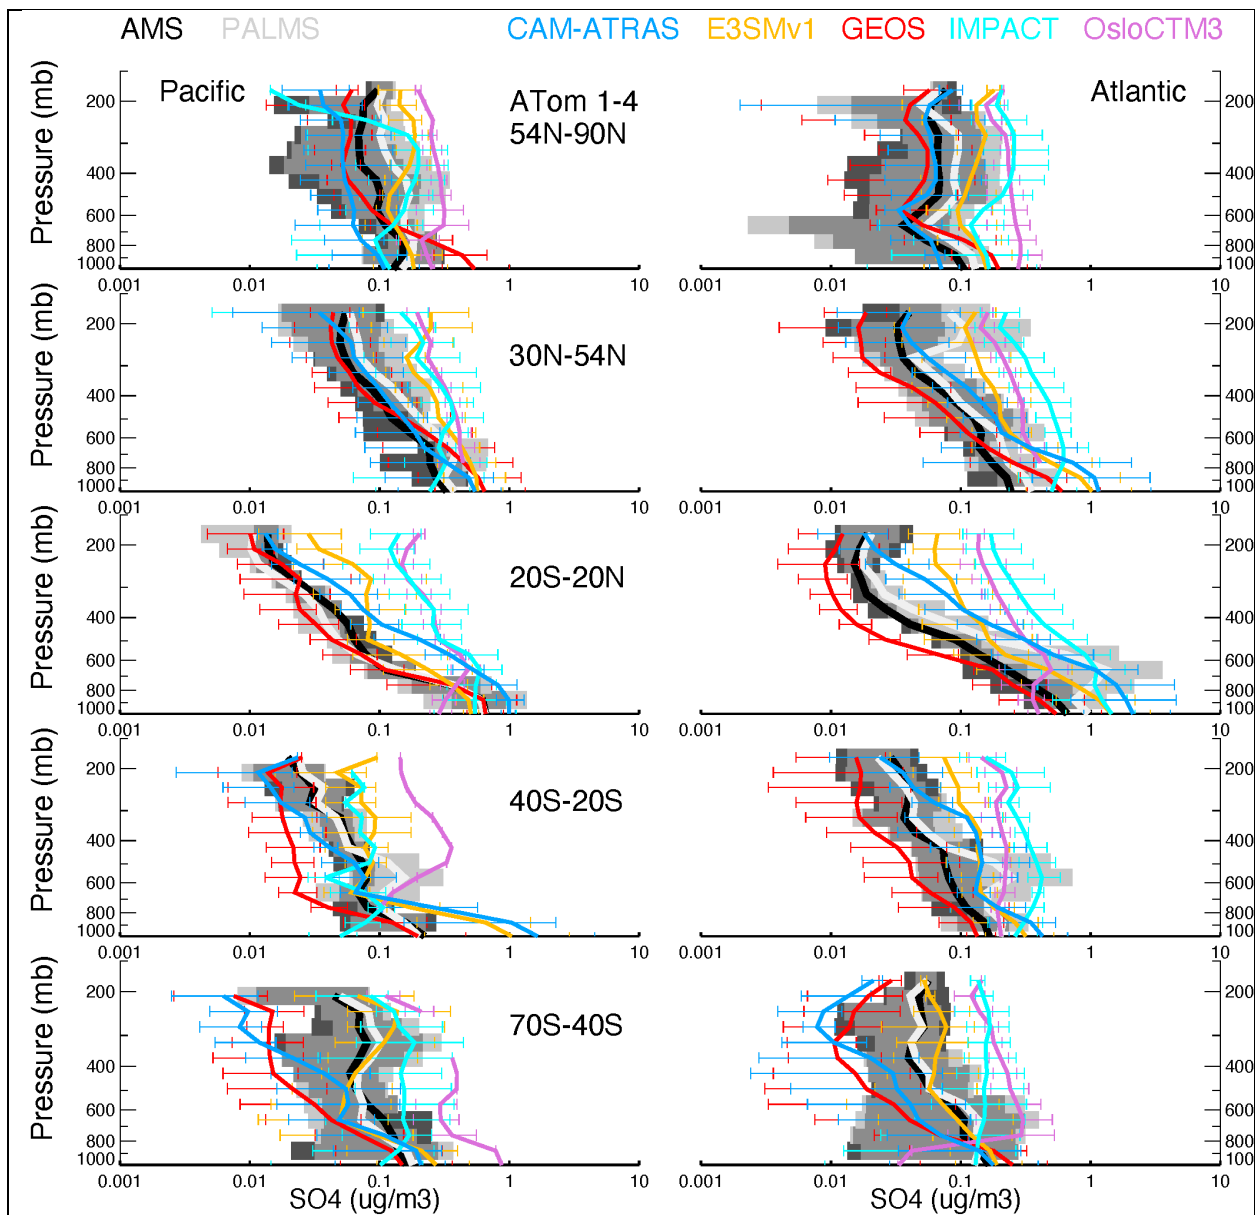

Figure 6. Observed and modeled vertical profiles of  $\text{SO}_4$  in 1-km vertical bins averaged for four ATom deployments (lines) and variation across the four AToms (shaded area for measurements and horizontal bars for simulations). ATom measurements are shown in black (AMS) and light grey (PALMS) while model results are shown in other colors. Comparisons are conducted only when both observational measurements above detect limitation are available. Comparisons are separated into five latitude bands from the Northern to the Southern Hemisphere, and into Pacific and Atlantic Basins.
