## 16 Abstract

17 The Last Glacial Maximum (LGM) was characterised by huge ice sheets covering the Northern Hemisphere, especially over  
18 North America, and by its cold climate. Previous authors have performed numerical simulations of the LGM to better  
19 understand coupled climate - ice sheet systems. However, the results of such simulations are sensitive to many model  
20 parameters. Here, we perform a 200-member ensemble of simulations of the North American and Greenland ice sheets and  
21 climate of the LGM with an ice sheet-atmosphere-slab ocean coupled model (FAMOUS-BISICLES) to explore sensitivities  
22 of the coupled climate-ice system to 16 uncertain parameters. In the ensemble of simulations, the global mean surface  
23 temperature is primarily controlled by the combination of parameters in the large-scale condensation scheme and the  
24 cumulus convection scheme. In simulations with plausible LGM global mean surface temperatures, we find that the albedo  
25 parameters have only a small impact on the Greenland ice volume due to the limited area of surface ablation associated with  
26 the cold climate. Instead, the basal sliding law controls the ice volume by affecting ice transport from the interior to the  
27 margin. On the other hand, like the Greenland ice sheet in future climate change, the LGM North American ice sheet volume  
28 is controlled by parameters in the snow and ice albedo scheme. Few of our simulations produce an extensive North  
29 American ice sheet when the global temperature is above 12°C. Based on constraints on the LGM global mean surface  
30 temperature, the ice volume and the southern extent of the North American ice sheet, we select 16 acceptable simulations.  
31 These simulations lack the southern extent of ice compared to reconstructions, though show reasonable performance on the  
32 ice sheet configuration and ice streams facing the Baffin Bay and the Arctic Ocean. The strong sensitivities of the North  
33 American ice sheet to albedo at the LGM may imply a potential constraint on the future Greenland ice sheet by constraining  
34 the albedo schemes.

35

## 36 1. Introduction

37 The rise in sea level predicted in the next several centuries associated with increasing greenhouse gases and global warming  
38 is one of the largest concerns of society and the climate science community. The most recent IPCC WG1 report projects a  
39 global mean sea level rise of more than 3 m under the high end SSP5-8.5 scenario for increase in radiative forcing in the next  
40 300 years (IPCC 2021). However, there are still large uncertainties in projections of sea level rise with the possibility of a  
41 much larger magnitude (Edwards et al. 2021). This large uncertainty in the projection of sea level rise reflects the present  
42 limited state of knowledge of several important processes, such as nonlinear behaviours in the ice sheet system (e.g.  
43 Gregoire et al. 2012, Abe-Ouchi et al. 2013, Golledge et al. 2019) and interactions of the climate and the ice sheets, which  
44 are expressed in climate-ice sheet coupled models (e.g. Deconto and Pollard 2016, Golledge et al. 2019, Gregory et al. 2020,  
45 Smith et al. 2021). This uncertainty shows the importance of improving our understanding of the ice sheet-climate coupled  
46 system and refining numerical models used for the future projection of climate and sea level rise.

47  
48 One method of evaluating climate-ice sheet coupled models and improving understanding of the climate-ice sheet coupled  
49 system is to simulate conditions of past periods. In this regard, the Last Glacial Maximum (LGM), which corresponds to  
50 approximately 21 thousand years before present (ka BP; Clark et al. 2009, Kageyama et al. 2021), is useful since both  
51 climate conditions and the ice sheet configurations are relatively well documented compared to previous periods of  
52 glaciation (Tarasov et al. 2012, Kageyama et al. 2021). It has been suggested that the LGM could be used to constrain  
53 climate sensitivity (Tierney et al. 2020), cloud processes (Zhu et al. 2022) and deep ocean circulation (Sherriff-Tadano et al.  
54 2023), implying that understanding this period has the potential to help constrain climate and ice sheet models and future sea  
55 level projections. During this period, weaker summer insolation and lower concentrations of greenhouse gases caused the  
56 climate to be colder, allowing ice sheets to expand over North America and Northern Europe. As a result, the global climate  
57 was colder by 1.7°C to 8.3°C (Holden et al. 2010, Schmittner et al. 2011, Tierney et al. 2020, Paul et al. 2021) and global  
58 mean sea level was approximately 120 m lower compared to modern (Clark et al. 2009, Gowan et al. 2021). The mass of the  
59 Greenland ice sheet is thought to have been larger by approximately by 2 to 5 m sea level equivalent (SLE) at the LGM  
60 (Clark and Mix 2002, Lecavalier et al. 2014, Bradley et al. 2018, Tabone et al. 2018) and of the Antarctic ice sheet by 5.6 to  
61 14.3 m SLE (e.g. Briggs et al. 2014). The Eurasian ice sheet is thought to have attained a volume of 24 m SLE (Hughes et al.  
62 2016), but by much the largest part of the 120 m SLE is attributed to the growth of the North American ice sheet (at least 60  
63 m SLE, e.g. Abe-Ouchi et al. 2015). The position of the margin of the North American ice sheet is constrained reasonably  
64 well by geological evidence and this line of evidence is often used to validate the performance of ice sheet models (e.g.,  
65 Dyke et al. 2002, Clark et al. 2009).

66  
67 Studies that simulate LGM climate and ice-sheets have primarily treated these components independently using separate  
68 numerical models. To investigate the effect of ice sheets on climate, following Manabe and Broccoli (1985), many  
69 simulations have been performed and compared, including in studies contributed to the long-running Paleoclimate Model  
70 Intercomparison Project (PMIP, Braconnot et al. 2007, 2012, Ivanovic et al. 2016, Kageyama et al. 2017). The ice sheet  
71 configuration was specified as a boundary condition in these simulations, which show the important role of the ice sheets on  
72 glacial climate, affecting surface temperature, precipitation, atmospheric and oceanic circulation (Smith and Gregory, 2012;  
73 Klockmann et al. 2016, Gregoire et al. 2018, Ivanovic et al. 2018, Sherriff-Tadano et al. 2021). To investigate the effect of  
74 climate on ice sheets, simulations of the LGM ice sheets have been performed with ice sheet models, either as full glacial  
75 cycle experiments (e.g. Abe-Ouchi et al. 2007) or equilibrium LGM experiments (e.g. Alder and Hostetler 2019). In these  
76 experiments, the ice sheet models were forced with climatic conditions based on outputs from general circulation models  
77 (Gregoire et al. 2012, Abe-Ouchi et al. 2013, Alder and Hostetler 2019, Niu et al. 2019, Blasco et al. 2021). They showed the  
78 critical effects of uncertain climatic conditions and albedo in causing a large diversity in the simulated ice sheet

79 configuration (Abe-Ouchi et al. 2007, Alder and Hostetler 2019, Niu et al. 2019, Blasco et al. 2021) together with  
80 uncertainties in basal sliding law (Gandy et al. 2019). These studies highlighted the strong interaction of climate and ice  
81 sheets and the importance of performing simulations with climate-ice sheet coupled models to better understand the coupled  
82 system.

83

84 Recent efforts in the modelling community in developing complex coupled climate-ice sheet models (e.g. Gregory et al.  
85 2012, Ziemen et al. 2014, Roche et al. 2014, Smith et al. 2021) mean that higher complexity coupled climate-ice simulations  
86 of the glacial period than have previously been possible may now be performed. Gregory et al. (2012) performed simulations  
87 of an ice sheet inception over North America with the climate-ice sheet coupled model FAMOUS-Glimmer. They showed  
88 the role of the albedo on the magnitude and speed of the inception. Ziemen et al. (2014) performed simulations of the ice  
89 sheet-atmosphere-ocean system with a more complex ice sheet-climate coupled model. Their simulation reproduced the  
90 climate and the ice sheets of the LGM reasonably well, while the southern extent of the North American ice sheet was  
91 somewhat smaller compared to reconstructions. This is partly due to the relatively coarse resolution of the atmospheric  
92 model (Ziemen et al. 2014), which means their model underestimated the stationary wave effect that cools the southern  
93 extent of the North American ice sheet and hence underestimates the ice area in that region (Roe and Lindzen 2001, Abe-  
94 Ouchi et al. 2007). Lofverstrom et al. (2015) performed simulations of the North American ice sheet and climate with an  
95 atmosphere-ice sheet-slab ocean coupled model in an idealised framework and showed the importance of interactions  
96 between atmospheric circulation, the Rocky Mountains and the ice sheet in shaping the ice sheet's zonally asymmetric  
97 features. Willeit and Ganopolski (2016) presented simulations of the last glacial cycle with an ice sheet model coupled to an  
98 Earth System model of intermediate complexity and discussed the role of the darkening effect of snow. Quiquet et al. (2021)  
99 performed simulations of the ice sheets and climate of the LGM and the last deglaciation with a coupled climate-ice sheet  
100 model. They managed to reproduce the overall characteristics of the evolution of climate and ice sheets and showed the  
101 effects of modulations in the oceanic circulation.

