8 **Abstract.** While various root-associated fungi could facilitate soil carbon (C) storage and therefore aid climate change  
9 mitigation, so far research in this area has largely focused on mycorrhizal fungi, and potential impacts and mechanisms for  
10 other fungi are largely unknown. Here, with the aim to identify novel organisms that could be introduced to crop plants to  
11 promote C sequestration, we assessed the soil C storage potential of 12 root-associated, non-mycorrhizal fungal isolates  
12 (spanning nine genera and selected from a wide pool based on traits potentially linked to soil C accrual) and investigated  
13 fungal, plant and microbial mediators. We grew wheat plants inoculated with individual isolates in chambers allowing  
14 continuous <sup>13</sup>C labelling. After harvest, we quantified C storage potential by measuring pools of different origin (plant vs soil)  
15 and of different stability with long-term soil incubations and size/density fractionation. We assessed plant and microbial  
16 community responses, as well as fungal physiological and morphological traits in a parallel *in vitro* study. While inoculation  
17 with three of the 12 isolates resulted in significant total soil C increases, soil C stability improved under inoculation with most  
18 isolates – as a result of increases in resistant C pools and decreases in labile pools and respired C. Further, these increases in  
19 soil C stability were positively associated with various fungal traits and plant growth responses, including greater fungal hyphal  
20 density and plant biomass, indicating multiple direct and indirect mechanisms for fungal impacts on soil C storage. We found  
21 more evidence for metabolic inhibition of microbial decomposition than for physical limitation under the fungal treatments.  
22 Our study provides the first direct experimental evidence in plant-soil systems that inoculation with specific non-mycorrhizal  
23 fungal strains can improve soil C storage, primarily by stabilising existing C. By identifying specific fungi and traits that hold  
24 promise for enhancing soil C storage, our study highlights the potential of non-mycorrhizal fungi in C sequestration and the  
25 need to study the mechanisms underpinning it.

## 26 **1 Introduction**

27 Despite soils having the capacity to sequester large amounts of atmospheric CO<sub>2</sub> and mitigate catastrophic climate change, the  
28 full potential of soil carbon (C) sequestration is yet to be realised (Field and Raupach, 2004; Scharlemann et al., 2014;  
29 Schlesinger, 1990). Moreover, rather than being protected, soils are becoming increasingly degraded globally due to intensive

30 agricultural practices - a situation that may worsen as C loss potentially accelerates with future climate scenarios (Hannula and  
31 Morriën, 2022; Lal, 2018). While soil C sequestration is becoming more broadly recognised as an important climate mitigation  
32 strategy, and as an approach to recover the multiple ecosystem services provided by soil C (Kopittke et al., 2022), its successful  
33 implementation first requires understanding of processes underpinning the storage of C in soil (Dynarski et al., 2020; Smith  
34 and Wan, 2019; Von Unger and Emmer, 2018). Knowledge of soil C storage has improved substantially in recent years, with  
35 it now understood to result from the balance of multiple, dynamic processes (that are further complicated by pedoclimatic  
36 context) determining C inputs to soil and their stabilisation (i.e. resistance to decay; Cotrufo and Lavallee, 2022; Derrien et  
37 al., 2023; Dignac et al., 2005; Dynarski et al., 2020; Jackson et al., 2017; Schmidt et al., 2011). Soil microbes act as key  
38 participants of these processes, as the stability of soil C is regulated primarily via their abilities to mineralise soil organic  
39 matter. Thus, soil microbes determine how long C of plant or microbial origin persists in soil, and can also influence how  
40 much C is available for stabilisation from their necromass and from plant inputs. However, the soil microbial community is  
41 complex, and largely unknown; hence, referred to as a “black box” (Mishra et al., 2023; Tiedje et al., 1999). Within this black  
42 box, fungi, both free-living and plant-associated, are considered particularly important for soil C storage; however, their  
43 impacts on soil C storage are both multifaceted and diverse.

44 The complexity in fungal impacts on soil C storage firstly arises from their abilities to influence both soil C inputs and their  
45 stability via multiple direct and indirect mechanisms occurring simultaneously (Hannula and Morriën, 2022; Kallenbach et al.,  
46 2016; Liang et al., 2019; Starke et al., 2021). In general, fungi that are present in soil (1) all produce hyphae and with them  
47 hyphal C inputs, (2) can alter plant health, growth, and C chemistry and allocation to soil, and (3) can influence the rest of soil  
48 microbial community structure and composition, thus impacting fungal-, plant-, and microbial-derived C, respectively  
49 (Clocchiatti et al., 2020; Hannula and Morriën, 2022; Rai and Agarkar, 2016; Stuart et al., 2022). All of these inputs, but  
50 particularly fungal and plant C, are potentially available for soil C storage but they require stabilisation in order to persist in  
51 soil long term. The broad and efficient enzymatic capabilities and extensive mycelial structure of fungi, as compared to the  
52 rest of the microbial community, allow them to competitively obtain soil C and transform it so that it can be readily sorbed  
53 and stabilised onto mineral surfaces (Boer et al., 2005; Hannula and Morriën, 2022). In addition, fungal necromass is  
54 considered to have a particularly strong affinity for mineral surfaces and is therefore an important source of stabilisable C  
55 (Sokol et al., 2019). The impact of fungi on soil structure and spatial heterogeneity, including promoting aggregate formation  
56 by enmeshing soil particles with their hyphae and producing various extracellular biopolymers, further protects C by physically  
57 constraining microbial decomposition, leading to greater persistence (Berg and Mcclaugherty, 2014; Dynarski et al., 2020;  
58 Kleber et al., 2011; Lehmann et al., 2017; Lützow et al., 2006; Schmidt et al., 2011).

