12

13 **Abstract.** Canada's forests play a critical role in the global carbon (C) cycle and are responding to unprecedented climate  
14 change as well as ongoing natural and anthropogenic disturbances. However, the representation of disturbance in boreal regions  
15 is limited in pre-existing land surface models (LSMs). Moreover, many LSMs do not explicitly represent subgrid-scale  
16 heterogeneity resulting from disturbance. To address these limitations, we implement harvest and wildfire forcings in the  
17 Canadian Land Surface Scheme Including Biogeochemical Cycles (CLASSIC) land surface model alongside dynamic tiling  
18 that represents subgrid-scale heterogeneity due to disturbance. The disturbances are captured using 30-m spatial resolution  
19 satellite data (Landsat) on an annual basis for 33 years. Using the pan-Canadian domain (i.e. all of Canada south of 76°N) as  
20 our study area for demonstration, we determine the model setup that optimally balances detailed process representation and  
21 computational efficiency. We then demonstrate the impacts of subgrid-scale heterogeneity relative to standard average  
22 individual-based representations of disturbance and explore the resultant differences between the simulations. Our results  
23 indicate that the modeling approach implemented can balance model complexity and computational cost to represent the  
24 impacts of subgrid-scale heterogeneity resulting from disturbance. Subgrid-scale heterogeneity is shown to have impacts 1.5  
25 to 4 times the impact of disturbance alone on gross primary productivity, autotrophic respiration, and surface energy balance  
26 processes in our simulations. These impacts are a result of subgrid-scale heterogeneity slowing vegetation re-growth and  
27 affecting surface energy balance in recently disturbed, sparsely vegetated, and often snow-covered fractions of the land surface.  
28 Representing subgrid-scale heterogeneity is key to more accurately representing timber harvest, which preferentially impacts  
29 larger trees on higher quality and more accessible sites. Our results show how different discretization schemes can impact  
30 model biases resulting from the representation of disturbance. These insights, along with our implementation of dynamic tiling

31 may apply to other tile-based LSMs. Ultimately our results enhance our understanding of, and ability to, represent disturbance  
32 within Canada to facilitate a comprehensive process-based assessment of Canada's terrestrial C cycle.

## 39 **1 Introduction**

40 Canada's forests play a critical role in the global carbon (C) cycle (Keenan and Williams, 2018; Lenton et al., 2008). Canada's  
41 forests are also responding to both unprecedented climate change and on-going anthropogenic disturbance (Lenton et al., 2008;  
42 White et al., 2017). Unfortunately, disentangling the relative impacts of disturbance processes and climate change on the  
43 Canadian forest C cycle is difficult (Sulla-Menashe et al., 2018; Goetz et al., 2005; Ju and Masek, 2016; Weber and Flannigan,  
44 1997). Process-based land surface models (LSMs) provide a tool to evaluate the impacts of both types of disturbance but there  
45 has only been limited representation of anthropogenic disturbance in regional or global C cycling assessments (Friedlingstein  
46 et al., 2019; Peng et al., 2014; Chaste et al., 2017; Hayes et al., 2012). Moreover, of those LSMs that do explicitly represent  
47 anthropogenic disturbance, only a small subset account for the resulting subgrid-scale heterogeneity (Le Quéré et al., 2018;  
48 Nabel et al., 2020; Pongratz et al., 2018). Here we demonstrate the impacts of disturbance and sub-grid scale heterogeneity on  
49 C and energy fluxes, by implementing a dynamic tiling scheme in the Canadian Land Surface Scheme Including  
50 Biogeochemical Cycles (CLASSIC).

51

52 Subgrid-scale landscape heterogeneity refers to any characteristic of the landscape that differs at scales below that of the main  
53 model grid, in this case, differences in tree age and biomass in burned or harvested subfraction of the grid cell. Tile-based  
54 LSMs, unlike individual-based models (i.e. models which simulate the landscape using several heterogeneous individuals), do  
55 not inherently represent subgrid-scale heterogeneity. Instead, the tile represents the average individual of a given plant function  
56 type (PFT) and thus represents the PFT's average state within the grid cell (e.g. a single height, biomass, etc.), which is used  
57 to simulate fluxes. Although most tile-based LSMs account for wood harvest, few represent the resulting subgrid-scale  
58 landscape heterogeneity and rather represent disturbances impact on the average individual PFT (Le Quéré et al., 2018;  
59 Pongratz et al., 2018; Nabel et al., 2020).

60

61 Stand-replacing forest disturbances (i.e. timber harvest and fire) directly impact forest C stocks through the removal of standing  
62 biomass (Wulder et al., 2020). In addition, stand-replacing disturbances also impact stand structure, especially in the case of

63 managed timber harvest (Pan et al., 2010; Kuuluvainen and Gauthier, 2018; Pan et al., 2013). The resulting stand structure  
64 impacts forest function such as the the exchange of matter and energy with the atmosphere as well as forest response to climate  
65 change (Erb et al., 2017; Luyssaert et al., 2014; Körner, 2006; Dore et al., 2010; Liu, 2005; Maness et al., 2012; Hirano et al.,  
66 2017). Historically 0.4% of Canada's ~650 Mh of forested ecosystems are affected by stand-replacing disturbance per year  
67 (White et al., 2017). The age structure of Canadian forests due to historical disturbance has impacted the strength of the  
68 historical C sink in Canadian forests (Kurz and Apps, 1999, 1993; Böttcher et al., 2008). Age structure resulting from  
69 disturbance also influences the surface energy balance of stands for example by altering sensible heat flux due to differences  
70 in snow cover and albedo and altering the seasonality of surface energy budgets and land surface properties (Liu, 2005; Maness  
71 et al., 2012). Therefore, it is key that we enhance our ability to accurately represent both disturbance processes and the influence  
72 of subgrid-scale heterogeneity that disturbances produce within LSMs.

73

74 Disturbance events impact the response of Canada's forests to climate change. The response of forest productivity, forest soil  
75 decomposition processes, and evaporation rates to warming, rising CO<sub>2</sub> concentrations, and changes to precipitation regimes  
76 will depend on stand structural characteristics and tree species characteristics (Hember et al., 2012; Kurz et al., 1997; Körner,  
77 2006; Shrestha and Chen, 2010; Bond-Lamberty and Gower, 2008; Czimczik et al., 2006; Kurz et al., 2008). Warmer  
78 temperatures and higher atmospheric CO<sub>2</sub> concentrations are likely to increase the productivity of boreal forests, whereas  
79 drought stress and changing disturbance regimes are likely to decrease productivity and enhance the decomposition of soil C  
80 leading to a patchwork of contrasting future responses (Babst et al., 2019; Reich et al., 2018; Lenton et al., 2008; Weber and  
81 Flannigan, 1997; Potapov et al., 2008; Ju and Chen, 2008; Sulla-Menashe et al., 2018). Complex changes in vegetation  
82 productivity have already been observed across the pan-Canadian domain due to the intermingling of different disturbance  
83 regimes and different vegetation sensitivity to climate change (Marchand et al., 2018; D'Orangeville et al., 2018; Ma et al.,  
84 2012; Girardin et al., 2016). Decreases in vegetation productivity are generally occurring in northwestern boreal forests,  
85 whereas southeastern boreal forests show positive trends (Marchand et al., 2018). Much of the landscape scale change in  
86 vegetation productivity detected across Canada's boreal forests is a product of or influenced by, stand-replacing disturbance  
87 (Hermosilla et al., 2015b, a). Some negative productivity trends in the southern fringes of western undisturbed forests can  
88 largely be attributed to moisture stress and some of the positive trends in cooler and wetter portions of eastern boreal forests  
89 can be attributed to warming (Marchand et al., 2018; Sulla-Menashe et al., 2018). Process-based models which represent both  
90 disturbance and the resultant subgrid-scale landscape heterogeneity can offer insight into the drivers of these complex trends  
91 (Böttcher et al., 2008).

92

93 CLASSIC is a tile-based LSM that can be coupled to the Canadian Earth System Model (CanESM). Several methods are  
94 available for representing disturbance history in tile-based LSMs. Some models represent the age classes within the stand using  
95 a fixed number of tiles to represent fractional areas below the scale of the main model grid (i.e. from 2 to 12 tiles) (Shevliakova  
96 et al., 2009; Yue et al., 2018a; Naudts et al., 2015; Yang et al., 2010; Stocker et al., 2014). Alternatively, several models

97 simulate subgrid scale forest structure using another model housed in a separate module coupled to the main model (Bellassen  
98 et al., 2010; Haverd et al., 2014). The module takes information about net primary productivity from the main model and uses  
99 it to simulate and track the growth of individual trees. The module then returns grid cell average state information (i.e. biomass  
100 and litter fluxes) which is used by the main model to simulate subsequent fluxes. Finally, a recently developed approach uses  
101 a fixed number of tiles to represent age classes (Nabel et al., 2020). Tile fractional area and associated state variables (i.e.  
102 biomass C) are horizontally exchanged between the tiles to represent processes like aging, harvest, and disturbance. Each  
103 approach entails a host of strengths and weaknesses as well as its own biases resulting from discretization error (Nabel et al.,  
104 2020; Fisher et al., 2018).