102

103 These previous studies provide very useful insight into the physical interactions within the coupled system, but the inherent  
104 uncertainty and sensitivity in the simulations to the selection of model inputs (including physical parameterisations) are not  
105 tested in any of these studies, because they each use a single version of a given model.

106

107 Perturbed parameter ensembles of simulations are a powerful way to estimate uncertainties originating from particular  
108 parameter values in a single model (Murphy et al. 2004, Sanderson 2011, Shiogama et al. 2012). For example, Rougier et al.  
109 (2009) analysed results from an ensemble performed under modern and future climate conditions with an atmosphere-slab  
110 ocean coupled general circulation model (HadSM3) and showed the critical role of entrainment rate in the cumulus cloud  
111 scheme and its interaction with large-scale condensation scheme on global climate. Gregoire et al. (2011) performed an  
112 ensemble of simulations with an atmosphere-ocean coupled general circulation model, FAMOUS, and found that the mid-  
113 latitude cloud parameters and sea ice albedo exert an important influence on global cooling at the LGM. Furthermore, they  
114 used their results to identify combinations of parameter values that optimise model skill in simulating both the pre-industrial  
115 and LGM, thus improving model flexibility. Gandy et al. (2023) recently performed ensemble simulations of the North  
116 American ice sheet and climate with an atmosphere-ice sheet coupled model FAMOUS-Ice (Smith et al. 2021). They  
117 showed the importance of ice and snow albedo in building the ice sheet due to strong summer insolation at the southern  
118 margin of the North American ice sheet. In this study, however, the sea surface temperature and the global temperature were  
119 fixed. As a result, the role of clouds on the climate and the effects of global mean surface temperature (GMST) on the ice  
120 sheet volume could not be examined.

121

122 Here, we perform a large ensemble of simulations of the North American and Greenland ice sheets and climate of the LGM  
123 with a version of the FAMOUS-Ice coupled atmosphere-ice sheet model, including a more sophisticated ice sheet model,  
124 BISICLES (Method, e.g. Smith et al. 2021). With this ensemble, we estimate the impact of uncertainty in the choice of  
125 parameter values implemented in the atmosphere and ice sheet components of the model, and we test the ability of the model  
126 to simulate ice sheets and climates very different from today. The results are evaluated against the LGM GMST, ice volume  
127 and southern extent of the North American ice sheet. Through these experiments, we aim to address the following questions:

- 128 • How do uncertain parameters affect the climate and ice sheets at the LGM?
- 129 • Is there a difference in important parameters between the North American and Greenland ice sheets?
- 130 • How well are the ice sheets simulated in this experiment, e.g. in terms of North American ice sheet volume, the  
131 southern extent of the North American ice sheet and the position of the ice streams?

132

133 The remainder of the paper is structured as follows. Section 2 gives a description of the model, the experimental design and  
134 the integration procedure. Section 3 reports on the results of the large ensemble. Section 4 discusses the results and the effect  
135 of biases in the model. Lastly, section 5 gives the conclusions.

136

## 137 2. Method

### 138 2.1 Model

139 Our simulations of the climate and ice sheets are performed with the atmosphere-ice sheet-slab ocean coupled model,  
140 FAMOUS-Ice (Smith et al. 2021, Gregory et al. 2020). FAMOUS is a low-resolution version of the atmosphere-ocean  
141 general circulation model (AOGCM) HadCM3; the horizontal resolution is  $7.5^\circ$  in longitude and  $5^\circ$  in latitude (Smith et al.  
142 2008, 2012). Due to the lower resolution, FAMOUS runs 10 times faster compared to HadCM3, while retaining a reasonable  
143 performance for the modern and the LGM climates (Smith et al. 2008, 2012, Smith and Gregory 2012). Benefitting from  
144 much cheaper computational cost, it is feasible to run multi-millennial simulations (Smith and Gregory 2012; Gregory et al.  
145 2020) and large ensembles (Gregoire et al. 2011), as required to meet our objectives.

146

147 The latest version of FAMOUS (FAMOUS-Ice, Smith et al. 2021) incorporates a downscaling scheme for the calculation of  
148 the surface mass balance (SMB) over ice sheets. In the downscaling scheme, 10 additional vertical tiles are added to better  
149 represent the elevation dependence of surface temperature and downward longwave radiation, following the method first  
150 used in Vizcaino et al. (2013). The downscaled temperature and longwave radiation are then utilised with downward  
151 shortwave radiation to calculate the SMB based on a surface energy budget and a multi-layer snow scheme, together with  
152 precipitation from the original FAMOUS grid. The model also incorporates an updated snow and ice albedo scheme, which  
153 accounts for albedo changes associated with modifications in surface air temperature (*daice*), grain size (*avgr*) and density of  
154 the snow (*fsnow*) (Smith et al. 2021, Table 1). As a result, the atmospheric model reproduces the general pattern of SMB  
155 over the modern Greenland ice sheet reasonably well (van de Wal et al. 2012, Smith et al. 2021) with some overestimation of  
156 the elevation of Equilibrium-Line Altitude (ELA; Smith et al., 2021, see also subsection 4.3).

157

158 Previous work with FAMOUS-Ice used prescribed climatological SSTs and sea-ice instead of an interactive ocean model  
159 (Gregory et al., 2020; Smith et al., 2021, Gandy et al. 2023). In the present study, we use a slab ocean model with the same  
160 horizontal resolution as the atmosphere. Inclusion of a slab ocean model allows the local and global SST and sea-ice to vary  
161 in response to changes in climate, which in our experiments are caused by modifications in parameters and the advance and  
162 retreat of ice sheets. In the slab ocean model, sea-ice is advected by the climatological monthly surface sea-water velocity of

163 the HadCM3 pre-industrial control experiment, with sea-ice convergence prevented when the local thickness exceeds 4.0 m.  
164 The local thickness of sea ice evolves due to snowfall, sublimation and melting at the surface, and melting and freezing at  
165 the base in response to heat exchange with the slab ocean. The SST is the temperature of a layer of water 50 m thick and  
166 evolves in response to surface energy exchange with the atmosphere and heat transport within the slab ocean. Since the slab  
167 ocean does not simulate ocean dynamics, climatological heat transport is prescribed within it as a monthly climatological  
168 field of heat convergence. The heat convergence field is obtained from a calibration experiment (Section 2.2) in which the  
169 model calculates the heat flux necessary to maintain a reference climatological state of SST and sea-ice.

170  
171 The slab ocean model is essentially the same as described by Williams et al. (2001), where it is used with the HadCM3  
172 AGCM, but the present study is the first to use it with the atmosphere resolution of FAMOUS. For this configuration, grid  
173 boxes which are partly land and partly sea were implemented in the slab ocean, as in the AGCM. In order to prevent unstable  
174 surface temperature feedbacks in coastal grid boxes with small sea fraction, we found that horizontal diffusion of heat in the  
175 slab ocean was needed (diffusivity  $10000 \text{ m}^2 \text{ s}^{-1}$ ); unlike the prescribed heat convergence, diffusive heat divergence responds  
176 to the time-dependent slab temperature gradient and thus dissipates local anomalies, but usually it is much smaller than the  
177 heat convergence. In order to prevent local build-up of excessively thick coastal sea ice, we allow horizontal diffusion of sea  
178 ice thickness (diffusivity  $5000 \text{ m}^2 \text{ s}^{-1}$ ) when the local thickness exceeds 4.0 m. To improve the reproduction of the reference  
179 sea-ice climatology, we adjusted the coefficients for sea-ice basal melting.