59 These various impacts of fungi on soil C storage are further complicated by fungal diversity, which occurs at the inter-genus,  
60 inter-species, and even down to the sub-species level (Andrade et al., 2016; Hiscox et al., 2015; Johnson et al., 2012; Juan-  
61 Ovejero et al., 2020; Plett et al., 2021). In plant-soil ecosystems, fungi exist either as free-living saprotrophs or as plant-

62 associated fungi, including mycorrhizal, endophytic, and parasitic fungi (Rai and Agarkar, 2016). Saprotrophic fungi are often  
63 assumed to promote soil C output, as they decompose soil organic matter due to being outcompeted by mycorrhizal fungi for  
64 plant C exudates, but as decomposition can increase the availability of C to be sorbed onto mineral surfaces, thereby fostering  
65 soil C stability, their net impacts on soil C storage may need further exploration (Fr ac et al., 2018; Hannula and Morri en, 2022;  
66 Lehmann and Rillig, 2015). Meanwhile, much of the research on the impacts of plant-associated fungi on soil C has focused  
67 on mycorrhizal fungi, particularly arbuscular mycorrhizal fungi and ectomycorrhizal fungi due to their dominance in their  
68 respective habitats (Jackson et al., 2017; Smith and Read, 2008). These fungi have additional impacts, to the general fungal  
69 impacts outlined above, on the inputs and stabilisation of C. As they transform and funnel plant C belowground, mycorrhizal  
70 fungi can increase and modify the quality of C inputs, for example by synthesising melanin for cell walls, which is considered  
71 to be highly stable and has been associated with decreased hyphal decomposability and increased soil C content (Fernandez  
72 and Kennedy, 2018; Fernandez and Koide, 2013; Zak et al., 2019; Zhu and Michael Miller, 2003). Due to their nutrient  
73 requirements and abilities to mine soil resources, they are thought to be strong competitors against saprotrophs for not only  
74 plant C but also soil nutrients, thereby suppressing microbial respiration, and resulting in greater C stability (Gadgil and Gadgil,  
75 1971; Averill and Hawkes, 2016). Some mycorrhizal fungi have limited abilities to directly and partially decay organic matter,  
76 and they can also prime saprotrophic microbes to decompose pre-existing soil C, thus having the potential to decrease C  
77 stability – though their net impact on soil C storage is not well understood (Frey, 2019). Despite the large diversity amongst  
78 fungi in plant-soil ecosystems, influences of non-mycorrhizal fungi, particularly other plant-associated fungi, on soil C storage  
79 have been studied in lesser detail compared to mycorrhizal fungi but do hold promise. For example, endophytic fungi could  
80 potentially be important for soil C storage due to their abilities to produce melanin and promote plant growth (Berthelot et al.,  
81 2017; He et al., 2019; Mandyam and Jumpponen, 2005; Rai and Agarkar, 2016). However, similar to mycorrhizal fungi, there  
82 are conflicting reports regarding their lifestyles, benefits or harms imposed on host plants, enzymatic and nutrient acquisition  
83 ability, or even whether they produce extraradical mycelium, suggesting there may be wide functional variation or plasticity  
84 within this fungal group (Addy et al., 2005; Mukasa Mugerwa and Mcgee, 2017; Rai and Agarkar, 2016). To better understand  
85 the diversity of fungal impacts on soil C storage, particularly soil C stability, focus is also needed on fungal types other than  
86 mycorrhizal fungi.

87 There is growing interest in searching and screening for organisms that, in addition to supporting plant productivity, may  
88 improve soil C storage in agricultural systems (Kaminsky et al., 2019; Islam et al., 2021; Salomon et al., 2022). Thus far,  
89 mycorrhizal fungi have received much attention in this area due to their better known impacts on plant health and soil C.  
90 However, as discussed above, other fungal types may also offer advantages to soil C storage and plant productivity but have  
91 been largely unexplored. With this objective in mind, in the current study we aimed to determine the net impacts of inoculation  
92 with diverse non-mycorrhizal fungi on soil C formation (by impacting the origin of soil C), and stability (by impacting C pools,  
93 dynamics, and fractions), and to investigate the mechanisms underpinning these impacts, both direct and indirect. We assessed

94 12 separate fungal species (spanning nine genera in the orders Chaetosphaeriales, Helotiales, and Pleosporales), isolated from  
95 roots collected from multiple soil environments across Australia and screened for traits that may support plant growth and soil  
96 C storage, such as capabilities to capture and solubilise nutrients from the soil. These fungi were selected with the specific aim  
97 to identify novel organisms that could potentially be introduced to crop plants to improve soil C accrual. In a pot study, we  
98 inoculated spring wheat (*Triticum aestivum*), an important cereal crop, with one of the 12 fungi and grew the plants for a full  
99 life cycle in <sup>13</sup>C-depleted CO<sub>2</sub> growth chambers to homogeneously label the plants during the full growth cycle, in order to  
100 distinguish soil C from plant-derived soil C. Following harvest, we assessed total C and its isotopic composition, and assessed  
101 C distribution among pools of different stability (labile, intermediate, and resistant) via four-month soil incubations, and  
102 evaluated the contribution of soil and plant C to these pools using isotopic analysis. These incubation-based assessments were  
103 accompanied by size and density fractionation analyses to quantify mineral-associated organic matter (MAOM), aggregate  
104 carbon (AggC), and particulate organic matter (POM). We then measured traits of the fungi and of the plants and microbial  
105 community to explore the potential direct and indirect mechanisms behind these impacts, respectively. We hypothesised that  
106 if a fungal species increased total soil C storage, this would be due primarily to increasing plant C inputs by supporting plant  
107 growth and also to stabilising existing soil C - so that fungi-driven increases in total soil C would be associated with more  
108 stable pools and fractions of C. We expected that these changes to soil C would be associated with fungal traits, alluding to  
109 direct mechanisms, as well as to increases in plant growth and shifts in microbial community composition, alluding to indirect  
110 mechanisms.

111

## 112 **2 Materials and methods**

113 The overall study design consisted of a wheat growth pot experiment, in which changes to soil, plant, and soil microbial  
114 communities in response to fungal inoculation were assessed, and a separate *in vitro* fungal growth assay, to measure fungal  
115 traits that could potentially be linked to observations made in the main experiment (Fig. A1).