105

106 In this study, to demonstrate the impacts of disturbance and sub-grid scale heterogeneity on C and energy fluxes, we implement  
107 a dynamic tiling scheme in CLASSIC. Our implementation is a modified version of approaches that use a fixed number of  
108 tiles to represent age classes within the stand and may apply to other tile-based LSMs. We build upon a version of CLASSIC  
109 tailored to the pan-Canadian domain using region-specific plant functional types (PFTs) and a 0.22° (~20 km x 20 km) common  
110 grid (Curasi et al., 2022). The age classes within the stand are represented using a variable number of sub-grid tiles of variable  
111 fractional area and subject to a user-determined maximum number of tiles available for the simulation. Tiles are split to  
112 represent disturbance and the resulting age and size structures. Tiles, and their underlying characteristics, are joined by the  
113 simulation either when the number of tiles reaches the user-determined maximum bound or pre-emptively based upon other  
114 user-determined parameters. The model is driven by externally forced harvest and fire from region-specific disturbance history  
115 drivers. We set an optimal maximum number of tiles available for the simulation by evaluating different model setups through  
116 model-on-model evaluation and assessing the run time of these setups. Finally, we compare the differences across runs to  
117 assess the impacts of the imposed trade-off between run time and a more detailed representation (i.e. more tiles). This  
118 investigation provides insight into the model configuration and role of fire, harvest, and tiling within CLASSIC, as a step  
119 towards a comprehensive process-based assessment of Canada's terrestrial C cycle. These insights may also apply to other tile  
120 base LSMs.

## 121 **2 Methods**

### 122 **2.1 Study area**

123 We use all of Canada south of 76°N as our simulation study area. Canada contains 650 Mha of forested land and 98 Mha (18%)  
124 of this forested land was disturbed from 1985 - 2015. On average each year 1.61 Mha is disturbed by wildfire, whereas 0.64  
125 Mha is disturbed by harvest (Hermosilla et al., 2019). Disturbance due to wildfire is most prevalent in northern boreal regions,  
126 whereas harvest and other anthropogenic disturbances are more common in southern boreal regions where wildfire is  
127 suppressed. The spatial extent of individual disturbances is highly variable. In Canada, over the course of a year, each  
128 contiguous timber harvest event clears on average  $98 \pm 115$  ha. These timber harvest patterns are heavily influenced by forest

129 management practices (Hermosilla et al., 2015b; White et al., 2017). Similarly, over the course of a year, each contiguous fire  
130 event burns  $324 \pm 633$  ha (Hermosilla et al., 2015b). The spatial scale of these change objects, sourced from 30-m spatial  
131 resolution Landsat imagery, falls well below the  $\sim 40,000$  ha resolution of the  $0.22^\circ$  pan-Canadian domain model grid. Located  
132 largely in southern latitudes, around 52% of Canada's forested land is considered managed forest (Stinson et al., 2011).  
133 Canada's forest structure is characterized by relatively young stands in central and northwestern Canada, with much older  
134 stands found in the Pacific coastal and interior forests in British Columbia (Maltman et al., 2023). Forest ages in Canada are  
135 the result of prevailing natural disturbance regimes and, to a lesser extent, forest management practices (Pan et al., 2013).

## 136 **2.2 The CLASSIC model**

137 CLASSIC is an open-source community model that couples the Canadian Land Surface Scheme (CLASS) (Verseghy, 2000,  
138 2017; Verseghy et al., 1993; Verseghy, 2007) and the Canadian Terrestrial Ecosystem Model (CTEM) (Melton and Arora,  
139 2016; Arora, 2003). CLASSIC v1.0 is described and evaluated by Melton et al., (2020) and Seiler et al., (2021). A detailed  
140 description of model updates and improvements to CLASSIC since v1.0 that are utilized by our simulations can be found in  
141 Asaadi et al. (2018), MacKay et al. (2022), and Curasi et al. (2022). We carry out simulations of the pan-Canadian domain  
142 using a parameterization of the model which includes Canada-specific plant functional types (PFTs) that were developed and  
143 evaluated by Curasi et al., (2022).

144

145 The CTEM dynamic vegetation sub-model simulates photosynthetic fluxes, at a thirty-minute time step in offline simulations,  
146 and the allocation of C within live vegetation to structural and non-structural components of leaves, stems, and roots at a daily  
147 time step. CTEM also simulates daily autotrophic respiration from leaves, stems, and roots and heterotrophic respiration fluxes  
148 from litter and soil C. The pan-Canadian parameterization of CTEM utilizes fourteen biogeochemical PFTs (Curasi et al.,  
149 2022). CTEM is coupled to CLASS on a daily time step and provides CLASS with vegetation height, leaf area index, biomass,  
150 and rooting depth. CLASS, in turn, provides CTEM with mean daily soil moisture, soil temperature, and net radiation incident  
151 on the land surface. CLASS simulates ground and canopy energy exchange from four possible subareas: bare ground, snow-  
152 covered bare ground, canopy-covered ground, and snow-covered canopy, on a thirty-minute time step. It uses 20 ground layers  
153 from 0.1 m to 30 m thick to a depth of over 61 m and simulates heat transfer within all permeable soil layers and the underlying  
154 bedrock. It also simulates water fluxes between the soil layers up until the depth of the impermeable bedrock layer, derived  
155 from Shangguan et al. (2017). CLASS models a single-layer canopy and uses five physics PFTs, which map directly onto the  
156 14 CTEM biogeochemical PFTs, in the pan-Canadian parameterization (Curasi et al., 2022).

## 157 **2.3 Dynamic tile representation of externally forced fire and harvest**

### 158 **2.3.1 The composite versus mosaic representation in CLASSIC**

159 CLASSIC can utilize either a composite (1 tile) or mosaic ( $>1$  tile) representation of the land surface. The composite  
160 representation simulates average individual PFTs for each grid cell and uses their average structural attributes (i.e. leaf area

161 index, height, and rooting depth) to simulate the energy balance, and physical environment (i.e. soil temperature). The  
162 structural attributes of all of the average individual PFTs that exist within a grid cell are averaged in proportion to their  
163 fractional coverages and the PFTs all experience a common land surface physical environment. For the composite  
164 representation, a disturbance event (i.e. wood harvest) takes C from the average individual PFTs pools proportional to the areal  
165 fraction disturbed (i.e. a complete harvest of 50% of the grid cell thereby removing 50% of the vegetation biomass; Figure 1).

166

167 The mosaic representation splits the grid cell into multiple tiles representing fractional areas of the grid cell. Each tile receives  
168 the same meteorological forcing but simulates its respective average individual of each PFT present, PFT structural attributes,  
169 and energy balance. The structural attributes of all the average individual PFTs that exist within each tile are averaged in  
170 proportion to their fractional coverages and the PFTs all experience a land surface physical environment common to that tile.  
171 The tiles are aggregated to the scale of the final model grid by accounting for each tile's fractional coverage of the grid cell.  
172 CLASSICs tiling capability has been used in the past to investigate the impacts of subgrid-scale heterogeneity in soil texture  
173 by breaking grid cells with heterogeneous soil textures into tiles (Melton et al., 2017). As well as vegetation cover (Melton  
174 and Arora, 2014; Li and Arora, 2012), and competition between plant functional types (Shrestha et al., 2016) by breaking grid  
175 cells with heterogeneous vegetation cover into tiles. These approaches result in regional differences in fluxes of up to 30%.  
176 We adapt the mosaic representation to dynamically create disturbance history tiles and represent the subgrid-scale  
177 heterogeneity resulting from disturbance (i.e. represent a complete harvest of an area corresponding to 50% of the grid cell as  
178 a 100% reduction of the vegetation biomass in a new subgrid tile that covers 50% of the grid cell; Figure 1). In our approach,  
179 the tiles serve to represent vegetation that is in different stages of recovery. Thus, the soil textures and vegetation fractional  
180 cover are the same for all tiles within a given grid cell.

### 181 2.3.2 Notation and background

182 We present generalized equations that illustrate the dynamic tiling calculations done by the model to split and join tiles. In  
183 these equations, scalars are lowercase letters (i.e.  $x = [1]$ ), vectors are bold lowercase letters (i.e.  $\mathbf{x} = [x_1, x_2, \dots, x_n]$ ), and  
184 matrices are bold uppercase letters (i.e.  $\mathbf{X} = (x_{1,1} \dots x_{1,n} \vdots \vdots x_{n,1} \dots x_{n,n})$ ). The model is set up to simulate state variables  
185 for a user-defined maximum number of tiles within a grid cell (i.e. the state variable  $\mathbf{x}_{\text{all}}$  with a length equal to the user-  
186 determined maximum number of tiles). Tiles can be set as either active or inactive in each timestep (Figure 1). When the model  
187 identifies active tiles for merging or splitting (e.g. sections 2.3.4, 2.3.5, and 2.3.6) they become candidate tiles. Depending  
188 upon the operation and the fraction of the grid cell involved, anywhere between one and the total number of tiles being actively  
189 simulated are candidate tiles for the merging or splitting operation. Because the maximum number of tiles is fixed, the model  
190 must manage the number of tiles being actively simulated. The model ensures that up to two inactive tiles are available to  
191 simulate disturbance each year (i.e. one for fire and one for harvest; see section 2.3.4). During the merging or splitting operation  
192 the model temporarily stores values from the candidate tiles before the operation (i.e.  $\mathbf{x}_{\text{pre}}$  of length  $n$  candidate tiles) and after  
193 the operation (i.e.  $\mathbf{x}_{\text{post}}$  of length  $n$  candidate tiles) and uses them to calculate the values for a new single output tile (i.e.  $\mathbf{x}_{\text{new}}$ ).

194 All these values are temporarily stored and used in calculations up until the point where the dynamic tiling operation is  
 195 complete, and the model's main data structures are updated.