180  
181 Instead of the Glimmer ice sheet model which was used in the previous studies of FAMOUS-Ice (Gregory et al., 2020; Smith  
182 et al., 2021, Gandy et al. 2023), we use the more complex and computationally demanding BISICLES model (Cornford et al.  
183 2013) for the ice sheet component of FAMOUS-Ice (hereafter referred to as FAMOUS-BISICLES). BISICLES is a  
184 vertically integrated ice sheet model, which has been mainly used for simulations of modern and future Greenland (Lee et al.  
185 2015, Smith et al. 2021b) and Antarctica (Martin et al. 2019, Smith et al. 2021b), and has recently been used to simulate past  
186 ice sheets over North America (Matero et al. 2020) and Northern Europe (Gandy et al. 2018, 2019, 2021). Whereas Glimmer  
187 uses the shallow ice approximation, BISICLES applies a L1L2 approximation, which allows more flexibility in sliding and  
188 flowing of the ice sheet especially at the ice shelf area (Cornford et al. 2013). In addition, the model is capable of changing  
189 spatial resolution according to the flow regime of the ice. In this study, a horizontal base resolution of 32 km is chosen, with  
190 refinement to 16 km at ice sheet margins. The choice of the resolution was made based on practical reasons regarding the  
191 computational expense. We show that this resolution is adequate for simulating large-scale glaciers in the northern area of  
192 the North American ice sheet (see subsection 4.2).

193  
194 We utilise a basal drag scheme introduced by Gandy et al. (2019), which explicitly expresses the thermodynamic interaction  
195 of the ice sheets and the underlying till. This scheme combines the Coulomb-friction law and Weertman-friction law  
196 depending on the water pressure in the bedrock sediment (Tsai et al. 2015). The basal drag follows the Weertman law under  
197 cold ice basal temperature and dry bedrock sediment. Under warm ice basal temperature and wet bedrock sediment, the basal  
198 drag follows the Coulomb-friction law. Depending on the depth of till water in the sediment, the friction of ice and bedrock  
199 changes. The depth of the till water is controlled by the balance of basal melting of the ice sheet and a parameter (*drain*) that  
200 controls the vertical till-stored drainage rate. Using this basal scheme in BISICLES simulations, Gandy et al. (2019)  
201 reproduced the features of known ice streams in the LGM British ice sheet.

202  
203 Changes in ice-sheet geometry, and the subsequent redistribution of the Earth's surface mass load, result in deformation of  
204 the Earth's topography through a series of interconnected processes known as glacial isostatic adjustment (GIA). An  
205 important impact of GIA for the purpose of ice-sheet modelling is the subsidence of the bedrock topography beneath an ice-

206 sheet. The rate of the solid Earth response towards isostatic equilibrium, which can range from centuries to millions of years,  
207 is viscoelastic in nature as a result of the rheological structure of the Earth and specific pattern of ice loading. In order to  
208 simulate the first-order effects of GIA on bedrock topography, we couple the ice-sheet model to a simple Elastic Lithosphere  
209 Relaxing Asthenosphere (ELRA) model which approximates this response by assuming a fully elastic lithosphere above a  
210 uniformly viscous asthenosphere (Kachuck et al. 2020). A relaxation time of 3000 years is applied in this model based on  
211 previous studies (Pollard and Deconto 2012).

212

213 In running FAMOUS-BISICLES, a 10 times acceleration is applied to the ice sheet model to save computational cost  
214 (Gregory et al. 2012, Ziemen et al. 2014). In this method, the ice sheet model is integrated for 10 years for every 1 year of  
215 climate simulation by FAMOUS. Gregory et al. (2012) and Gregory et al. (2020) show that 10 times acceleration has a small  
216 to negligible impact on the simulated ice sheet evolution in FAMOUS, supporting the use of this technique.

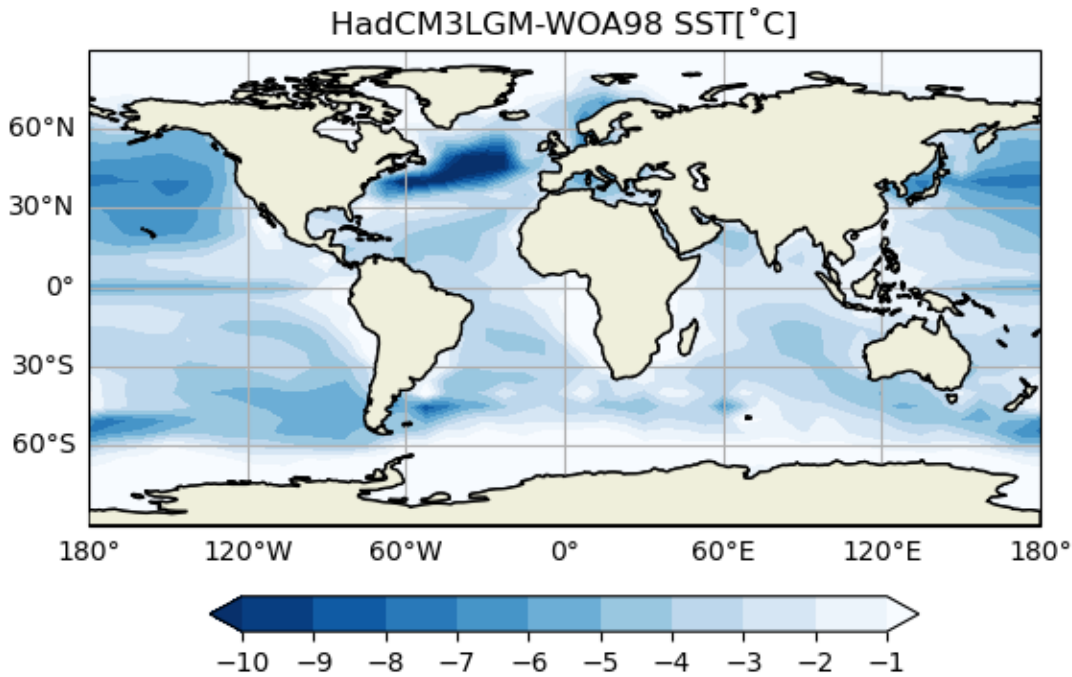

## 217 **2.2 Experimental design**

218 Our experiments mainly follow the protocol of PMIP4 LGM simulations (Kageyama et al. 2017, 2021), which specifies the  
219 insolation, atmospheric concentration of Greenhouse gases ( $\text{CO}_2=190$  ppm,  $\text{CH}_4=375$  ppb,  $\text{NO}_2=200$  ppb, all by volume) and  
220 configurations of continental ice sheets. The Eurasian and Antarctic ice sheets are fixed to the reconstruction of GLAC-1D  
221 (Tarasov et al. 2012) in our setup, while the North American and Greenland ice sheets are simulated with BISICLES. While  
222 the protocol specifies the insolation forcing of 21 ka BP, here we use the insolation of 23 ka since the ice sheet at the LGM is  
223 likely still adjusting to earlier forcing (Abe-Ouchi et al. 2013).

224

225 For calibrating the slab ocean heat convergence (Section 2.1), we use the SST and sea-ice climatology from a previous LGM  
226 simulation performed with HadCM3, shown in Fig. 1 (Izumi et al., 2023). Their simulated GMST exhibits a cold LGM  
227 climate, having a global cooling of 6.5 K. This value is similar to Tierney et al. (2020), who estimate 6.5 K to 5.7 K. For  
228 simplicity of design and clarity of interpretation, the oceanic heat flux is fixed among all the ensemble simulations, thus  
229 assuming no changes in the oceanic heat transport in response to the different parameter values in each member.

230

231

232 Fig. 1 Annual mean sea surface temperature anomaly fields (K, colour) between a HadCM3 LGM simulation and modern  
 233 observation (World Ocean Atlas 1998). The sea surface temperature field from HadCM3 is used as the target sea surface  
 234 condition for our prescribed slab ocean setup.

235

236 We perform 200-member ensemble simulations by varying 16 parameter values associated with climate and ice dynamics, as  
 237 summarised in Table 1, using a Latin-hypercube sampling method (Williamson 2015), assuming a uniform value probability  
 238 across each parameter range, in order to explore the full ranges of the 16-dimensional parameter space. The Latin-hypercube  
 239 sampling technique is useful as it allows exploration of all the uncertain parameter spaces in an efficient way. While some  
 240 cancellations among parameters can cause lower correlation values between inputs and outputs, the method also provides  
 241 quantitative insights on the complex interactions among different parameters (e.g. Fig. 6 and Fig. S7 in this study).