### 116 **2.1 Experiment set up and maintenance**

117 Twelve fungal isolates were originally isolated from surface-sterilised roots of multiple species of grasses and shrubs from  
118 across diverse natural environments in southeast Australia and screened for traits that may support plant growth and soil C  
119 storage by Loam Bio Pty Ltd (Orange, New South Wales, Australia). Briefly, the screening process included assessing  
120 successful colonisation of crop plants (including wheat), testing for responses of soil properties to inoculation, and assessing  
121 interactions of the fungi with other bacteria and fungi. The fungal isolates, including endophytic fungi and potentially  
122 saprotrophic or other fungi, comprised: *Thozetella*, *Paraconiothyrium*, three *Darksidea*, *Leptodontidium*, *Clohesyomyces*, two  
123 *Phialocephala*, *Acrocallymma*, *Periconia*, and *Ophiosphaerella* species.

124 Pure cultures of these isolates were maintained on 1/10 strength potato dextrose agar (PDA). Surface-sterilised (2% NaOCl)  
125 and moistened seeds of Australian wheat cultivar Condo (*Triticum aestivum*) were incubated at room temperature for 48 h.  
126 Clay loam soil was obtained from an agricultural field where the past 10 years of land use history included wheat, barley,  
127 canola, and sorghum (4.3% C, 0.39% N, pH 5.85; Table B1). The soil was sieved through 2 mm, and was not sterilised before  
128 use in this experiment.

129 The experimental setup consisted of 12 fungal treatments (seven replicates per treatment) and an uninoculated treatment (six  
130 replicates) applied to “planted” pots, which were distributed among six CO<sub>2</sub>-controlled growth chambers (Climatron-1260;  
131 Thermoline, Wetherill Park, New South Wales, Australia). Each chamber contained one replicate per treatment for replicates  
132 1 to 6, and replicate 7 was distributed among the chambers. The CO<sub>2</sub>-controlled growth chambers were modified using the  
133 approach by Cheng and Dijkstra (2007) to achieve continuous <sup>13</sup>C-labeling of plant tissues. Briefly, the chambers were adapted  
134 to take an influx of naturally <sup>13</sup>C-depleted CO<sub>2</sub> ( $\delta^{13}\text{C} = -31.7 \text{ o/oo} \pm 1.2$ ) during the photoperiod, combined with a continuous  
135 supply of external CO<sub>2</sub>-free air, and set to 450 ppm CO<sub>2</sub> concentration. Chambers were adjusted to a 16 h/8 h photoperiod,  
136 22°C/17°C, 60% relative humidity, and 500  $\mu\text{mol m}^{-2} \text{ s}^{-1}$  light intensity. For planted replicates, three 7 mm agar squares from  
137 actively growing 1/10 PDA fungal culture plates were placed near three sterile seeds in 2 L plastic pots (at a depth of 2-3 cm)  
138 containing 1800 g of the non-sterile soil. Uninoculated planted pots (“absent/control”) received three agar squares from  
139 uninoculated plates. Each agar square contained approximately 1.3 mg C. Smaller pots (containing 500 g of soil) for  
140 “unplanted” control pots (four replicates per treatment) were set up three days later using two agar squares (as they contained

141 less soil than the planted pots), as controls for impacts of fungi in the absence of plants, adding to 142 pots in total. After 10  
142 days of growth, seedlings were thinned to one per pot.

143 Pots were regularly and uniformly watered with tap water. Pots within each chamber were randomly repositioned four times  
144 throughout the experiment. The chamber atmosphere was sampled weekly to confirm that the atmospheric CO<sub>2</sub> was sufficiently  
145 depleted in <sup>13</sup>C via a pump system into a Tedlar® SCV Gas Sampling Bag and δ<sup>13</sup>C analysis in a PICARRO G2201i isotopic  
146 CO<sub>2</sub>/CH<sub>4</sub> analyser (Picarro Inc., Santa Clara, CA, USA).

## 147 **2.2 Harvest and plant biomass measurement**

148 Once the plants had senesced and the grain had ripened, at 18 weeks of growth, wheat spikes and shoots were cut off, dried  
149 at 70°C and weighed. The intact root-containing soil was preserved in the pots by freezing at -20°C immediately after shoots  
150 were cut to stop all decomposer activity to retain the C status generated by the treatment until ready for subsampling and  
151 processing. After two days of thawing at 4°C, soil was removed from the pots and a subsample for fractionation analysis was  
152 collected from near the root crown and oven-dried at 40°C. The main root system was gently shaken of soil and 1/3 of the  
153 roots were cut, washed, patted dry, frozen at -20°C prior to root morphology measurement. The rest of the soil was  
154 homogenised before subsamples collection. A subsample for phospholipid fatty acid (PLFA) analysis was frozen at -20°C. A  
155 subsample for soil moisture content was weighed and dried at 105°C. A subsample for soil incubations was oven-dried at  
156 40°C and sieved at 2 mm, and of this, a further subsample for isotope analysis was dried at 105°C. To obtain total root mass,  
157 first the root/soil ratio outside the main root system was estimated by collecting the root mass of the remaining soil (after all  
158 subsampling) via wet sieving (500 µm) and oven-drying at 40°C. The root mass of the soil subsamples was calculated using  
159 this ratio and the amount of soil in all subsamples.

## 160 **2.3 Root morphology**

161 To evaluate root morphology, a potential indirect mechanism for fungal impacts on soil C storage, washed, dried, and frozen  
162 root subsamples were arranged with minimal overlap for digital scanning (Epson Expression 11000XL scanner, Epson,  
163 Macquarie Park, Australia). Images were analysed with WinRhizo Pro software 2015 (Regent Instruments Inc., Quebec City,  
164 Canada) to obtain root average diameter (mm), specific length as the ratio of length to dry mass (cm mg<sup>-1</sup>), tissue density as  
165 mass per unit volume (g cm<sup>-3</sup>), specific surface area as the ratio of area to dry mass (cm<sup>2</sup> g<sup>-1</sup>), and branching as the number of  
166 forks per unit of mass (number mg<sup>-1</sup>). Following root morphology assessment, the root subsample was oven-dried at 40°C  
167 for determination of total root mass.