196

### 197 2.3.3 Dynamic tiling splits and joins

198 Dynamic tiling allows the model to split grid cells into subgrid tiles during the model run or join existing subgrid tiles. Dynamic  
 199 tiling operations (splitting/joining) occur on January 1st at the annual time step alongside rigorous checks to ensure water,  
 200 mass, and energy conservation. The area occupied by a given tile is a fraction of the grid cell land area between zero and one  
 201 (i.e.  $\mathbf{a}_{all}$  with length equal to the user-determined maximum number of tiles). The sum of  $\mathbf{a}_{all}$  for all the active tiles within a  
 202 grid cell must equal one. When tiles are split the fractional area occupied by the single new tile ( $a_{new}$ ) must be less than the  
 203 sum of the vector of fractional areas of the candidate tiles ( $\mathbf{a}_{pre}$  of length  $n$  candidate tiles). The candidate tiles' fractional areas  
 204 are a product of the dynamic tiling operations that occur in all previous time steps. When the first dynamic tiling operation in  
 205 a run occurs  $\mathbf{a}_{pre} = [1]$ , but  $\mathbf{a}_{pre}$  is a much more complex vector in subsequent operations (e.g.  $\mathbf{a}_{pre} = [0.1, 0.2, 0.3]$ ). The  
 206 candidate tiles are later assigned a vector of new fractional areas adjusted to account for the new tile and the decrease in size  
 207 of the candidate tiles ( $\mathbf{a}_{post}$  also of length  $n$  candidate tiles; Eqn. 1).

$$208 \quad a_{new} < \sum_{i=1}^n a_{pre,i}$$

$$209 \quad a_{post,n} = a_{pre,n} - a_{new} \frac{a_{pre,n}}{\sum_{i=1}^n a_{pre,i}} \quad (1)$$

210 When tiles are joined by the model the fractional area of the new tile is the sum of the vector of the fractional areas of the  
 211 candidate tiles. The candidate tiles are later assigned fractional areas of zero (Eqn. 2).

$$212 \quad a_{new} = \sum_{i=1}^n a_{pre,i}$$

$$213 \quad a_{post} = 0 \quad (2)$$

214 For a tile or group of tiles to be split or joined they must pass rigorous checks that ensure they share the same abiotic  
 215 characteristics and static fractional PFT cover. These characteristics (i.e. soil texture, soil permeable depth, and PFT fractional  
 216 coverage) are copied directly to the new tile by the split or join. Mass-based variables (i.e. vegetation C pool mass, soil C pool  
 217 mass, soil water, ponded water, and water held in the vegetation canopy) are split or joined using fractional area-based weighted  
 218 averages to ensure mass balance. The value of the mass-based variable in the new tile ( $\mathbf{M}_{new}$  for  $l$  layers and  $o$  PFTs;  $\text{kg m}^{-2}$ )  
 219 is the average of the values for the candidate tiles ( $\mathbf{M}_{pre}$  of length  $n$  candidate tiles for  $l$  layers and  $o$  PFTs;  $\text{kg m}^{-2}$ ) weighted  
 220 by the fractional areas of the candidate tiles (Eqn. 3).

$$221 \quad m_{new,lo} = \frac{\sum_{i=1}^n m_{pre,ilo} a_{pre,i}}{\sum_{i=1}^n a_{pre,i}} \quad (3)$$

222 Temperature-based variables (i.e. temperatures of the vegetation canopy, ponded water, snowpack, and soil) are split or joined  
 223 using a fractional area-based weighted average that blends the different temperature materials from the candidate tiles. The  
 224 value of a given temperature for the new tile ( $t_{new}$  for  $l$  layers; K) is a function of the temperatures in the candidate tiles ( $T_{pre}$   
 225 of length  $n$  candidate tiles for  $l$  layers; K) weighted by the fractional areas of the candidate tiles before the split, the masses of  
 226 the pools which track that temperature ( $M_{pre}$  of length  $n$  candidate tiles for  $l$  layers and  $m$  pools;  $\text{kg m}^{-2}$ ), and the specific heat  
 227 capacities which characterize those mass pools ( $c$  for  $m$  pools;  $\text{J kg}^{-1} \text{K}^{-1}$ ; Eqn. 4).

$$228 \quad t_{new,l} = \frac{\sum_{i=1}^n (t_{pre,il} a_{pre,i} \sum_{j=1}^m (m_{pre,ilj} c_j))}{\sum_{i=1}^n (a_{pre,i} \sum_{j=1}^m (m_{pre,ilj} c_j))} \quad (4)$$

### 229 2.3.4 Dynamic tiling management

230 The maximum number of dynamic tiles in a given simulation is limited by a parameter set at the start of the model run. If this  
 231 upper limit is reached, tiles are joined based on a similarity criteria. By default, the model selects the two tiles with the most  
 232 similar vegetation heights and joins them. The model uses the vector of tile average vegetation heights ( $\mathbf{h}$  of length  $n$  for a total  
 233 number of tiles; m) and calculates the absolute difference between all possible combinations of the elements therein (i.e. using  
 234 the nested iterators  $n1$  and  $n2$ ). The resulting absolute difference matrix of tile average vegetation heights ( $\Delta\mathbf{H}$  a  $n1$  total  
 235 number of tiles by  $n2$  total number of tiles matrix; m) is used to judge the similarity between tiles. The tile average vegetation  
 236 height is a function of each PFT height ( $\mathbf{H}$  of length  $n$  total number of tiles for  $o$  PFTs; m) and the PFT fractional coverage  
 237 within the tile ( $\mathbf{F}$  of length  $n$  total number of tiles for  $o$  PFTs; Eqn 5; Figure S1). In the default case, the two tiles with the  
 238 minimum  $\Delta\mathbf{H}$  are joined when the maximum number of dynamic tiles is reached.

$$239 \quad \Delta\mathbf{h}_{n1,n2} = |\mathbf{h}_{n1} - \mathbf{h}_{n2}|$$

$$240 \quad \mathbf{h}_n = \frac{\sum_{o=1}^{\# \text{ of PFTs}} h_{n,o} f_{n,o}}{\sum_{o=1}^{\# \text{ of PFTs}} f_{n,o}} \quad (5)$$

241 An optional relative height threshold ( $rht$ ; unitless) allows for tiles to be pre-emptively joined at a yearly time step before  
 242 reaching the maximum number of dynamic tiles. The  $rht$  can be conceptually thought of as breaking the tiles into equally  
 243 spaced bins organized by vegetation height. It is used to calculate a threshold value from the maximum tile average vegetation  
 244 height ( $\mathbf{h}$ ; m). The threshold logically determines which pairs of tiles are pre-emptively joined at a yearly time step based on  
 245 the absolute differences in their tile average vegetation heights ( $\Delta\mathbf{H}$ ; m; Eqn 6; Figure S1).

$$246 \quad \Delta\mathbf{H} < rht * \max(\mathbf{h}) \quad (6)$$

247 When the  $rht$  parameter is used, the optional tile preservation parameter ( $tpp$ ; number of tiles) prevents tiles with the shortest  
 248 average vegetation height from being merged. That is the model, starting with the tile with the shortest average vegetation  
 249 height, retains that number of tiles,  $tpp$ . This means the tiling scheme will carry out pre-emptive joins based upon  $rht$  while  
 250 preserving young recently disturbed tiles and explicitly representing early successional differences in fluxes (Bellassen et al.,  
 251 2010; Zaehle et al., 2006; Nabel et al., 2020). When dynamic tiling is active, the time since disturbance is tracked in all tiles.

252 Time since disturbance increases at the CTEM timestep (i.e. daily). Any disturbance events applied to a particular tile resets  
253 its time since disturbance to zero.

254

### 255 **2.3.5 Externally forced fire**

256 Externally forced fire builds upon the pre-existing fire module within CLASSIC (Melton and Arora, 2016; Arora and Melton,  
257 2018). The annual fractional burned area in a grid cell is read from a file. The model assumes that fire impacts all non-crop  
258 PFTs.

259

260 If dynamic tiling is not active, biomass from the average individual and the litter pool burns proportional to the requested  
261 fractional burned area. If dynamic tiling is active, a new tile with a fractional area equal to the fractional burned area is split  
262 from the active tiles within the grid cell and subsequently burned. Depending upon the requested fractional burned area and  
263 the conditions in the grid cell the model uses anywhere between one and the total number of tiles being actively simulated as  
264 candidate tiles for this splitting operation.

265

266 To determine the candidate tiles for this splitting operation, the model ranks the tiles based on their probability of fire ( $\mathbf{p}$  of  
267 length  $n$ ) conditional on the total aboveground biomasses available for burning ( $\mathbf{b}$  of length  $n$ ; kg C m<sup>-2</sup>).  $\mathbf{p}$  is a linear function  
268 of the lower biomass threshold (0.4 kg C m<sup>-2</sup>) under which fire cannot sustain itself and the upper biomass threshold over  
269 which fire has a probability of one (1.2 kg C m<sup>-2</sup>; Eqn. 7) (Moorcroft et al., 2001; Kucharik et al., 2000; Melton and Arora,  
270 2016).

$$271 \quad p_n = \max \left[ 0, \min \left( 1, \frac{b_n - 0.4}{1.2 - 0.4} \right) \right] \quad (7)$$

272 The model initially selects tiles with a  $p$  of one as candidate tiles to be split to yield the tile to be burned. However, if these  
273 selected tiles do not contain enough fractional area to simulate the fractional burned area requested, the model selects tiles with  
274 a  $p$  less than one from largest to smallest (Figure S1). Externally forced fire uses a single probability ( $\mathbf{p}$ ) to rank tiles, whereas  
275 CLASSIC's standard fire module uses three probabilities to calculate the burned area: the probability of fire conditional on  
276 total aboveground biomasses available for burning, the combustibility of the fuel based on its moisture content, and the  
277 presence of an ignition source (Arora and Boer, 2005; Arora and Melton, 2018). We make this simplification here because the  
278 fractional burned area comes from a file and all the tiles within a grid cell experience the same driving meteorology limiting  
279 differences in moisture content and ignition (Melton et al., 2017; Melton and Arora, 2014). With either dynamic tiling active  
280 or inactive, we calculate the C emissions to the atmosphere using pre-defined PFT-specific fire emission fractions for each  
281 live vegetation component (i.e. both structural and non-structural leaves, stems, and roots) as well as the litter pool ( $\nu$ ; Table  
282 1). We calculate the quantity of live vegetation C transferred to the litter pool as a result of fire-related mortality using pre-  
283 defined PFT-specific mortality fractions ( $\Theta$ ; Table 1). Externally forced fire does not impact crop PFTs and thus their biomass  
284 never combusts nor experiences fire-related mortality.