242

243 The choice and the range of the parameter values in FAMOUS are modified following Gregoire et al. (2012) and Gandy et  
 244 al. (2023). In BISICLES, the range of sliding law parameters are modified following sensitivity experiments of Gandy et al.  
 245 (2019). For *drain*, which specifies the vertical till-stored drainage rate, the value is very uncertain and hence we varied it to  
 246 ensure that the till of the interior of the ice sheet remains dry. Much lower values for *drain*, as used in Gandy et al. (2019) in  
 247 their simulation of the much smaller British-Irish ice sheet, result in unphysically wet basal conditions and fast sliding in our  
 248 simulations so we used a higher range. For *n*, which specifies the coefficient in Glen’s flow law, the range is selected in a  
 249 practical way; applying a high value increases the calculation time by more than 10 times due to very large ice velocities and  
 250 the resulting refinement in several locations. Hence, the range of *n* is necessarily capped for its upper limit at 3.1, where our  
 251 technical tests indicated that the simulations will most likely complete within a feasible run length (two months of wallclock  
 252 time). During the ice sheet spin-up phase (see subsection 2.3) we specify a constant SMB. The value of this *smb* is varied  
 253 across the ensemble so that the ice volume at the initiation of FAMOUS-BISICLES coupling has a spread of 25 m SLE,  
 254 which is similar to the uncertainty in the global ice volume estimates at the LGM (e.g. Abe-Ouchi et al. 2015). For

255 simplicity, we apply spatially uniform basal heat fluxes of  $158 \text{ mW/m}^2$  and  $100 \text{ W/m}^2$  under the grounded and floating ice  
 256 respectively, without testing other values. However, these choices need to be reassessed in the future, because the basal heat  
 257 flux over both the continent (e.g. Margold et al. 2018) and the ocean can vary spatially.