## 168 **2.4 Plant and soil isotope and chemical analysis**

169 To determine the contribution of soil- versus plant-derived C to total C in soils under wheat, isotopic compositions and C/N  
170 content of ground shoots and soil were assessed using an elemental analyser interfaced to a continuous flow isotope ratio mass  
171 spectrometer (UC Davis Stable Isotope Facility, Davis, California, USA). The proportion of original soil C present in the soil  
172 of each pot after plant growth was calculated via isotopic partitioning following Eq. (1):

173 Soil proportion. Soil =  $\frac{(\delta^{13}\text{C}_{\text{Soil}} - \delta^{13}\text{C}_{\text{UP-Soil}})}{\delta^{13}\text{C}_{\text{P}} - \delta^{13}\text{C}_{\text{UP-Soil}}}$ ,

174 where  $\delta^{13}\text{C}_{\text{Soil}}$  is the  $^{13}\text{C}$  isotopic composition of soil measured in each planted pot,  $\delta^{13}\text{C}_{\text{UP-Soil}}$  is the mean  $^{13}\text{C}$  isotopic  
175 composition of soil in unplanted controls, and  $\delta^{13}\text{C}_{\text{P}}$  is the  $^{13}\text{C}$  isotopic composition of the plant shoots in each planted pot.  
176 The plant C proportion (including C from other biological sources) was defined as 1 minus the soil C proportion. These  
177 proportions were then applied to the measured C concentrations in each pot to calculate plant- and soil-derived C amounts.

## 178 **2.5 Soil incubations**

179 To evaluate fungal impacts of fungal isolates on on C distribution across pools of different stability (labile, intermediate, and  
180 resistant), we assessed microbial CO<sub>2</sub> production during 135-day laboratory incubations of soil harvested at the time of wheat  
181 harvest. Headspace samples from incubation jars containing 30 g soil, incubated under standard temperature and moisture  
182 conditions (25°C and 42% gravimetric moisture, respectively), were collected on 16 occasions over the course of 135 days.  
183 Following incubation, we fitted a decay model exponential decay equations to estimate decay kinetic parameters. Kinetic  
184 parameters derived from mid- to long-term soil incubation are sensitive functional measures of changes in the distribution and  
185 stability of C pools resulting from previous exposure to experimental treatments (Carney et al., 2007; Carrillo et al., 2011; Jian  
186 et al., 2020; Langley et al., 2009; Taneva and Gonzalez-Meler, 2008). Measured CO<sub>2</sub> production rates over time were fitted to  
187 a two-pool exponential decay model to estimate the size of the labile and intermediate C pools and their mean residence time  
188 (MRT; Cheng and Dijkstra, 2007; Wedin and Pastor, 1993). The size of the resistant pool was calculated as the difference  
189 between the total measured organic C and the sum of the estimated labile and intermediate pools. This same procedure was  
190 also applied to the portion of CO<sub>2</sub> that was released from the originally present soil C (soil-derived C, i.e. not plant-derived  
191 C), which was determined via isotopic partitioning of plant vs. soil-derived CO<sub>2</sub>. Based on these, we calculated total CO<sub>2</sub>  
192 released from plant- and soil-derived C during the full length of the incubation. See Supplementary Methods for full details on  
193 incubations, isotopic partitioning, and decay curve fitting.

## 194 **2.6 Soil fractionation analysis**

195 Soil fractionation analysis was performed as an alternative method to soil incubations for understanding fungal impacts on C  
196 stability. Hereafter we refer to the pools measured via fractionation analysis as “fractions”, as opposed to “pools” measured  
197 via soil incubations. The analysis was performed according to a method developed by (Poeplau et al., 2017; Poeplau et al.,  
198 2018) and adapted by Buss et al. (2023, in review) involving high throughput physical fractionation into conceptually  
199 designed soil C fractions - mineral-associated organic matter (MAOM), aggregate carbon (AggC), and particulate organic  
200 matter (POM). See Supplementary Methods for further details.

## 201 **2.7 Soil PLFA analysis**

202 Total microbial community size and composition are also potential indirect drivers of fungal impacts on soil C storage.  
203 Microbial PLFAs in soils were extracted from 2 g of freeze-dried soil harvested from the wheat growth experiment, following  
204 the high throughput method developed and described by Buyer and Sasser (2012; see Supplementary Methods).

## 205 **2.8 *In vitro* fungal assessment**

206 To assess morphological and chemical properties of the fungal isolates (used in the wheat growth experiment) as potential  
207 drivers of fungal impacts on soil C storage, a separate *in vitro* plate assay was performed using 1/2 PDA plates incubated in  
208 the dark at 23-25°C (see Supplementary Methods). Radial growth rate was calculated by measuring colony areas every two-  
209 to-three days using ImageJ (National Institutes of Health, Bethesda, Maryland, US; Schneider et al., 2012). Growth rate was  
210 calculated by subtracting the colony area from an earlier sampling point from that of the following sampling point. Hyphal  
211 density was calculated as the final fungal biomass per final colony area. C and N content were measured by Dumas combustion  
212 using a El Vario cube analyser (Elementar, Langenselbold, Germany).

## 213 **2.9 Data and statistical analysis**

214 ANOVA of soil C properties and experimental variables was performed in R (v. 4.1.2; R Core Team, 2021), followed by  
215 Dunnett's post-hoc test to determine which treatment groups were significantly different to the uninoculated control group or  
216 Tukey's post-hoc test to determine significant differences between inoculated groups. Principal component analysis (PCA) of  
217 soil C property data was performed to identify soil C properties associated with fungi-driven increases in soil C. Redundancy  
218 analyses (RDA) of soil C property data as response variables and either plant and microbial community data or using *in vitro*  
219 fungal assessment data as explanatory variables were performed to identify explanatory variables for fungi-driven increases in  
220 soil C and its stability. Both analyses were performed using the vegan package in R (Oksanen et al., 2020). Missing values (17  
221 values across 46 total variables) in the PCA and RDA datasets were replaced with the treatment mean.