285

### 286 **2.3.6 Externally forced harvest**

287 Harvest simulates the removal of biomass from the landscape because of logging activities and builds upon the pre-existing  
288 land use change module within CLASSIC (Arora and Boer, 2010). The annual fractional harvested area on a per grid cell basis  
289 is read from a file. The model assumes that all harvest events are clear-cuts that impact some fraction of the simulated grid  
290 cell.

291

292 If dynamic tiling is not active, the average individual is harvested proportional to the requested fractional area. If dynamic  
293 tiling is active, a new tile with a fractional area equal to the requested fractional area is split from the oldest undisturbed active  
294 tile, and the entire new tile is harvested. If the harvested area requested exceeds the fractional area of the oldest undisturbed  
295 active tile the model selects additional active tiles as candidate tiles from oldest to youngest until there is sufficient fractional  
296 area.

297

298 In either case, the harvested aboveground biomass (i.e. both non-structural and structural stem and leaf C) is split into three  
299 streams using fractions developed by Arora and Boer 2010. These streams contribute C to the atmosphere, slash/pulp and  
300 paper products pool, and durable wood products pool. The fractions of harvested aboveground biomass allocated to each stream  
301 ( $\epsilon$ ; Table 2) depend upon whether the PFT is woody or herbaceous and in the case of woody PFTs the aboveground biomass  
302 density. Unlike the procedure described by Arora and Boer (2010) where root biomass is transferred to the slash/pulp and  
303 paper products pool, we transfer harvested root biomass to the applicable PFT and soil depth-specific litter pools.

304

## 305 **2.4 Model forcing**

### 306 **2.4.1 Meteorological drivers and landcover**

307 CLASSIC requires seven meteorological forcing variables: incoming shortwave radiation, incoming longwave radiation, air  
308 temperature, precipitation rate, air pressure, specific humidity, and wind speed. We use the interpolated and disaggregated  
309 meteorological forcing described in detail by Meyer et al. (2021) and Curasi et al. (2022) (GSWP3–W5E5–ERA5) in our  
310 simulations. The 1901 – 1978 portion of the forcing comes from the Inter-Sectoral Impact Model Intercomparison Project  
311 GSWP3–W5E5 and the 1979–2018 portion comes from the ERA5 time series bias corrected to match the means of the  
312 overlapping period in the GSWP3–W5E5 (Kim, 2017; Lange, 2019, 2020a, b; ECMWF, 2019). The atmospheric CO<sub>2</sub>  
313 concentrations (1700 - 2017) were obtained from the global carbon project (Trends in atmospheric carbon dioxide, National  
314 Oceanic & Atmospheric Administration, Earth System Research Laboratory (NOAA/ESRL), 2022; Friedlingstein et al., 2022).

315

316 We set the fractional coverage of PFTs using the remotely sensed 14 PFT-hybrid land cover product generated by Wang et al.  
317 (2022) and expanded upon and evaluated by Curasi et al. (2022). This land cover corresponds to the year 2010. This land cover  
318 product combines information from the North American Land Change Monitoring System land cover (Latifovic et al., 2017),  
319 the National Terrestrial Ecosystem Monitoring System (NTEMS)(Hermosilla et al., 2018, 2016), satellite-derived maps of the  
320 National Forest Inventory attributes (Beaudoin et al., 2018), and British Columbia’s biogeoclimatic ecosystem classification  
321 map (MacKenzie and Meidinger, 2018; Salkfield et al., 2016). Using a land cover that does not vary in time (i.e. static land  
322 cover as opposed to dynamic or prescribed land cover changes) allows us to focus on the influence of fire, harvest, and dynamic  
323 tiling on the model outputs.

324

#### 325 2.4.2. Fire and harvest forcing

326 We develop fire and harvest drivers that detail the per-grid cell annual fractional area harvested or burned between 1740 and  
327 2017 (Figure 2a, b). For the satellite era (1985 - 2017) we use remotely sensed 30-m spatial resolution records of harvest and  
328 fire events. These data were derived from Landsat by using breakpoint detection to identify changes and trends (Hermosilla et  
329 al., 2016, 2015a), followed by a random forest classification of change types (Hermosilla et al., 2015b). We mask the remotely  
330 sensed harvest records to include only private, long-term tenure, and short-term tenure forests, as indicated by Stinson et al.,  
331 (2019).

332

333 Before the availability of the remotely sensed records used herein (pre-1984), to our knowledge, there are no spatially explicit  
334 pan-Canadian integrated harvest and fire data sets available. Therefore, to represent the impact of historical disturbance on the  
335 model state we employ established methods for inferring disturbance events from stand age (Nabel et al., 2020; Kurz et al.,  
336 2009; Chen et al., 2000, 2003). We also focus our analysis of the CLASSIC simulations on the satellite era (1985 - 2017) due  
337 to uncertainties in inferred historical disturbance and the model state before the satellite era. Maltman et al., (2023) derived a  
338 30-m resolution stand age map for 2019 from Landsat and MODIS data utilizing three methods. The methods included  
339 disturbance detection for stands between 0 and 34 years of age, detection of spectral signals indicative of recovery for stands  
340 between 34 and 54 years of age, and inverting allometric equations for stands between 54 and 150 years of age. We infer the  
341 year in which the last disturbance occurred from the stand age. For example, a 40-year-old forest in 2019 is assumed to have  
342 been last disturbed in 1979. We use regional averages of the per-pixel ratio of burned to total disturbed area from the first  
343 decades of the satellite era (1985 - 1995) to fraction total inferred disturbance into fire and harvest.

344

345 However, pre-1984 disturbance that has been inferred from stand age does not align with available aspatial records of total  
346 harvested and burned area within Canada. Therefore, we utilize the aspatial records to bias-correct the 1740 – 1984 disturbance  
347 that has been inferred from stand age to ensure the total values match the available historical records. From 1740 - 1920, we  
348 utilized aspatial records of total disturbed area derived from 1920 stand age, with harvest held constant ( $0.3 \text{ Mha yr}^{-1}$ ) (Chen  
349 et al., 2000; Kurz et al., 1995). From 1920 – 1984 we utilized aspatial records of the total harvested and burned area within

350 Canada from Skakun et al., (2021) and World Resources Institute (2000). We utilize bias correction that retains the spatial  
 351 patterns of pre-1984 disturbance inferred from stand age while correcting positive and negative biases to match the aspatial  
 352 records. This necessitated two distinct bias correction methods. For years with positive biases, the positive bias indicates that  
 353 there is sufficient disturbance inferred from stand age. In these cases, a uniform bias correction factor can be used to scale  
 354 down disturbance. Years with negative biases, however, do not contain sufficient disturbance as inferred from stand age. Here  
 355 residual disturbed area from nearby years needs to be added to the year under consideration to match the aspatial records level  
 356 of disturbance while preserving the spatial patterns derived from stand age. Because the uncertainty of stand age estimates  
 357 increases further into the past, the negative bias correction is carried out starting in 1984 and looping backward annually until  
 358 1740 (Maltman et al., 2023).

359  
 360 First, for years in which burned or harvested area inferred from stand age ( $\mathbf{D}_{inferred}$  for  $i$  years,  $l$  grid cells;  $m^2$ ) exceeded the  
 361 aspatial records ( $\mathbf{d}_{aspatial}$  for  $i$  years;  $m^2$ ) we correct the positive biases. We calculate an aspatial bias-correction factor ( $f$  for  $i$   
 362 years; unitless; eqn. 8).

$$363 \quad f_i = \frac{\left( \left( \sum_{l=1}^{\# \text{ of grid cells}} d_{inferred,il} \right) - d_{aspatial,i} \right)}{\left( \sum_{l=1}^{\# \text{ of grid cells}} d_{inferred,il} \right)} \quad (8)$$

364 Because the pre-1985 records are aspatial, the bias correction factor is temporally explicit but uniformly applied across space.  
 365 When we apply the bias-correction factor to the inferred disturbance time series the result is a new time series with all the  
 366 positive biases corrected ( $\mathbf{D}_{downsc}$  for  $i$  years,  $l$  grid cells;  $m^2$ ; eqn. 9).

$$367 \quad d_{downsc,il} = d_{inferred,il} - d_{inferred,il} f_i \quad (9)$$

368 When we apply the bias-correction factor we retain the spatially and temporally explicit residuals ( $\mathbf{D}_{residual}$  for  $i$  years,  $l$  grid  
 369 cells;  $m^2$ ; eqn. 10).

$$370 \quad d_{residual,il} = d_{inferred,il} - d_{downsc,il} \quad (10)$$

371 Second, for years in which burned or harvested area inferred from stand age falls below that indicated in the aspatial records,  
 372 we correct the negative biases by adding in the residuals from nearby years (Figure 3). We loop backward in time from 1984  
 373 to 1740 and accumulate residuals ( $\mathbf{r}_{moving}$  for  $l$  grid cells;  $m^2$ ) extending as far back in time as needed to exceed the aspatial  
 374 record for the year under consideration ( $\mathbf{d}_{aspatial,i}$ ). We calculate an aspatial bias-correction factor ( $f$ ; unitless) and use it to apply  
 375 a fraction of  $\mathbf{r}_{moving}$ , to the inferred disturbance time series and subtract the residuals used from  $\mathbf{r}_{moving}$ . When the spatially  
 376 explicit residuals are exhausted (~1920 for fire only) they are replenished using the entire gridded remotely sensed and stand  
 377 age inferred disturbance record. This procedure continues until all the negative biases have been corrected between 1984 and  
 378 1740 yielding the final spatially explicit time series ( $\mathbf{D}_{final}$  for  $i$  years,  $l$  grid cells;  $m^2$ ).