258

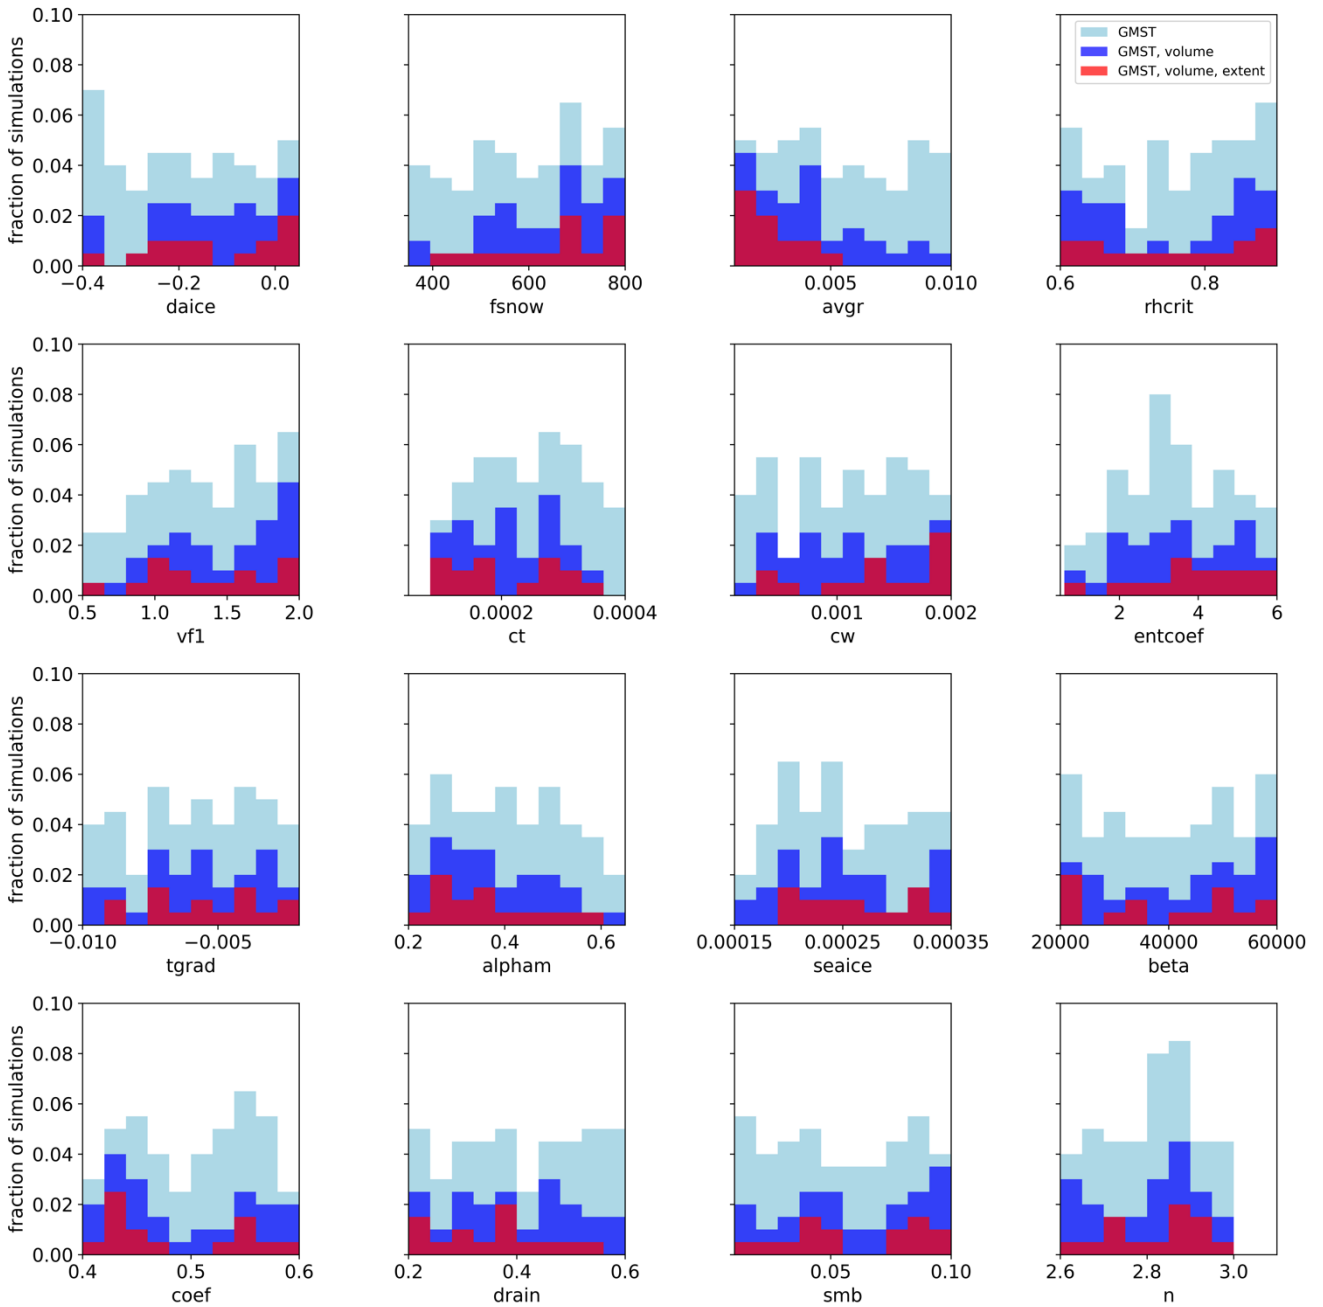

259 Table 1 Summary of parameters modified in the ensemble simulations. ND stands for non-dimensional.

Name	Min value	Max value	Unit	Note
daice	-0.4	0.05	$K^{-1}$	Darkening effect of warm surface air temperature on bare ice in the albedo scheme, mimicking water collecting at the surface. Minimum value reduces the bare ice albedo to as low as 0.15 (Smith et al. 2021).
fsnow	350	799	$kg \text{ m}^{-3}$	Density threshold for snow in the albedo scheme beyond which the surface starts to be regarded as bare ice. Higher values correspond to using brighter albedoes for denser snow and tends to increase ice sheet albedo (Smith et al. 2021).
avgr	0.001	0.01	$\mu\text{m}^{-3}$	Dependence of snow albedo on increasing grain size. Higher value enhances the darkening of snow over time and reduces the snow albedo (Smith et al. 2021).
rhcrit	0.6	0.9	ND	Threshold of relative humidity to form large-scale clouds (Smith, 1990).
Vfl	0.5	2.0	$m \text{ s}^{-1}$	Speed of ice sedimentation (Heymsfield, 1977).
ct	0.00005	0.0004	$s^{-1}$	Conversion rate of cloud liquid water droplets to precipitation (Smith, 1990)
cw	0.0001	0.002	$kg \text{ m}^{-3}$	Threshold value of cloud liquid water for formation of precipitation (Smith, 1990). Only values over land are modified.
entcoef	0.6	6.0	ND	Entrainment rate coefficient. Higher value enhances mixing of an ascending convective plume with ambient dry air.
tgrad	-0.01	-0.002	$K \text{ m}^{-1}$	Air temperature lapse rate used during the downscaling to ice sheet surfaces. Larger negative values correspond to stronger lapse rate effects (Smith et al. 2021).
alpham	0.2	0.65	ND	The lowest value of albedo in the sea ice scheme.
seaice	0.00015	0.00035	$m^2 \text{ s}^{-1}$	Efficiency of heat exchange between the base of sea ice and ocean. Higher value increases the heat flux and causes a retreat of sea ice.
beta	20000	60000	$Pa \text{ m}^{-1/3} a^{1/3}$	Coefficient in Weertman-friction law. Higher value corresponds to stronger friction between the ice base and the dry bedrock (Gandy et al. 2019).
coef	0.4	0.6	ND	Coefficient in Coulomb-friction law (Gandy et al. 2019).
drain	0.2	0.6	$m \text{ yr}^{-1}$	Magnitude of drainage removing water from the till. Higher value removes water rapidly from the till hence increases the Coulomb-friction (Gandy et al. 2019).
smb	0.01	0.1	$m \text{ yr}^{-1}$	Magnitude of temporally constant and spatially uniform surface mass balance (expressed as equivalent liquid water volume flux) applied during the standalone BISICLES spin-up. Higher values result in a larger

				ice sheet at the beginning of the FAMOUS-BISICLES coupled simulation.
n	2.6	3.1	ND	Coefficient in Glen's flow law.