222 Curve fitting of CO<sub>2</sub> rate dynamics was done using the non-linear modelling platform in JMP 16.1.0 and the biexponential  
223 four-parameter decay model using all replicates of a treatment. We used nonlinear least square curve fitting to test if the models  
224 were significantly different between a fungal treatment and uninoculated control, using the nls function in R.

225

## 227 3.1 Several non-mycorrhizal fungal species increased soil C under wheat plants

228 We inoculated wheat plants (*Triticum aestivum*) with one of 12 fungi (non-mycorrhizal) isolated from plant roots. After four  
 229 months of plant growth, there was a positive but varied effect of fungal inoculation on soil C content compared to the  
 230 uninoculated control group ( $p < 0.05$ ; Fig. 1, Table B2). This effect was not observed in soils that received the same fungi but  
 231 were unplanted ( $p = 0.22$ ; Fig. 1). We found significant isolate-specific increases in soil C content of the planted treatments  
 232 under inoculation with *Thozetella* sp., *Darksidea* sp. 3, and *Acrocalymma* sp., relative to the uninoculated control, of 9.4%  
 233 (percentage of change), 7.5, and 7.8, respectively. Nitrogen levels were generally higher in the soils of the inoculated and  
 234 planted treatments compared to the uninoculated control and were generally higher in the treatments where C was also higher  
 235 (Table B2).

237 **Figure 1. Changes in total soil C under inoculation with different fungal isolates compared to an uninoculated control.**  
238 **Values indicate percentage of change relative to mean of uninoculated control (blue line). Error bars indicate standard**  
239 **error, n=7 for inoculated treatments, n=6 for control. ANOVA results for planted and unplanted are presented.**  
240 **Asterisks indicate significant differences with control (Dunnett test,  $p < 0.05$ ). C concentrations are presented in Table**  
241 **B2.**

### 242 **3.2 Fungi-dependent increases in soil C are associated with changes in soil C pools, origin and stability**

243 To understand the underlying mechanisms of the fungal isolate-dependent increases in soil C content and potential shifts in  
244 sources and stability of the resulting soil C, we performed C isotope analysis, soil incubations, and soil C fractionation analysis.  
245 Isotopic partitioning of C into plant- and soil-derived C revealed how changes in these pools contributed to changes in total  
246 soil C (Fig. 2a, Table B2). Planting reduced total soil C, compared to initial C prior to planting ( $t = 4.13$ ,  $p < 0.001$ ), as expected  
247 due to C inputs stimulating decomposition (rhizosphere priming). This reduction was due to decreases in soil-derived C, which  
248 were generally not counteracted by newly added plant-derived soil C - which on average represented 3.8% ( $\pm 0.2$ ) of total soil  
249 C (Fig. A2a). Soil C increases under fungal inoculation had different origins depending on the fungal treatment.. One of the  
250 fungal treatments whereby total soil C significantly increased (*Thozetella* sp.) tended to contain higher levels of plant-derived  
251 C ( $p = 0.06$ ). However, overall, the higher total soil C content relative to controls correlated more closely with higher soil-  
252 derived C (Pearson's  $R = 0.93$ ,  $p < 0.01$ ), than with plant-derived C (Pearson's  $R = 0.02$ ,  $p = 0.83$ ). All three fungal treatments  
253 resulting in significant increases in total soil C showed increases in soil-derived C but these were not statistically significant.

254

255

257 **Figure 2. Distribution of total soil C in plant- and soil-derived pools (A) and among labile, intermediate, and resistant**  
 258 **pools (B) in soil under inoculation with different fungal isolates or under no inoculation (Absent/control). (A): Plant-**  
 259 **and soil-derived C from C isotope partitioning (see Materials and methods). Black asterisks indicate significant**  
 260 **differences in total C with control and white asterisks differences in plant-derived soil C with control (Dunnnett test, p**

261 < 0.1); (B): Pools estimated from decay models derived from soil incubation (see Materials and methods). Crosses  
262 indicate significant differences in the dynamics of total C decomposition (decay curves models, Table B3) compared to  
263 the uninoculated control. Asterisks indicate significant differences in total C or resistant C against control (Dunnett  
264 test,  $p < 0.05$ ). Error bars indicate standard error of total C,  $n=7$  for inoculated treatments,  $n=6$  for uninoculated  
265 control. Note y axis scale.

266 Incubation of soils after plant harvest demonstrated impacts of several fungal species on the dynamics of C decomposition and  
267 the distribution of C among soil pools of different stability. The dynamics of total C decomposition (decay curves models  
268 derived from incubations) were significantly different to the control under half of the isolates (Table B3, Fig. A3). These  
269 included the three isolates that produced higher total C pools: *Thozetella* sp., *Darksidea* sp. 3, and *Acrocalymma* sp. Soil-  
270 derived C decomposition curves (from isotopic partitioning of respiration) were also significantly different to the controls  
271 under the same fungal treatments as well as *Leptodontidium* sp. Estimated pools from these decay curves showed significantly  
272 higher total resistant C (up to 86% of C), compared to controls (76% of C), under eight of the 12 isolates, including the three  
273 treatments where total C increased the most (Fig. 2b, Fig. A2b, Table B3). In terms of other pools, MRT of the total labile C  
274 was significantly lower under inoculation with *Darksidea* sp. 1 compared to the control, whereas MRT of the soil-derived  
275 labile C was significantly higher under inoculation with *Periconia* sp. (Table B3). In terms of intermediate pool MRTs, controls  
276 and fungal treatments were not significantly different.