379

## 380 2.5 Simulation protocol

381 We carry out a total of fourteen simulations using a common simulation protocol to investigate the impact of different  
382 maximum numbers of available tiles, *rht*, and *tpp* (Table 3). *rht* (0.04 - 0.16, unitless) can be conceptually thought of as  
383 breaking the range of tile average vegetation heights into between 24 and 6 equally spaced bins depending upon its value (e.g.  
384 (1 bin  $\text{m m}^{-1}$  / 6 bins) =  $0.16 \text{ m m}^{-1}$ ). *tpp* (4 - 6 tiles) can be conceptually thought of as the maximum number of discrete  
385 disturbance events that the model can simulate in a grid cell over 2 - 3 years (e.g. (1 harvest tile  $\text{yr}^{-1}$  + 1 fire tile  $\text{yr}^{-1}$ ) \* 3 yrs  
386 = 6 tiles).

387

388 We spin up the model to equilibrium conditions corresponding to the year 1700 and then do a transient run over the period  
389 1700 to 2017. For the spin up we loop the earliest 25 years of climate data available (1901 - 1925) and hold atmospheric  $\text{CO}_2$   
390 concentrations constant at the pre-industrial (1700) level. The 1700 - 1900 portion of the transient run uses the same loop of  
391 1901 - 1925 climate, but transient atmospheric  $\text{CO}_2$  concentrations. The 1900 - 2017 portion of the transient run uses transient  
392 atmospheric  $\text{CO}_2$  concentrations and evolving GSWP3–W5E5–ERA5 climate. During the full transient simulation from 1740  
393 - 2017, the fire and harvest are applied (see Section 2.4). The 14 transient simulations utilize their individual unique, lang  
394 surface representation (i.e. composite or mosaic) maximum number of available tiles, *rht*, and *tpp* for the entire 1700 – 2017  
395 run (Table 3). The CLASSIC nitrogen cycling module is not active in these simulations (Asaadi and Arora, 2021; Arora and  
396 Boer, 2010).

## 397 2.6 Model evaluation

398 We carry out model-on-model comparisons for a selection of variables and model configurations for the satellite era portions  
399 of our simulations (1985 - 2017) to select the model setup that optimally balances detailed process representation and model  
400 run time (Table 3). This model-on-model approach has the benefit of canceling out any pre-existing biases in the model and  
401 focuses our results on the impacts of subgrid-scale heterogeneity, and discretization error alone (similar to Torres-Rojas et al.,  
402 2022; Moorcroft et al., 2001). We also use these evaluations to demonstrate the relative impact of representing subgrid-scale  
403 heterogeneity within our modeling framework. We evaluate a suite of C cycling and surface energy balance-related variables  
404 including the land carbon pool (cLand), vegetation C (cVeg), soil C (cSoil), gross primary productivity (GPP), autotrophic  
405 respiration (Ra), heterotrophic respiration (Rh), ecosystem respiration (ER), leaf area index (LAI), sensible heat flux (HFSS),  
406 latent heat flux (HFSL), albedo (ALBS), fire emissions (fFire), total deforested C (fDeforestTotal), and cumulative deforested  
407 C (the running sum of fDeforestTotal starting in 1985; fDeforestCumulative).

408

409 To select the optimal maximum number of tiles available for the simulation as well as the *rht* and *tpp* we calculate the mean  
410 squared deviation (**msd** for *j* model runs detailed in Table 3 over the 1985 - 2017 period) between the model runs under  
411 evaluation and the reference 32-tile run. The 32-tile run is the reference point as it is the simulation with the least compromise

412 between runtime and simulation detail and is assumed to best represent the impacts of disturbance in CLASSIC.  $msd_j$  is the  
 413 mean of the squared differences between the annual summary (i.e. means for fluxes and sums for pools) of each variable for  
 414 the 32-tile run ( $\hat{\mathbf{x}}_{32tile}$  containing  $i$  years) and that for the simulations under evaluation ( $\hat{\mathbf{X}}$  containing  $i$  years for  $j$  model runs;  
 415 Eqn 11).

$$416 \quad msd_j = \frac{1}{33} \sum_{i=19}^{2017} (\hat{x}_{j,i} - \hat{x}_{32tile,i})^2 \quad (11)$$

417 We also use a normalized response metric ( $\Delta \bar{\mathbf{X}}_{norm}$  for,  $j$  model runs,  $k$  variables; Eqn 12) to evaluate the relative impacts of  
 418 disturbance and subgrid-scale heterogeneity on the simulations. The normalized response metric is a unitless summary statistic.  
 419 It's strength is that a wide range of variables with different units can be visualized on the same axis to make relative  
 420 comparisons of their simulated responses to disturbance and tiling. For a given variable, the metric normalizes each variable's  
 421 output ( $\mathbf{X}$  for  $i$  years,  $j$  model runs,  $k$  variables,  $l$  grid cells) using the minimum and maximum across all the outputs ( $\mathbf{X}_{norm}$  for  
 422  $i$  years,  $j$  model runs,  $k$  variables,  $l$  grid cells; Eqn 12). Each normalized variable is averaged across the model domain and run  
 423 years ( $\bar{\mathbf{X}}_{norm}$  for,  $j$  model runs,  $k$  variables; 1985 - 2017) considering each model grid cell's area ( $a_{grid\ cell}$ ,  $m^2$ ). Finally, the  
 424 absolute value of the difference between  $\bar{\mathbf{X}}_{norm}$  for the desired runs (1-tile/not-disturbed, and 32-tile run) and the 1-tile/disturbed  
 425 run is calculated (Eqn 12).

$$426 \quad x_{norm,i,j,k,l} = \frac{(x_{i,j,k,l} - \min(X_k))}{(\max(X_k) - \min(X_k))}$$

$$427 \quad \bar{x}_{norm,j,k} = \frac{\sum_{i=1985}^{2017} (\sum_{l=1}^{\# \text{ of grid cells}} x_{norm,i,j,k,l} a_{grid\ cell,l})}{33 (\sum_{l=1}^{\# \text{ of grid cells}} a_{grid\ cell,l})}$$

$$428 \quad \Delta \bar{x}_{norm,j,k} = |\bar{x}_{norm,j,k} - \bar{x}_{norm,1-tile/disturbed,k}| \quad (12)$$

429 All plots are created using R or the External Dynamic and Interactive Framework Integrating CLASSIC Experiments  
 430 (EDIFICE) Python suite (Hijmans et al., 2015; R core team, 2013).

### 431 3. Results and discussion

#### 432 3.1 Disturbance events within Canada

433 For the period represented by satellite data in this study, the highest total disturbed areas are in central boreal regions of the  
 434 country and are attributable to wildfire events (Figure 2c). In contrast, harvest concentrates on the west coast and eastern boreal  
 435 and maritime regions of the country. The annual total disturbed area differs widely between years during the satellite era  
 436 (Figure 2a,b). In aggregate, harvest occurs in ~2% of the land area modeled, and fire occurs in ~6% from 1985 to 2017. The  
 437 total number of simulated disturbance events is moderate with 89% of the grid cells incorporating 32 or fewer simulated  
 438 disturbance events during the satellite era and 61% incorporating 11 or fewer (Figure 2d,e). Our aspatial tiling scheme operates  
 439 on an annual timestep and therefore the maximum number of possible events in the 1985 - 2017 drivers is 66 (i.e. a harvest

440 and fire each year for 33 years; Figure 2e). Generally, beyond 11 simulated disturbance events, there is a limited correlation  
441 between the number of simulated disturbance events and the total area disturbed (Figure 2e).

### 442 **3.2 Model parameterization**

443 The change in the msd (Figures 4a-h) as the maximum number of available tiles for the run increases from 1 to 32 exhibits a  
444 roughly exponential decline for surface energy balance (HFSS, HFLS) and C cycle-related variables (cLand, GPP, ER, LAI).  
445 The msd is near zero at 7 – 12 tiles. The 32-tile simulation captures all the discrete disturbance events from 1985 - 2017 across  
446 most of the model domain (Figure 2). However, a simulation that resolves all the disturbance events between 1740 and 2017  
447 as tiles would require far more than 32 tiles, in many forested areas, and be computationally intractable. However, we infer  
448 from the exponential (e.g. rather than linear) decreasing rate of change in Figures 4a-f that our reference 32-tile simulation has  
449 minimal discretization error and converges on the results of that computationally intractable simulation (Torres-Rojas et al.,  
450 2022; Nabel et al., 2020; Nocedal & Wright 2006). The difference in msd between the 32-tile tile simulation and that  
451 computational intractable simulation would likely be vanishingly small, similar to the difference between the 25-tile and 32-  
452 tile simulations (Nabel et al., 2020; Fisher et al., 2018; Ellner and Guckenheimer, 2011; Gelman and Hill, 2006). These roughly  
453 exponential declines in msd reflect the model's ability to discretize patches of vegetation in different stages of recovery using  
454 greater numbers of tiles. This is reflected in how the statistical distributions of aboveground tree biomass in forested grid cells  
455 change as more tiles are utilized in the simulation (Figure 5a).

456

457 Disturbance-related variables including fFire, as well as fDeforestedTotal exhibit a less sharp decline when going from one to  
458 seven tiles and approaches zero at 12 tiles (Figures 4g-h). This reflects the role of selecting and splitting tiles in different phases  
459 of recovery on these processes and the extent to which recovering tiles with lower aboveground tree biomass are represented  
460 in the simulation (Figure 5a). As a result, there is a discontinuity between representing these processes using average  
461 individuals, a small number of highly heterogeneous tiles, and many tiles (Figures 4g-h, 5a). This pattern is also likely  
462 influenced by the relatively low magnitude of the differences between the simulations when, compared to the fluxes themselves  
463 (Figure 6a,h,i).