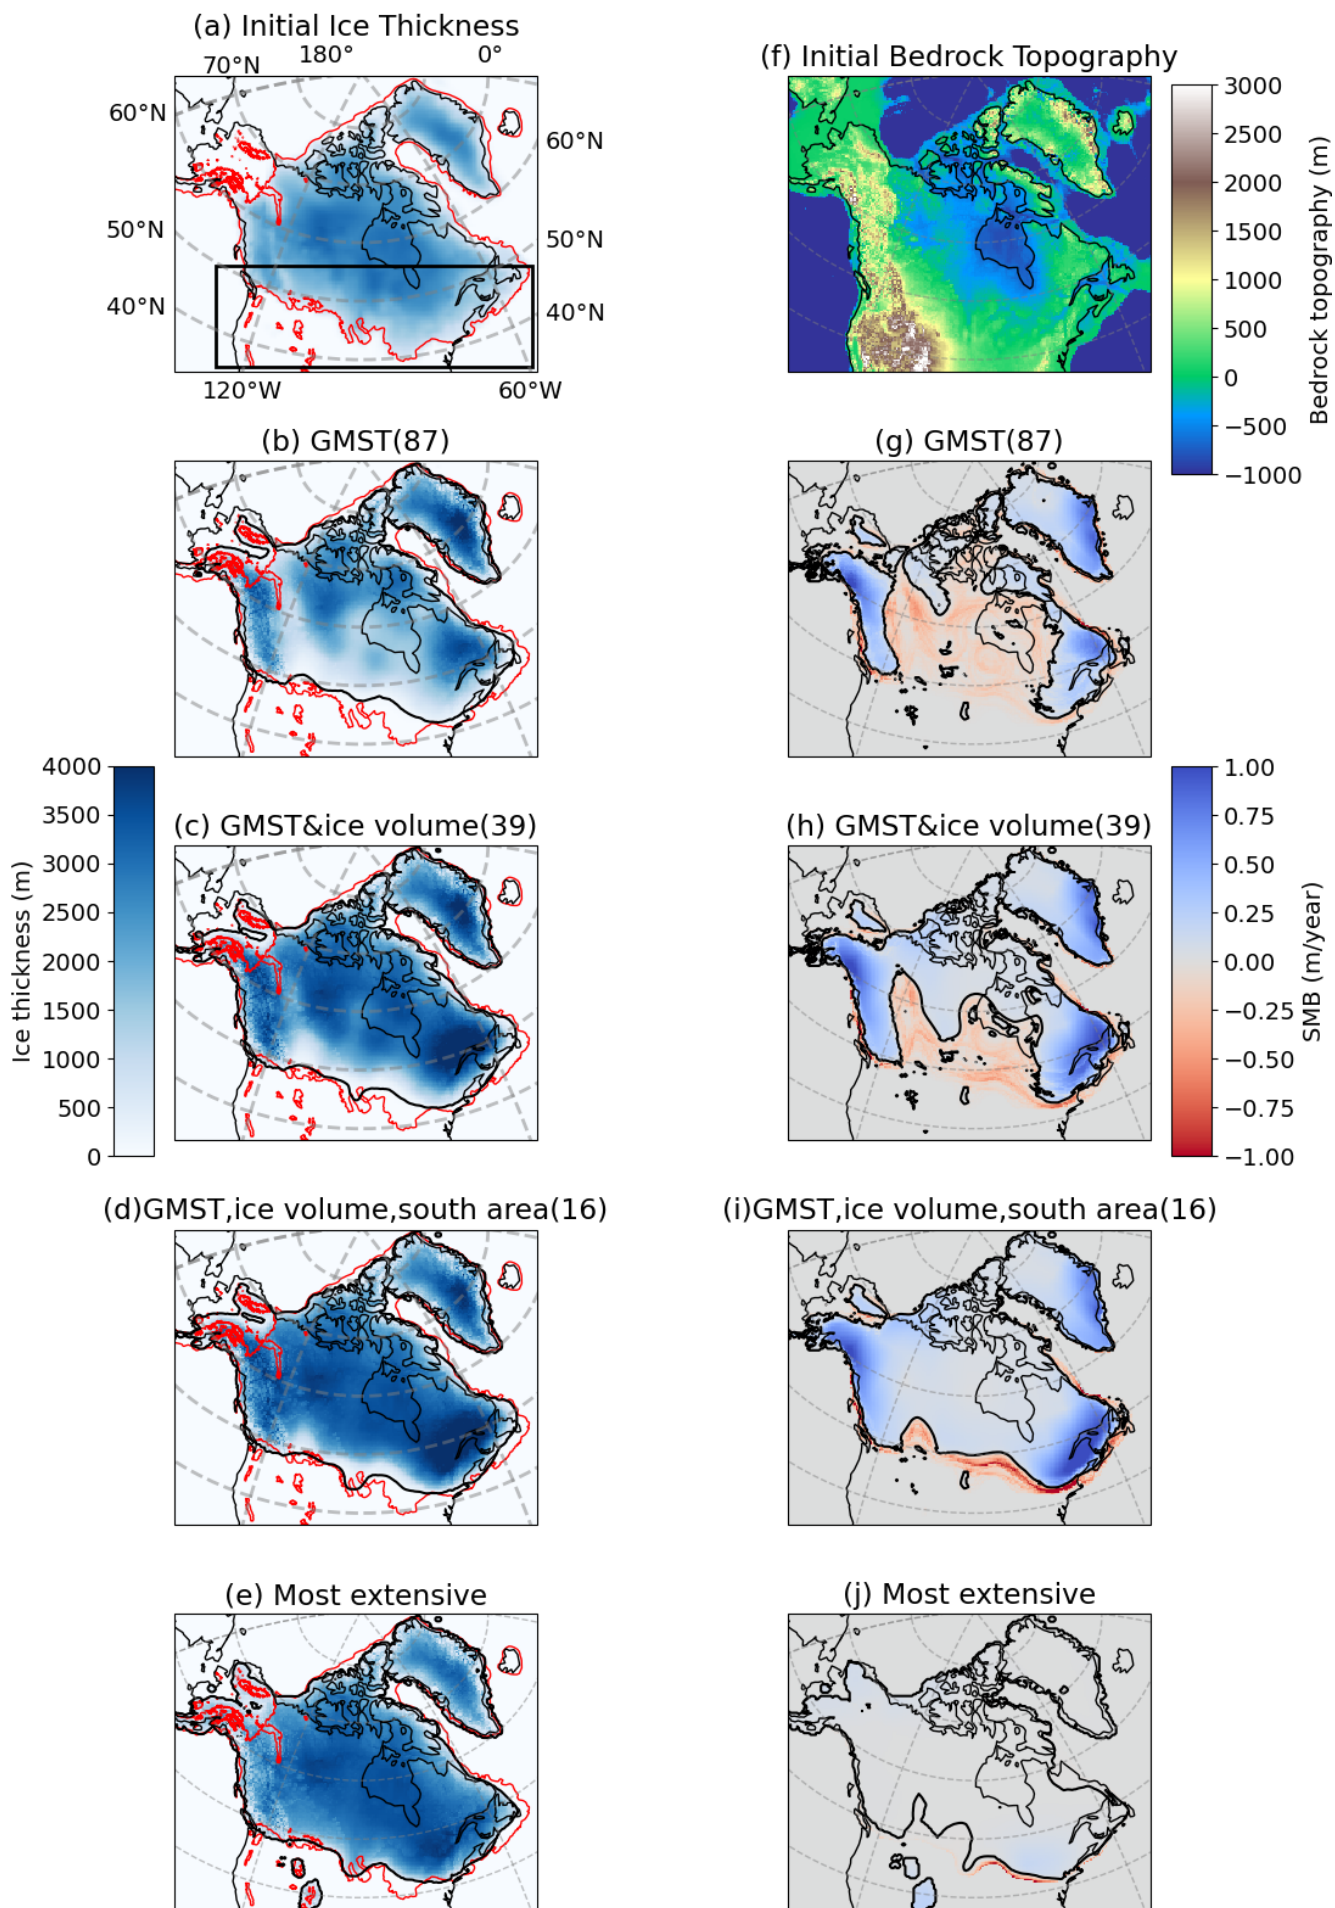

Fig. 2 Fraction of the 200 simulations which satisfy the constraints as a function of each of the parameters. 200 members are uniformly distributed in each parameter range based on the latin-hypercube sampling method (approximately 20 simulations per each parameter bin). Light blue: ensemble members satisfying the global mean surface temperature (GMST) constraint, Dark blue: ensemble members satisfying both the GMST and the North American ice volume constraints, Red: ensemble members satisfying the southern North American ice sheet margin constraints in addition to the GMST and the North American ice volume constraints.

270

### 2.3 Integration procedure

271 Model simulations are all initiated from a static, isothermal (ice temperature 253 K) ice sheet and bedrock topography of  
272 21ka BP of GLAC-1D (Fig. 3a, f, Tarasov et al. 2012). The simulations have two phases. First, there is an initial spin-up of  
273 5000 ice sheet years with stand-alone BISICLES, where the ice sheet model parameter values are chosen according to the  
274 ensemble Latin Hypercube sampling, but the associated climate parameter values are not used because there is no climate  
275 model. In place of the climate model, a constant-in-time surface mass balance (*smb*, Table 1) and atmospheric surface  
276 temperature of 253K are applied uniformly over the ice. Note that the ice temperature is allowed to evolve in the simulation.  
277 The *smb* value is varied across the ensemble to produce a variety of total ice volumes (Fig. S1), because total ice volume is  
278 highly uncertain in reconstructions and could be important given the dependence of ice sheet simulation on initial conditions  
279 (Abe-Ouchi et al. 2013). The spin-up phase also gives the ice sheet model physics time to adjust from the prescribed initial  
280 condition, i.e. it allows BISICLES to smooth out the blocky surface of the ice sheet reconstruction, providing some stability  
281 to the simulations when they are subsequently coupled to the climate (FAMOUS) in the second phase. By the end of the  
282 spin-up phase, 200 unique ice sheets have been modelled, providing the starting condition for simulations with BISICLES  
283 coupled to FAMOUS in the second phase. In FAMOUS-BISICLES, *smb* is redundant and the climate parameters chosen by  
284 Latin Hypercube are used in FAMOUS, with the same ice sheet parameter combinations as in the spin-up phase. In the  
285 second phase, the simulations run for 5000 ice sheet (500 climate) years, which is insufficient to reach a quasi-equilibrium  
286 state, but sufficiently long to see the effects of important parameters on the climate and ice sheets. For some of the best-  
287 performing simulations, the integration is extended for another 5000 ice years, during which the configuration of the ice  
288 sheet shows only modest further changes (Fig. S2).

289

291 Fig. 3 Spatial maps of the initial condition for the ice sheet model, and results from the FAMOUS-BISICLES ensemble after  
 292 5000 ice sheet years. (a) ice topography [m] and (f) bedrock topography [m] from Tarasov et al. (2012). (b-e/top) Spatial  
 293 maps of ice thickness [m] and (g-j/bottom) surface mass balance (SMB) [m/year] from ensemble means. (b, g) 87 members  
 294 satisfying the Global mean surface temperature (GMST) constraint, (c, h) 39 members satisfying both GMST and ice volume  
 295 constraints, (d, i) 16 members having the largest southern extent of North American ice sheet that satisfies GMST and  
 296 volume constraints and (e, j) the member with most extensive southern ice area in the ensemble simulations. The thin black  
 297 contour corresponds to the modern coastline, whereas the thick black contour in (g-j) corresponds to the zero line of SMB.  
 298 Red contours in (a)-(e) correspond to the ice extent of Dalton et al. (2020). Black contours in (b)-(e) correspond to the ice  
 299 extent of the ensemble mean defined as 100 m ice thickness. Black rectangle in (a) shows the region where the southern  
 300 extent of the North American ice sheet is calculated (e.g. Fig. 11).

## 301 2.4 Constraints

302 Three metrics are used to evaluate the large-scale feature of the ensemble simulations. These are the annual mean LGM  
 303 GMST, the ice volume of the North American ice sheet and the southern extent of the North American ice sheet.

304

305 For the global temperature, we create our LGM constraint by adding estimates of the LGM global cooling to the  
 306 Preindustrial GMST of 13.7 °C (1880-1900, NOAA National Centers for Environmental Information (2023)) with an  
 307 uncertainty of  $\pm 0.1^\circ\text{C}$  (one standard deviation of global temperature during this period). According to previous studies, the  
 308 LGM global cooling relative to the Preindustrial has a range of  $-1.7^\circ\text{C}$  to  $-8.3^\circ\text{C}$  (e.g.,  $-1.7^\circ\text{C}$  to  $-3.7^\circ\text{C}$  with a probability of  
 309 90% in Schmittner et al. (2011) and  $-4.6^\circ\text{C}$  to  $-8.3^\circ\text{C}$  with a probability of 90% in Holden et al. (2010), see Fig. 4a in Tierney  
 310 et al. 2020). To objectively cover all the possibilities, we take into account all of these studies to define our range of  
 311 plausible LGM GMST. Assuming the LGM cooling is normally distributed, this gives a mean cooling of  $5^\circ\text{C} \pm 3.3^\circ\text{C}$  with  
 312 a probability of 90% (one standard deviation is  $\pm 2.0^\circ\text{C}$ ). Combining the uncertainties associated with the Preindustrial  
 313 GMST and the LGM global cooling gives one standard deviation of the uncertainty of

$$314 \sqrt{(0.1)^2 + (2.0)^2} = \pm 2.0^\circ\text{C}$$

315 in the actual LGM GMST (66% probability). To be conservative and take into account model uncertainty, we apply three  
 316 standard deviations ( $\pm 6.0^\circ\text{C}$ ) as the uncertainty ranges. This gives an actual LGM GMST of approximately  $2.7^\circ\text{C}$  to  $14.7$   
 317  $^\circ\text{C}$  ( $8.7^\circ\text{C} \pm 6.0^\circ\text{C}$ ), with a probability of at least 99% (Pukelsheim 1994).