277 Soil incubations and partitioning of respiration revealed fungal effects on the degree of stability of total C, soil-derived C, and  
278 plant-derived C over time, which we assessed as the proportion of what was present at harvest that was respired over the full  
279 incubation. Significantly lower proportions of total and soil-derived C were respired under all fungal treatments compared to  
280 the controls ( $p < 0.001$ ; Fig. A4), indicating increased stability. In contrast, plant-derived respired C was significantly lower  
281 (more stable) than the controls only with *Thozetella* sp. ( $p < 0.05$ ).

282 From fractionation analysis, %C and %N of the AggC fraction, i.e. the fraction of intermediate stability whereby C is protected  
283 in aggregates, were found to have significant fungal effects, with *Thozetella* sp. and *Periconia* sp. exhibiting significantly  
284 higher levels of both C and N, and *Ophiosphaerella* sp. and *Phialocephala* sp. 1 exhibiting significantly higher levels of N  
285 compared to controls (Table B4). Significant fungal effects were not observed in the MAOM and POM fractions.

286 We performed PCA to identify soil C properties associated with fungi-driven increases in soil C (Fig. 3). Most of the variance  
287 was explained by PC1 and 2 (58%). Greater total soil C (C) was closely associated with soil-derived C (SC), but not plant-  
288 derived C (PC), at time of harvest and soil N. Soil C was also related with the resistant C pools (total (TRC) and soil-derived  
289 (SRC)). The treatments with lowest total soil C (mainly the control, followed by *Clohesyomyces* sp., and *Phialocephala* sp. 1;  
290 Fig. 1) were associated with higher proportions of total and soil-derived C respired during incubation indicating that the C

291 remaining at harvest was inherently less stable. %C of the AggC and MAOM fractions, generally considered to be more stable  
 292 fractions of C, were not clearly associated with soil C or the resistant C pools, nor with any fungal treatments.

293

294 **Figure 3. Fungi-dependent increases in soil C largely relate to measures for soil C stability. Principal component**

### 302 **3.3 Fungi-dependent increases in soil C and its stability are positively associated with plant growth and microbial** 303 **community composition**

304 We assessed plant and microbial community variables, including plant biomass, shoot C/N content, root morphology, and total  
305 microbial community size and composition derived from PLFA analysis. Overall, while variation among fungal isolates was  
306 observed, no significant differences were observed between the inoculated and uninoculated plants for any of the plant or  
307 microbial community variables measured, although average spike mass of *Thozetella*-inoculated plants was significantly  
308 higher than that of uninoculated plants (Table B5-6).

309 To identify plant and microbial community variables potentially involved in the fungal isolate-dependent changes in soil C  
310 properties, we performed RDA using plant and microbial community data and the soil C property data used in the PCA (Fig.  
311 4). Variance explained by RDA1 and 2 was 14.28 and 4.72%, respectively. The cluster of soil C properties that were found to  
312 be closely associated with *Thozetella* sp. in the PCA (e.g. soil-derived C, resistant C pools; Fig. 3) also trended positively with  
313 plant biomass and growth (spike and shoot mass, shoot C/N ratio, and root fork number) and with the PLFA-assessed fungal  
314 to bacterial ratio. *Acrocalymma* sp. and *Darksidea* sp. 3 were more associated with root growth traits, and were also associated  
315 with plant-derived C. The low soil C treatments (uninoculated control, *Clohesyomyces* sp., and *Phialocephala* sp. 1) and their  
316 associated soil C properties (i.e. respired C) were related to shoot C and N.

317

318

319 **Figure 4. Fungal treatments resulting in increased soil C and its stability are associated with plant growth. Redundancy**

334 proportion; TIC, total intermediate C ( $\mu\text{g g}^{-1}$  soil); TLC, total labile C ( $\mu\text{g g}^{-1}$  soil); TRC, total resistant C ( $\mu\text{g g}^{-1}$  soil);  
335 TRpP, total C respired proportion.

### 336 3.4 Fungi-dependent increases in soil C and its stability are associated with denser fungal hyphae and higher fungal 337 C/N ratio

338 Fungal isolates showed strong differentiation in all of the *in vitro*-assessed variables relating to growth and C/N content  
339 (statistically significant effects on all variables,  $p < 0.001$ ; Table B7). Biomass, colony area, and growth rate tended to be  
340 positively associated variables, and were higher in several treatments including *Acrocalymma* sp., *Darksidea* sp. 3, and  
341 *Phialocephala* sp. 1. In contrast, *Thozetella* sp. and *Clohesyomyces* sp. tended to have lower values for these variables, but  
342 *Thozetella* sp. had significantly higher hyphal density than all other treatments.

343 We performed a separate RDA to identify fungal variables potentially involved in increases in fungi-dependent soil %C and  
344 its stability, using *in vitro* fungal assessment data and the soil C property data (Fig. 5). Compared to the RDA using plant and  
345 microbial community data (Fig. 4), greater proportions of variance were explained in this RDA by RDA1 and 2 (21.1 and 9%,  
346 respectively). Fungal colony area and hyphal density were close to opposite in their direction, with the high soil C treatment  
347 *Thozetella* sp. closely associated with hyphal density and the low soil C treatment *Clohesyomyces* sp. more associated with  
348 colony area. Similarly, fungal colony maximum growth time and rate (denoting slower and faster fungal growth, respectively)  
349 were in opposing directions. Along this axis, the high soil C treatment *Darksidea* sp. 3 was closely associated with maximum  
350 fungal growth rate. Respired C proportions were closely associated with fungal N content and were opposite resistant C  
351 fractions, which were associated with fungal C/N ratio and hyphal density.