464

465 The run time for the satellite-era simulation (1985 - 2017) with 1-tile is ~318 CPU hours (i.e. the sum of time utilized by all  
466 cores across multiple machines; Xeon Platinum 8380). Compared to the 1-tile run, the 32-tile run, 12-tile and optimized runs  
467 consume 14 times, 3 times, and 2 times as many CPU hours respectively. The run time of the simulations increases linearly  
468 between one and twelve tiles (Figure 4i) but increases more rapidly from eighteen to thirty-two tiles due to the increasingly  
469 large multidimensional per-tile structures in memory. The intercept (i.e. the overhead for pre-processing meteorological files  
470 and initializing MPI sessions to run the model with a single tile) is around three times the slope (i.e. the time required to run  
471 each additional tile) for simulations with less than 12 tiles. This suggests that the splitting operations involved in simulating  
472 additional tiles are computationally efficient and do not dramatically increase the run time (Nabel et al., 2020).

474 As with all modeling exercises, we must balance model accuracy, complexity, and computational efficiency. We, therefore,  
475 use simulations with 12 tiles to set the *rht* (i.e. the relative height threshold for preemptively joining tiles) and *tpp* (i.e. the  
476 number of preserved recently disturbed tiles) parameter values. Simulations using 12 tiles and different *rht* and *tpp* parameters  
477 are very similar in terms of run time, and surface energy balance and C cycle-related variables exhibit no consistent patterns  
478 (Figures S2a-f, i). There is a gradual increase in *msd* for *fFire* and *fDeforestedTotal* as *rht* and *tpp* increase (Figures S2g-h).  
479 However, these differences are again of relatively low magnitude, compared to the fluxes themselves (Figure 6a,h,i). Therefore,  
480 we chose an *rht* of 0.16 and a *tpp* of 4 to maximize computation efficiency. The optimal parameterization has *msd* values  
481 similar to those of a run with twelve tiles, but at a lower run time (~23% less; Figure 4i). The optimal model nearly  
482 approximates the heterogeneous tile structure of the more complex 32-tile simulation and represents forested areas with low  
483 aboveground tree biomass like the 32-tile simulation, in line with observations of aboveground tree biomass from the NFI  
484 (Figure 5b). However, it may over smooth the transition between low and high biomass areas (i.e. the ~2 - 3 gC m<sup>-2</sup> range in  
485 Figure 5b) thereby impacting the size classes of the tiles selected for splitting during the disturbance simulation (Figure 4g-h).  
486 Nonetheless, the optimal simulation effectively balances computational efficiency and discretization error.

### 487 3.3 Impacts on simulated variables

488 The response of the modeled variables to dynamic tiling (i.e. 1-tile/disturbed v.s. 32-tile, as illustrated in Figure 1, Table 3)  
489 often meets or exceeds their response to disturbance alone (i.e. 1-tile/not-disturbed vs. 1-tile/disturbed; Figure 6a). The impact  
490 of the optimal tiling scheme is minimal by comparison and, therefore, we focus on comparisons between the 1-tile/not-  
491 disturbed, 1-tile/disturbed, and 32-tile outputs (Figures 6b-i, S3). C cycle-related variables including *cVeg*, and LAI show the  
492 strongest response to disturbance, whereas energy balance-related variables including HFLS, HFSS, and ALBS show the  
493 weaker responses. Many variables also respond strongly to dynamic tiling including LAI, Ra, and *cVeg* (Figure 6a,b,e). Select  
494 surface energy balance-related variables including HFLS, HFSS, and ALBS respond more strongly to dynamic tiling than  
495 disturbance alone (Figure 6a). These strong responses further reinforce the impact of disturbance-induced subgrid-scale  
496 heterogeneity on ecosystem processes and the value of representing this heterogeneity within models (Bellassen et al., 2010;  
497 Zaehle et al., 2006; Nabel et al., 2020; Körner, 2006; Dore et al., 2010; Luyssaert et al., 2014; Erb et al., 2017).

498

499 Disturbance-related variables such as *fFire* exhibit little difference with subgrid-scale heterogeneity (Figure 6h), whereas  
500 *fDeforestCumulative* increases slightly (Figure 6i). These patterns occur as fire can potentially impact all subgrid stands above  
501 a certain biomass threshold (Eqn. 7) while wood harvest preferentially impacts the tiles with the largest aboveground biomass  
502 (i.e. approximating the highest quality tiles being harvested). Biomass removal by disturbance leads to a ~1.6 Pg decrease in  
503 *cVeg* across Canada (an 8% decrease) while the subgrid level (tiled) representation of these processes leads to another ~1 Pg  
504 decrease (Figure 6b). LAI mirrors these same patterns with a 4% decrease due to disturbance and another 4% decrease with  
505 the subgrid level (tiled) representation (Figure 6e). As a result of disturbance, *cSoil* decreases at a higher rate from 1985 to

506 2017, whereas cVeg increases at very similar rates  $\sim 0.035 \text{ Pg y}^{-1}$  (Figure 6b,c). For GPP and Ra, the impact of dynamic tiling  
507 is  $\sim 1.5 - 2.5$  times the impact of disturbance alone (Figure 6a,d). This offset in GPP and Ra is likely in part a product of  
508 dynamic tiling simulating the naturally slower process of recovery from bare ground versus recovery of an average individual  
509 with substantial pre-existing biomass and leaf area (Zachle et al., 2006; Körner, 2006; Dore et al., 2010; Luyssaert et al., 2014).  
510 This slower recovery likely also contributes to the losses in cVeg between the 1-tile/disturbed and 32-tile simulation.

511  
512 Dynamic tiling has impacts on HFLS, HFSS, and ALBS  $\sim 1.5 - 4$  times the impact of disturbance alone (Figure 6a). The relative  
513 impact on HFLS is the more muted of the three possibly because while removing vegetation causes a decrease in transpiration,  
514 evaporation from the ground surface increases (Figure 6g). Dynamic tiling does appear to have larger impacts on ALBS where  
515 the surface becomes brighter and by extension, HFSS decreases (Figure 6a,f). This occurs as the model with dynamic tiling is  
516 capable of representing sparsely vegetated and often snow-covered fractions of the land surface as a result of recent disturbance  
517 (Bright et al., 2013; Nabel et al., 2020). These impacts are muted or absent when disturbance is simulated by an average  
518 individual model because only a proportion of the average individual's biomass is removed with enough remaining to support  
519 a tall dense canopy that obscures the ground surface and recovers quickly.

520  
521 The relative impacts of subgrid-scale heterogeneity demonstrated herein are robust given our model-on-model approach which  
522 cancels out pre-existing biases. This is evident in model runs using alternative pre-1985 fire and harvest scenarios that are bias  
523 corrected to match their respective means from the observed period (Figure S4a-b). These alternative scenarios have a limited  
524 impact on the modelled statistical distributions of aboveground tree biomass (figure 5a,S4c). Moreover because our statistical  
525 analysis focus on the period during which disturbance observations are available (1985-2017) and because of the statistical  
526 metrics utilised in our model-on-model comparisons (eqn 12) the differences in  $\Delta \bar{X}_{\text{norm}}$  with these alternative scenarios (Figure  
527 S4d) are an order of magnitude smaller than in shown figure 6a. Our evaluations provide insights into the impacts of subgrid-  
528 scale heterogeneity alone further reinforcing its importance and the value of representing it within models.

#### 529 **4. Conclusion: Implications for representing disturbance and subgrid-scale heterogeneity in LSMs**

530 The dynamic tiling scheme presented in this study could form the basis for a more detailed representation of land use change  
531 and resultant subgrid-scale heterogeneity in CLASSIC, the land surface component of the LSM CanESM (Melton et al., 2020;  
532 Seiler et al., 2021; Swart et al., 2019). Our tiling scheme has several advantages over other methods. It uses a relatively large  
533 number of dynamic tiles as opposed to a small fixed number of tiles, which allows for a more granular representation of  
534 vegetation recovery following disturbance (Shevliakova et al., 2009; Yue et al., 2018a; Naudts et al., 2015; Yang et al., 2010;  
535 Stocker et al., 2014). It also explicitly simulates C and energy exchanges using tile average rather than grid cell average  
536 properties thus fully simulating the impacts from the removal of vegetation by harvest or fire (Bellassen et al., 2010; Haverd  
537 et al., 2014; Melton and Arora, 2014). Most importantly, the scheme is dynamic and has no designated size or age class bins;  
538 the number of simulated tiles increases as disturbances occur and then are managed by on-demand or pre-emptive joins (Nabel

539 et al., 2020; Shevliakova et al., 2009; Naudts et al., 2015; Bellassen et al., 2010). The tiling routine adapts its size distribution  
540 in response to lower disturbance frequencies, more extreme individual disturbance events, and potentially the addition of new  
541 PFTs while remaining computationally efficient. Finally, the tiling scheme can preserve young, recently disturbed tiles which  
542 may improve its representation of early successional differences in GPP, LAI, and cVeg (Bellassen et al., 2010; Zaehle et al.,  
543 2006; Nabel et al., 2020). In the context of pan-Canadian or global offline simulations within CLASSIC, this dynamic tiling  
544 scheme presents the opportunity for more detailed and efficient representations of LULCC than is achievable by simply  
545 increasing the spatial resolution of the model, which is limited by model inputs such as meteorological forcing or coupling  
546 considerations within CanESM. Future LULCC representations could implement more complex tile harvesting schemes to  
547 represent forest management (i.e. thinning, re-planting, clearcut avoidance, or low-intensity harvest) (Puettmann et al., 2015;  
548 Pan et al., 2010) or introduce tiles to account for new LULCC processes and states such as rangelands, pasture, fertilizer use,  
549 and irrigation (Shevliakova et al., 2009). Other disturbances including insect damage, wind damage, and landslides could  
550 likewise be represented using dynamic tiling. Insects in particular are an important disturbance agent in Canada that have more  
551 spatially widespread impacts than fire and harvest, but greater variation in severity (Kurz et al., 2008; Chen et al., 2000). Non-  
552 stand replacing impacts such as due to insect defoliation or drought stress can be detected, but determination of severity or  
553 longer-term impacts remain difficult to quantify. Representing these disturbance events requires consistent spatially explicit  
554 time series of the forcings, which are not widely available at present (Pongratz et al., 2018; Erb et al., 2017). This would also  
555 require careful consideration of the impacts of the disturbance in question. We can infer from our results that low-severity non-  
556 stand replacing disturbances may not require a tiled representation.