318

319 For the ice volume constraint, previous studies have suggested that the volume of the North American ice sheet was likely to  
 320 be larger than 70 m sea level equivalent (c.f. Abe-Ouchi et al. 2015). To account for model uncertainty and to be  
 321 conservative, we apply a minimum reasonable North American ice volume of 60 m SLE as a constraint. Applying an upper  
 322 ice volume limit may also be important in constraining the parameter space. However, in general, equilibrium LGM  
 323 simulations tend to overestimate the ice volume if once the simulation has a net positive SMB (e.g. Alder and Hostetler  
 324 2019). In this regard, setting an upper limit can be tricky, and therefore needs to be examined in a different experimental set-  
 325 up.

326

327 The southern extent of the North American ice sheet is used to select the best-performing simulations, rather than as a strict  
 328 constraint, because all ensemble members show a smaller southern area of the ice sheet than reconstructions (see Section  
 329 4.1). Areas of grid cells covered by the ice sheet in the box shown in Fig. 3a are calculated. This area corresponds to the  
 330 south of the Hudson Bay. Simulations with the southern area covering 60% of the reconstructed area (Dalton et al. 2020) are  
 331 considered to satisfy our constraint.

332

333 In the end, sixteen simulations simultaneously satisfy our constraints on temperature, ice volume and extent.

### 334 3. Results

#### 335 3.1 Response of the GMST

336 Fig. 4 summarises the temporal evolution of annual mean GMST in the ensemble of simulations. After the first 300 ice sheet  
337 years, climates reach a quasi-equilibrium. The results show a wide variety of simulated global temperatures, ranging from -  
338 10°C to 40°C. Such a wide range is frequently observed under parameter ensemble simulations (e.g. Joshi et al. 2010,  
339 Gregoire et al. 2011). The diverse response of GMST is largely explained by two parameters in the cloud schemes;  $ct$  in the  
340 large-scale condensation scheme and  $entcoef$  in the cumulus convection scheme (Fig. 5). The correlation coefficients of these  
341 parameters with the global temperature at ice years 200-290 are 0.622 for  $ct$  and -0.574 for  $entcoef$ , respectively. In contrast,  
342 other parameters appear to have a smaller effect, according to the correlation analysis (Fig. 5). For the sea ice albedo, this  
343 relatively muted sensitivity may be related to the use of a slab ocean model, which underestimates the strong interactions  
344 between sea ice and oceanic heat transport over the Southern Ocean that amplifies the surface cooling at high latitudes  
345 (Ogura et al. 2004, Zhu et al. 2021). Including a dynamical ocean may increase the importance of sea ice albedo on the  
346 GMST, as shown by Gregoire et al. (2011).

347

348 Roles of  $ct$  and  $entcoef$  in governing GMST are further explored by means of a pair plot in Fig. 6. This figure compares the  
349 relationship of these two parameters to GMST. The results show a positive correlation between global-scale warming and  $ct$ ,  
350 which is associated with an increase in precipitation efficiency, reducing the life cycle of mid-latitude clouds, causing a  
351 decrease in the cloud cover and a decrease in the planetary albedo. As a result, more shortwave radiation is absorbed and the  
352 planet warms (Joshi et al. 2010, Sherriff-Tadano et al. 2023). Conversely, global-scale warming occurs with decreasing  
353  $entcoef$  (Fig. 6), as the entrainment rate of ambient dry air in the tropics reduces, and the vertical transport of moisture to the  
354 high troposphere and lower stratosphere enhances. The planet then warms up due to the strong greenhouse gas effect of the  
355 water vapour (Joshi et al. 2010). Similar responses are observed in Joshi et al. (2010), who performed ensemble simulations  
356 under modern and future climates and showed that low values of  $entcoef$  were unrealistic based on the amount of water  
357 vapour in the lower stratosphere. Consistently, ensemble members with very low values of  $entcoef$  are more likely to be  
358 ruled out for producing implausible GMSTs, depending on the effect of the combinations of the other parameters (Fig. 6).  
359 For ensemble members satisfying the temperature constraint (black outlined coloured dots in Fig. 6), the overall cooling and  
360 warming effects of  $ct$  and  $entcoef$  are largely cancelled out by each other.

 378 scheme) and  $entcoef$  (entrainment rate in the cumulus convection scheme) on GMST (colours, °C). Filled circles outlined in  
 379 black are those satisfying the temperature evaluation criterion.

### 380 3.2 Response of the North American ice sheet

381 Similar to the diversity in simulated GMST, the evolution of the ice sheet after the coupling to FAMOUS shows a wide  
 382 range of responses (Fig. 7). Starting from combined ice sheet volumes of 80 to 105 m SLE (sum of North American and  
 383 Greenland ice sheets), the ensemble members produce combined ice volumes between 0 and 120 m SLE at the end of the  
 384 5000-ice year integration. In some simulations, even the Greenland ice sheet disappears completely associated with the very  
 385 high global temperature (Fig. 4). Note that some simulations with high  $n$  values or very warm climates (that cause all of the  
 386 ice to rapidly disappear) crash during the integration. In total, 139 members (~ 70% of the ensemble) complete the entire  
 387 5000 ice years. Eighty-seven members satisfy the global temperature constraint (Fig. 5 and Fig. 6) , and 39 members also  
 388 satisfy the North American ice volume constraint of at least 60 m SLE. The additional constraint on the southern extent of  
 389 the North American ice sheet selects the 16 best performing simulations (Fig. 2).

390

391 Fig.7 Evolution of the North American and Greenland combined SLE ice volume in the FAMOUS-BISICLES LGM  
 392 ensemble. Note that the modern ice volume of 7.3 m SLE on Greenland is *included*; the ice volume is *not the difference*  
 393 between LGM and present. Each grey line represents one ensemble member. Blue lines are the members satisfying our  
 394 chosen GMST evaluation criteria. Histograms on the right show the number of simulations in each temperature bin; grey: all  
 395 members and blue: members satisfying the GMST constraint.

396

397 To explore which parameters are causing the variety of outcomes for the simulated North American ice volume, scatter plot  
 398 and correlation analyses are performed (Fig. 8). Here, the ensemble members that both satisfy the GMST constraint and have  
 399 completed 5000 ice years are used (87 members). The analysis shows important impacts from parameters in our ice sheet  
 400 surface albedo scheme that have a direct influence on the albedo that is diagnosed for bare ice or uncompacted snow  
 401 surfaces; *avgr* (snow ageing effect), *daice* (melt pond effect), and *fsnow* (the weighting of snow and ice albedo based on the  
 402 density of snow) showing correlations of -0.56, -0.475 and 0.372, respectively, with ice volume (see Table 1 for the effects  
 403 of each parameter). Similar results are obtained for the analysis on the southern extent of the North American ice sheet (Fig.  
 404 S4).

405

406 Additional analysis exploring the combined effect of three parameters in the albedo scheme reveals a strong dependence  
 407 between *daice* and *fsnow* (Fig. S7); the ice volume is less sensitive to *daice* when *fsnow* has a large value. This is reasonable  
 408 as a large value of *fsnow* means that most of the snow/ice will be diagnosed as snow due to the high value of density  
 409 threshold. As a result, the darkening effect for the old ice (*daice*) has only a minor influence.