353

354 **Figure 5. Fungal isolates involved in increased soil C and its stability have denser hyphae. Redundancy analysis (RDA)**  
 355 **showing the fungal variables (blue text) driving changes in soil C properties (red text) associated with the various fungal**  
 356 **isolates (symbols). Soil C properties were measured via isotope analysis, soil incubations, and fractionation analysis of**  
 357 **soil from wheat experiment. Fungal variables were measured in an *in vitro* plate assay and values were averaged for**  
 358 **the RDA. Fungal (F.) variable abbreviations: F.B, biomass (g); F.C, %C; F.CA, final colony area (cm<sup>2</sup>); F.CN, C/N**

359 ratio; F.ECA, estimated final colony area ( $\text{cm}^2$ ); F.HD, hyphal density ( $\text{mg cm}^{-2}$ ); F.MGR, maximum growth rate ( $\text{cm}^{-1}$   
360  $\text{day}$ ); F.MGT, time to maximum growth (days); F.N, %N. Soil C properties: AFC, aggregate C fraction – %C; C,  
361 %C; MFC, MAOM fraction – %C; N, %N; PC, plant-derived C ( $\mu\text{g g}^{-1}$  soil); PFC, POM fraction – %C; PRpP, plant-  
362 derived C respired proportion; SC, soil-derived C ( $\mu\text{g g}^{-1}$  soil); SIC, soil-derived intermediate C ( $\mu\text{g C g}^{-1}$  soil); SLC,  
363 soil-derived labile C ( $\mu\text{g C g}^{-1}$  soil); SRC, soil-derived resistant C ( $\mu\text{g C g}^{-1}$  soil); SRpP, soil-derived C respired  
364 proportion; TIC, total intermediate C ( $\mu\text{g g}^{-1}$  soil); TLC, total labile C ( $\mu\text{g g}^{-1}$  soil); TRC, total resistant C ( $\mu\text{g g}^{-1}$  soil);  
365 TRpP, total C respired proportion.

367 Discussions on soil C sequestration as a climate change strategy have largely focused on one side of the soil C storage system  
368 - increasing C inputs into soil (promoting soil C formation). However, increased soil C storage can also be achieved through  
369 reductions in soil C outputs. In this study, we drew our attention to fungi that have potential in improving soil C storage but  
370 that are often overlooked in this area of research, using a high resolution, multifaceted approach combining isotopic labelling,  
371 soil incubations, and soil fractionation analysis, as well as an *in vitro* study in parallel. Our study supports the notion that  
372 inoculation with non-mycorrhizal root-associated fungi can improve soil C storage via multiple direct and indirect mechanisms  
373 determining C inputs and stabilisation. Mechanisms that increased the stability of existing C were more common across the  
374 diverse fungal treatments than those increasing the input of new C.

375 Despite our finding that bulk soil C increased significantly under only three fungal treatments, in support of our hypothesis  
376 our incubations revealed significant increases in directly and functionally assessed soil C stability (i.e. increases in resistant  
377 pools and decreases in respired C during incubation) under most of the fungal treatments, with the stabilised C being original  
378 soil C, not new inputs of C. Thus, as well as contributing to evidence that fungal inoculation can lead to increased soil C  
379 content (e.g. Kallenbach et al., 2016), our study provides direct evidence from plant-fungi soil systems for non-mycorrhizal  
380 fungi-driven improvements to soil C storage primarily via enhanced stability of soil C. This is emphasised by our findings that  
381 the treatments whereby soil C content was the lowest (control, *Clohesyomyces* sp., and *Phialocephala* sp. 1) were associated  
382 with higher proportions of total and soil-derived C respired during incubation - indicating that the C remaining at harvest under  
383 these treatments was inherently more prone to decomposition (i.e. less stable). Increased stability of soil C primarily results  
384 from inhibition of microbial decomposition (Cotrufo and Lavelle, 2022), which can occur by a variety of reasons including  
385 reduced saprotrophic activity due to microbes being outcompeted for nutrients (Boer et al., 2005), increased input of fungal,  
386 more readily stabilised C (Sokol et al., 2019), and increased soil aggregation (Lehmann et al., 2020). We investigated multiple  
387 potential mediators for the observed increases in soil C stability in our study and found some leads. We found that increased  
388 fungal C/N ratio and hyphal density may be important for stability of soil C (while fungal N corresponded with decreased  
389 stability). Fungi with denser hyphae can promote soil aggregation, as soil particles get more entangled and stabilised in dense  
390 hyphae (Dignac et al., 2017). Our study substantiates previous assertions that fungal trait expression is relevant to soil C  
391 stability: fungi that exhibited an exploitative growth strategy (denser hyphae) were found to more closely associated with soil  
392 C stability, while fungi that exhibited a more exploratory strategy (faster growth) were positively associated with respired C  
393 and less stable C pools (Camenzind et al., 2020; Fernandez et al., 2019; Fernandez and Koide, 2013; Jackson et al., 2017;  
394 Lehmann et al., 2020; Schmidt et al., 2011; Zanne et al., 2020). These findings support the notion that an exploitative growth  
395 strategy may be more conducive to competition with saprotrophs for nutrients, leading to reduced decomposition (Bödeker et  
396 al., 2016).