557

558 Finally, our model-on-model evaluation provides insights into the biases induced in specific variables by the absence of  
559 dynamic tiling or particular dynamic tiling setups, which may apply to other similar tile-based LSMs/discretized schemes  
560 (Nabel et al., 2020; Fisher et al., 2018). These results are strengthened by our model-on-model approach which acts to cancel  
561 out pre-existing biases to demonstrate the impacts of subgrid-scale heterogeneity, and discretization error alone (Figure  
562 S4)(Torres-Rojas et al., 2022; Curasi et al., 2022; Melton et al., 2017; Melton & Arora 2014; Moorcroft et al., 2001).  
563 Representing subgrid-scale stand structure leads to differences in land-use emissions if particular size or age classes within the  
564 grid cell are preferentially impacted by fire or harvest (Nabel et al., 2020; Shevliakova et al., 2009; Yue et al., 2018b). Our  
565 results suggest that representing a relatively small number of heterogeneous tiles may yield undesirable biases when compared  
566 to simulations using a larger number of tiles (Figures 4a-h, 6a) (Yue et al., 2018a; Shevliakova et al., 2009; Stocker et al.,  
567 2014; Yang et al., 2010). For a tile-based LSM to represent these subgrid impacts the simulation needs to be sufficiently  
568 complex and judiciously implemented and tested. In the case of CLASSIC, we find that 7 – 12 tiles optimally balances detailed  
569 representation and computational costs. An *rht* of 0.16 and a *tpp* of 4 increases computation efficiency with little impact on  
570 the level of detail represented. Likewise, subgrid-scale stand structure impacts C fluxes, vegetation C stocks, and energy fluxes  
571 (Erb et al., 2017; Luysaert et al., 2014; Körner, 2006; Dore et al., 2010). These subgrid-scale impacts can be of similar  
572 magnitude to the impacts of disturbance alone, further reinforcing their significance (Figure 6).

573

574 Ultimately, Canadian forest ecosystems are critical components of the global C cycle which are responding to unprecedented  
575 climate change. Quantifying historical disturbances and evaluating the impacts of different methods of representing  
576 disturbance will improve the representation of the terrestrial C cycle in LSMs. This understanding will also facilitate a  
577 comprehensive, process-based assessment of Canada's future terrestrial C cycle and its response to both disturbance events  
578 and climate change.

#### 579 **Code and data availability**

580 The Canadian Forest Service land cover and maps of forest disturbance described herein for Canada's forested ecosystems are  
581 open access and are freely available at [https://opendata.nfis.org/mapserver/nfis-change\\_eng.html](https://opendata.nfis.org/mapserver/nfis-change_eng.html). The Stinson et al., (2019)  
582 forest management product is available through the Government of Canada's Open Data Portal  
583 (<https://open.canada.ca/data/en/dataset/d8fa9a38-c4df-442a-8319-9bbcbdc29060>). The current version of CLASSIC is  
584 available via the project website: <https://gitlab.com/cccma/classic>. The model version, additional software, setup files, and  
585 outputs used herein are archived on Zenodo (<https://doi.org/10.5281/zenodo.8302974>).

#### 586 **Author contributions**

587 S.R.C., J.R.M., and E.R.H. conceived of the analysis and methodology. S.R.C. conducted the formal analysis, visualization,  
588 and software development, and wrote the original draft. J.R.M. and E.R.H. obtained funding for and oversaw the work. T.H.  
589 and M.A.W. contributed the National Terrestrial Ecosystem Monitoring System data and to the disturbance-forcing  
590 development. All authors contributed to writing and editing the manuscript.

#### 591 **Competing interests**

592 The authors declare that they have no conflict of interest.

#### 593 **Acknowledgments**

594 We would like to thank Mike Brady (ECCC) for his assistance in processing the disturbance data, Ed Chan for his assistance  
595 with the model software and setting up the original model initialization files and meteorological drivers, and Libo Wang for  
596 creating the original land cover products and cross-walking tables. We acknowledge the support of the Natural Sciences and  
597 Engineering Research Council of Canada (NSERC), ALLRP 556430-2020. We also thank the anonymous reviewers for their  
598 constructive comments.

857

858 **Figure 1: Illustrative diagram contrasting the composite (1-tile) and mosaic (>1 tile) representations of disturbance implemented**  
 859 **herein assuming a hypothetical scenario where 50% of a grid cell undergoes timber harvest. The fraction of a grid cell that is**  
 860 **occupied by a tile is denoted above each tile. Tiles that are not active have a gray background (e.g. Tile 3 across all time steps).**

861

862 **Figure 2: Plots of the disturbance drivers over time. a) annual total burned and b) harvested area from 1740 - 2020. Observed**  
 863 **indicates the period that uses the Landsat fire and harvest observations (Hermosilla et al., 2016, 2015a, b). Bias-corrected with**  
 864 **aspatial records indicates the period where the disturbance was inferred from 2019 stand age (Maltman et al., 2023) and bias-**  
 865 **corrected using aspatial harvested and burned area (Skakun et al., 2021; World Resources Institute, 2000; Van Wagner, 1988). Bias-**  
 866 **corrected with aspatial inferred records and bias-corrected with constant value indicate the period where the inferred disturbance**  
 867 **was bias-corrected based on Kurz et al., (1995) and Chen et al., (2000) respectively. The aspatial records line is the nine-year running**  
 868 **mean, min., and max. of the aspatial total harvested and burned area data sets. c) Per-grid cell total area disturbed (1985 - 2017)**  
 869 **and d) the total number of simulated events (1985 - 2017). e) Per-grid cell total area disturbed, excluding un-disturbed cells, plotted**  
 870 **against the total number of simulated events. The black line is a LOESS curve. Note that a simulated event combines all the individual**  
 871 **fire or harvest events that occur in a grid cell in a single year, with a maximum of two simulated events per year (one fire and one**  
 872 **harvest) occurring in each grid cell.**