397 Our PLFA-assessed finding regarding fungal to bacterial ratio points towards a second likely mechanism for the increases in  
398 soil C stability – greater proportion of fungal C, which becomes stabilisable necromass. Fungal necromass is a significant  
399 source of soil C inputs, and can in some cases make up the majority of SOM (Wang et al., 2021). Substrates with high C/N  
400 ratios, such as fungal biomass or necromass, are generally associated with reduced decomposition rates, although C/N ratio is  
401 not the sole determinant of substrate decomposition and C/N ratios can in fact be altered by, rather than alter the activity of,  
402 soil microbial communities (Marañón-Jiménez et al., 2021; Smith and Wan, 2019; Schneckner et al., 2019). Compared with  
403 other substrates, however, necromass is a particularly stabilisable form of C as it can bind to the surfaces of MAOM or be  
404 stabilised on aggregates, where it is physically protected from decomposition (Sokol et al., 2019). For these reasons, we  
405 expected to see positive associations between soil C stability and aggregate and MAOM soil fractions, which are considered  
406 to signify increased and longer-term stability (Dynarski et al., 2020; Hemingway et al., 2019; Islam et al., 2022; Poeplau et al.,  
407 2018; Poeplau et al., 2017). However, in our study these fractions were not strongly associated with soil C content or its  
408 distribution in pools, nor were they as influential on differences between fungal treatments. While this lends support to the  
409 notion that microbial decomposition of soil C was metabolically inhibited (as discussed above), rather than physically limited,  
410 our findings may be explained to some extent by methodology. A potential explanation for our findings is that although fungal  
411 necromass may have been abundant, the experimental conditions may have been unsupportive of MAOM formation (e.g. the  
412 high C content of the unplanted soil may have meant that MAOM content was already at saturation level and new MAOM was  
413 not able to form). Other potential explanations are that the MAOM fraction could possibly take longer than the experimental  
414 timeframe to change substantially, or that the MAOM estimation method may carry greater error, thus making detection of  
415 responses more difficult. Nonetheless, our study detected increases in total C, and C stability that were not associated with  
416 MAOM, suggesting that soil fractionation analyses do not entirely accurately reflect natural soil C distribution and stability  
417 which can be detected functionally via soil incubations. Further studies utilising the combined approach of soil incubations  
418 and soil fractionation analysis, such as studies using soil with lower C content or studies over a longer time period, may shed  
419 light on how findings from the two methods can be compared. However, our findings call for caution in directly equating  
420 operationally defined MAOM pools and their size with C stability and suggest that functionally assessing C dynamics may be  
421 more effective in some cases.

422 In terms of improvements to soil C content, of the three fungal treatments whereby soil C increases were significant, only one  
423 was accompanied by increases in plant-derived C (*Thozetella* sp.). While we expected that there would be some variation in  
424 the fungal impacts on soil C storage due to the diversity amongst the fungi included in this study, this finding is in contrast to  
425 our expectation that increases in plant-derived C would be the main mechanism involved in C increase. As plant growth  
426 promotion and changes in nutrient uptake is a well-known characteristic of some fungi (Hossain et al., 2017), the increase in  
427 plant-derived C with *Thozetella* sp. may have been related to the increases in quantity or quality of plant inputs related to the  
428 shifts in plant variables of *Thozetella* sp. (spike mass, shoot biomass, and shoot C/N ratio). Our results from the isotopic

429 partitioning of respiration from soil incubations further indicate that the plant-derived C present in soil and that contributed to  
430 total soil C increase under inoculation with *Thozetella* sp. was more stable compared to the control or other treatments. Fungal-  
431 derived C could also have contributed to size and stability of plant-derived C, if the fungi took up plant-derived C. Thus, in  
432 addition to increasing plant inputs, *Thozetella* sp. appears to have been more active in stabilising those inputs via the  
433 mechanisms discussed above.

434 Our study addresses key knowledge gaps in the ways fungi affect soil C storage. We have explicitly demonstrated that  
435 inoculation with non-mycorrhizal fungi can improve soil C content and, moreover, soil C stability - supporting the general  
436 agreement in this field that microbial transformations of soil C and microbially driven changes to soil structure are as important,  
437 if not more important, than the characteristics of the inputs themselves for soil C storage (Dynarski et al., 2020; Hannula and  
438 Morriën, 2022). When it comes to evaluating the potential of fungi to support soil C storage, our findings indicate that it is  
439 important to consider not only increases in soil C but also their impact on the stability of C. Among the diverse fungi studied,  
440 these improvements in soil C stability largely resulted from reductions in C outputs by increasing stable C pools and resistance  
441 of existing soil C to decomposition. We emphasise that these findings from our study are net outcomes of fungal inoculation,  
442 which can impact soil C either via direct mechanisms, or indirect mechanisms, including interactions of the fungi with the  
443 surrounding soil ecosystem. While potential mechanisms behind the improvements in soil C stability depended on fungal  
444 identity, our study points towards metabolic inhibition (rather than physical limitation) of microbial decomposition for which  
445 growth characteristics such as density of fungal hyphae and fungal C/N ratio may be important indicators – thus, fungal trait  
446 expression may be a proxy for fungal influences on soil C storage. However, more work is needed to test whether or not  
447 physical limitation of microbial decomposition leads to enhanced soil C stability by these fungi. More rarely, the improvements  
448 to soil C storage involved the effects of fungal inoculation on host plant growth and C inputs (directly as plant or plant-derived  
449 fungal C). While total soil C content increased significantly only under a minority of fungal treatments, the significant and  
450 common fungi-driven increases in stability we observed could potentially lead to even greater increases in soil C content and  
451 its persistence over time - however experiments with longer timeframes are needed to test this idea. This study and continued  
452 work will advance knowledge of these mechanisms and support the search and potential implementation of root-associated  
453 fungi to improve soil C storage, which will aid soil C sequestration strategies.

562  
563

564 **Code availability**

565  
566 Scripts for data and statistical analyses will be made available according to the journal's policies when the manuscript is  
567 accepted for publication.

568

569

570

571 **Author contribution**

572

573 YC, JP and LCG designed the study; ES, LCG and WB performed the research; ES wrote the first draft of the manuscript, and  
574 all authors contributed to revisions.

575

576

577 **Competing interests**

578

579 The research was partially funded by SoilCQuest2031 who provided the fungal cultures and soil. This funding was provided  
580 independently of research findings. SoilCQuest2031 did not attempt to influence the interpretations or conclusions of the work.  
581 The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be  
582 construed as a potential conflict of interest.

583

584 **Acknowledgements**

585 This project was supported by Western Sydney University Research Partnership Program and by SoilCQuest2031 (Orange,  
586 New South Wales, Australia). We acknowledge assistance from Guy Webb and Suresh Subashchandrabose for providing soils  
587 and cultures. We also thank Andrew Gherlenda for assistance with the growth chamber experiment, Russell Thomson for help  
588 with nonlinear least square curve fitting, UC Davis Stable Isotope Facility, Environmental Analysis Laboratory, and  
589 Pushpinder Matta for running the nutrient analyses, and Sophia Bruna, Hui Zhang, and Asel Weerasekara for help with the  
590 experiment harvest.