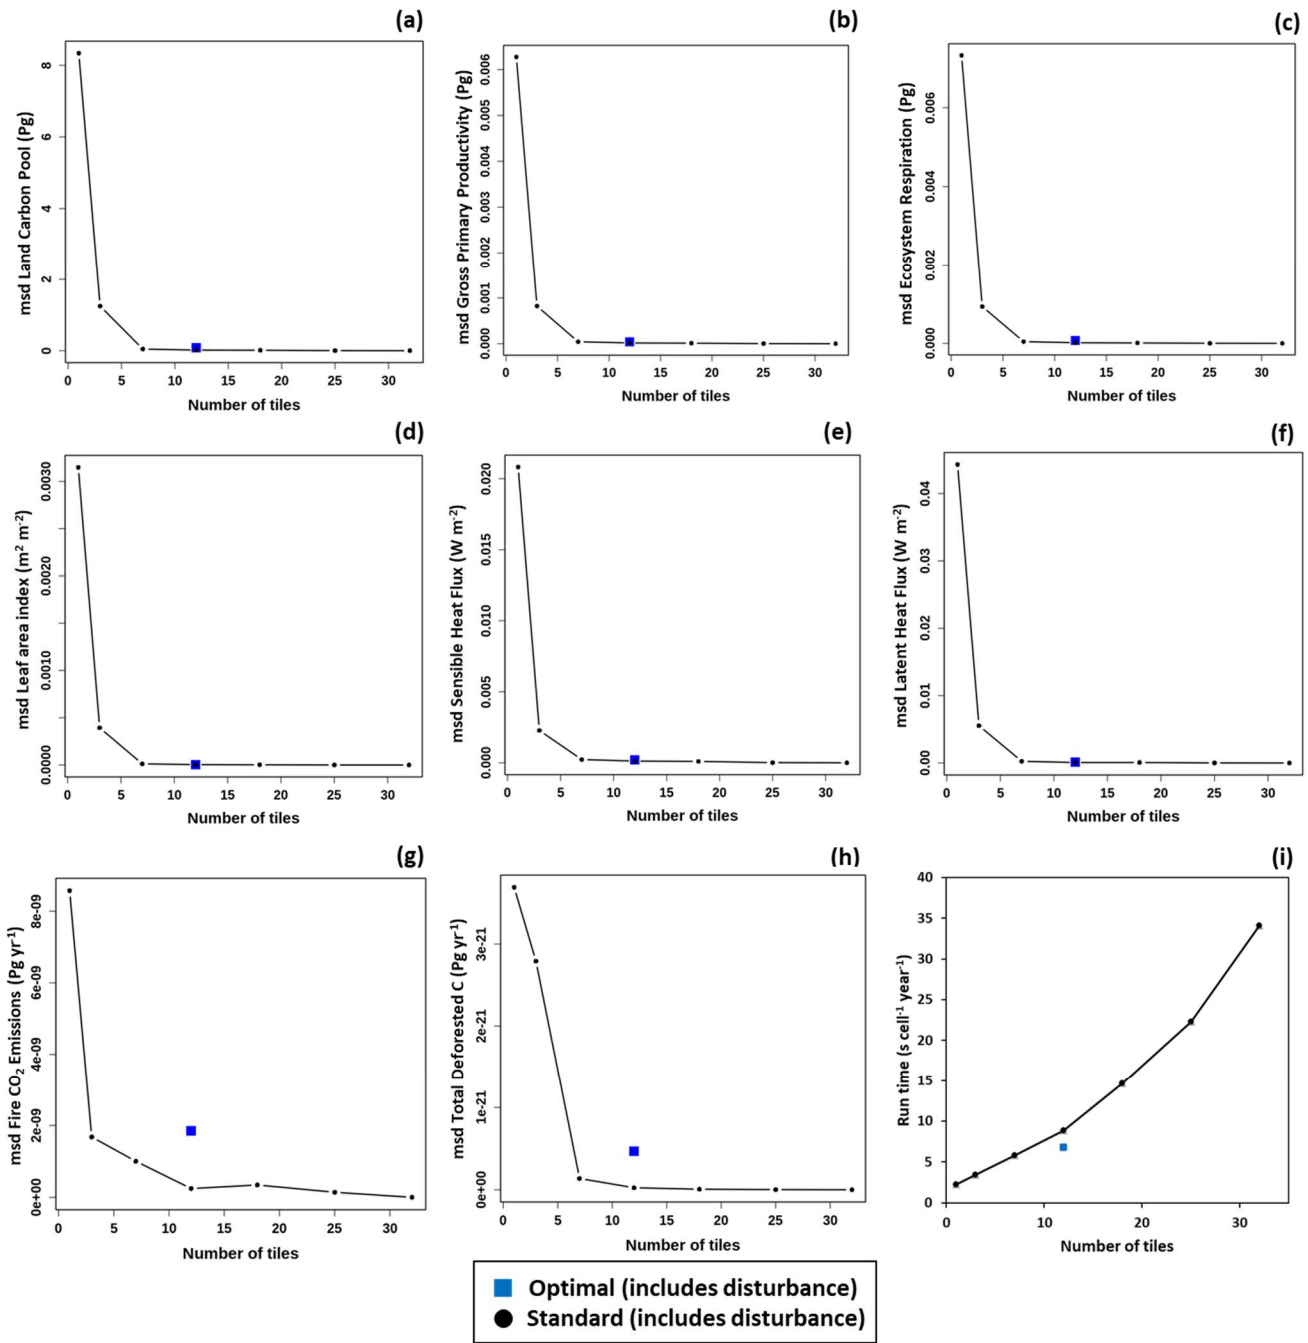

873

874

875

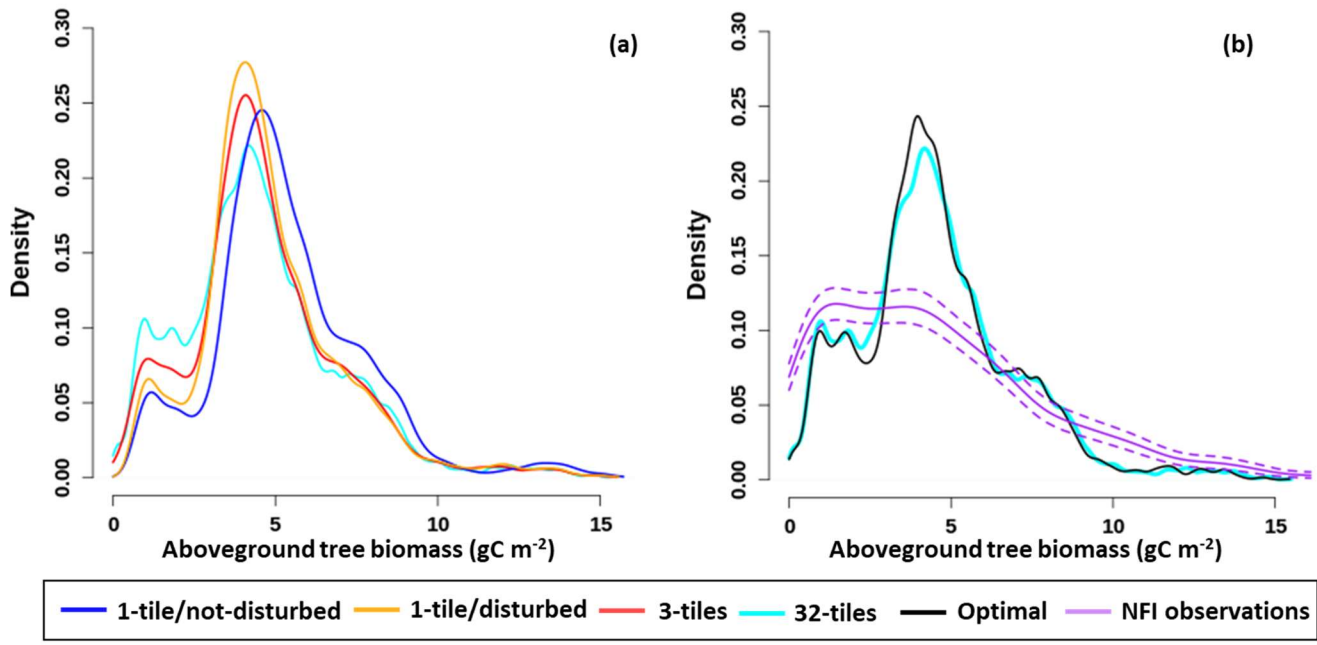

876

Figure 3: A schematic diagram of the negative bias correction algorithm with applicable equations and logical tests. <sup>1</sup>Not shown: When the spatially explicit residuals are exhausted they are replenished using the entire remotely sensed and stand age inferred disturbance record.

877

878 **Figure 4: Plots of the mean squared deviation (msd; 1985 – 2017; Eqn 11) for a) the land carbon pool (cLand), b) gross primary**  
 879 **productivity (GPP), c) ecosystem respiration (ER), d) leaf area index (LAI), e) sensible heat flux (HFSS), f) latent heat flux (HFSS),**  
 880 **g) fire emissions (fFire), and h) total deforested carbon (fDeforestTotal) for model runs including disturbance with varying numbers**  
 881 **of tiles (1 – 32) compared against the run including disturbance with the largest number of tiles (32). i) The run time for each**  
 882 **configuration. Values are also shown for the optimal model run including disturbance with 12 tiles (tile preservation parameter [tpp]**  
 883 **= 4; and relative height threshold [rht] = 0.16).**

Figure 5: Weighted histogram of aboveground tree biomass for forested areas of Canada at the end of a) a selection of model runs including the 1-tile/not-disturbed run, 1-tile/disturbed, 3-tiles, and 32-tiles. As well as for b) 32-tile, optimal (12 tiles, 4 preserved tiles, and a threshold of 0.16), and observations from the National Forest Inventory (NFI) (Gillis et al., 2005). All runs using >1 tile include disturbance. The bootstrapped 95% CI for the NFI observations is also shown. The contributions of all forested subgrid areas weighted by their fractional area within the modeled region are considered. An area is classified as forested if it contains at least 50% tree cover.

892

893 **Figure 6:** a) Plot of the normalized response metric ( $\Delta\bar{X}_{norm}$ ; Eqn 12) for the 1-tile/not-disturbed versus 1-tile/disturbed and 1-  
 894 tile/disturbed versus 32-tile for vegetation carbon (cVeg), soil carbon (cSoil), gross primary productivity (GPP), autotrophic  
 895 respiration (Ra), heterotrophic respiration (Rh), leaf area index (LAI), sensible heat flux (HFSS), latent heat flux (HFLS), albedo  
 896 (ALBS), fire emissions (fFire), and total deforested carbon (fDeforestTotal). Time series plots of b) cVeg, c) cSoil, d) GPP, e) LAI f)  
 897 HFSS, g) HFLS, h) fFire, and i) cumulative deforested carbon (fDeforestedCumulative; the running sum of fDeforestTotal starting  
 898 in 1985) for 1-tile/not-disturbed, the 1-tile/disturbed, 32-tile and optimal ( $tpp = 4$ ;  $rht = 0.16$ ; purple). All runs using >1 tile include  
 899 disturbance. In the “a” panel a normalized response of zero indicates that there are no differences between the runs. \*denotes  
 900 disturbance-related fluxes that are omitted in the 1-tile/not-disturbed model run.

901 **Tables**

902 **Table 1:** The PFT-specific fire emission fractions ( $\upsilon$ ) used to calculate C emissions to the atmosphere due to fire for each live  
 903 vegetation component (i.e. both structural and non-structural leaves, stems, and roots) and the litter pool. As well as the PFT-specific  
 904 mortality fractions ( $\Theta$ ) used to calculate the quantity of C from each live vegetation component transferred to the litter pool. Crop  
 905 PFTs are not impacted by fire and therefore not assigned fractions (Melton and Arora, 2016).

PFT type	green leaves		brown leaves		stems		roots		litter
	combusted ( $\upsilon_L$ )	litter ( $\Theta_L$ )	combusted ( $\upsilon_B$ )	litter ( $\Theta_B$ )	combusted ( $\upsilon_S$ )	litter ( $\Theta_S$ )	combusted ( $\upsilon_R$ )	litter ( $\Theta_R$ )	combusted ( $\upsilon_D$ )
Tree	0.42	0.20	-	-	0.12	0.60	0.00	0.10	0.30
Herbaceous	0.48	0.10	0.54	0.06	0.00	0.00	0.00	0.25	0.42
Shrub	0.42	0.20	-	-	0.12	0.60	0.00	0.10	0.36

**Table 2: The fraction of harvest-affected biomass transferred to different wood product pools for herbaceous PFTs and woody PFTs ( $\epsilon$ ). The fractions for woody PFTs differ depending on aboveground biomass density (Arora and Boer, 2010).**

	Aboveground biomass density (kgC m <sup>-2</sup> )	Fraction of deforested biomass emitted to the atmosphere ( $\epsilon_A$ )	Fraction of deforested biomass as slash/pulp and paper products ( $\epsilon_D$ )	Fraction of deforested biomass as durable wood products ( $\epsilon_S$ )
Woody PFTs	> 4.0	0.15	0.70	0.15
	1.0 - 4.0	0.30	0.70	0.00
	< 1.0	0.45	0.55	0.00
Herbaceous PFTs	NA	0.45	0.55	0.00