410

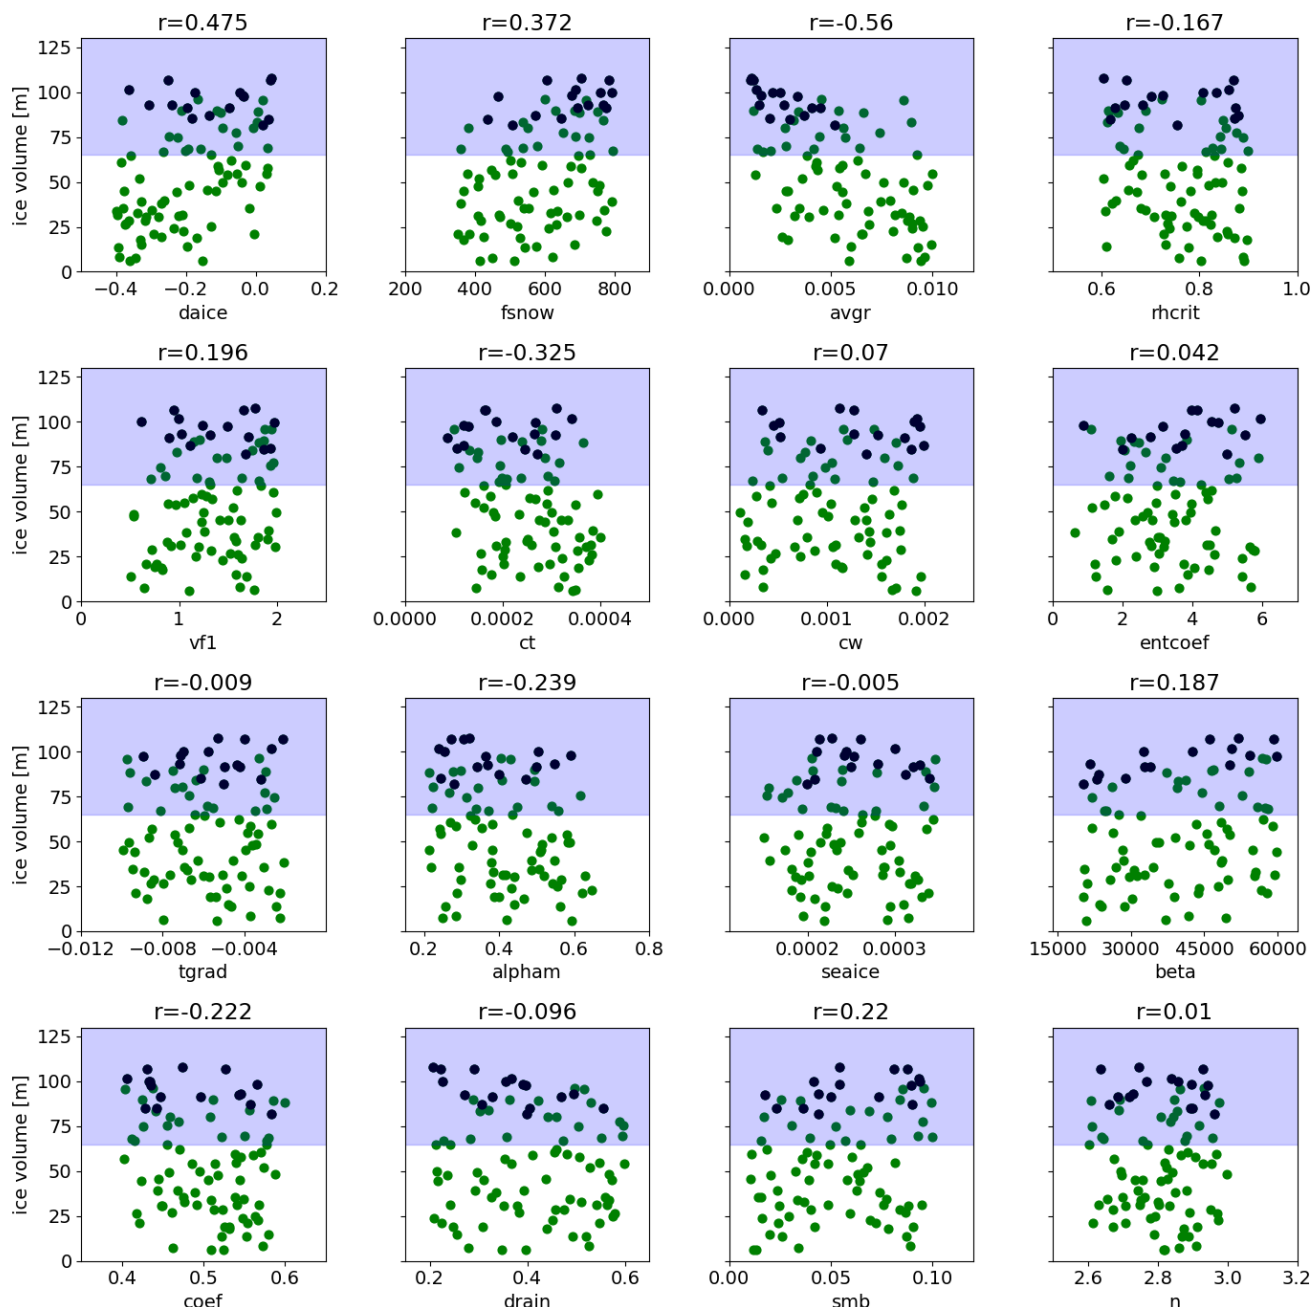

411 The effects of other climate parameters are weaker compared to those of albedo parameters. Among these,  $ct$  shows the  
412 largest correlation value of -0.325. This is reasonable since the low value of  $ct$  corresponds to a colder global climate (Fig.  
413 5), hence a colder local climate over the ice sheet, allowing the large ice sheet to be sustained (see also section 3.4 and Fig.  
414 11). On the other hand, the 87 not-ruled-out-yet simulations are relatively insensitive to  $entcoef$  (Fig. 8). This may in part be  
415 due to the screening out effect of ensemble members with low values of  $entcoef$  that causes drastically warm climates. We  
416 should also note that the cloud parameters exert some local influences on accumulation patterns, e.g. over the Gulf stream  
417 region (Fig. S6); larger values of  $ct$  and  $cw$  correspond to an increase in the amount of snowfall in this area. However the  
418 overall low correlation values between  $cw$  and the ice volume of North America shows a relatively weak effect of  
419 accumulation on the simulated ice volume.

420

421 Correlation analysis shows a very weak effect from basal drag parameters ( $beta$  and  $coef$ ) on the ice volume (Fig. 8) and the  
422 southern extent (Fig. S4). The correlation value of  $smb$ , which controls the initial ice volume when the coupled climate-ice  
423 sheet phase of each simulation starts, is also low ( $r=0.22$ ). This suggests only a weak connection between final ice sheet  
424 volume at 5000 years and its initial volume at the beginning of the coupled simulations (Similar results are also obtained for  
425 ice volume changes in the first 500 years, Fig. S3). This is due to the large modifications in snow/ice albedo in our ensemble  
426 design, which is capable of drastically altering the magnitude of absorbed solar radiation over the ice sheet (e.g. Abe-Ouchi  
427 et al. 2013). For other dynamical ice sheet parameters ( $drain$  and  $n$ ), the correlations are generally even lower. Overall, the  
428 North American ice sheet volume is much less sensitive to uncertainty in ice sheet dynamics than ice sheet albedo and  
429 climate in our parameter space.

430

431 Interestingly, we find that the main results showing the importance of albedo parameters can be found in the first 500 ice  
432 sheet years by analysing the relation of ice volume changes and each parameter (106 members, Fig. S3). Similar results are  
433 also obtained by Gregory et al. (2020), who show that the SMB of the first 100 years can be a good predictor of the final  
434 steady state ice sheet mass of modern and future Greenland. These results suggest that significant computational cost could  
435 be saved for at least an initial exploration of model sensitivity to uncertain parameter values (e.g. if designing a multi-wave  
436 ensemble experiment).

437

438 Fig. 8 Relationship between North American ice volume at 5000 ice years in FAMOUS-BISICLES and each perturbed  
 439 parameter. Only those ensemble members that satisfy the GMST constraint are used. Correlation values are displayed above  
 440 each panel. Black dots correspond to the best sixteen members. The uncertainties in the North American ice volume  
 441 constraint are shaded blue.

442

443 To explore our preferred parameter space that produces good climate and ice sheets at the LGM, the distributions of  
 444 parameters satisfying the applied constraints are examined (Fig. 2). Results show that some of the parameter ranges may be  
 445 ruled out due to poor resulting simulation performance, such as values below 400 of *fsnow*, values above 0.006 of *avgr*,  
 446 values below 0.00008 of *ct* and values above 3.0 of *n*. Additionally, from Fig. S7, a combination of low values in both *daice*  
 447 and *fsnow* may be ruled out. Runs that satisfy the constraints tend to have parameters that lead to higher albedo values. For  
 448 other parameters, it is shown that values across any individual parameter range in the ensemble can produce reasonable  
 449 GMSTs and ice sheets, depending on their combination with others.

450

451 The performance of the simulated ice extent in the best sixteen simulations (Fig. 3d) is further evaluated against the ice  
452 extent reconstruction from Dalton et al. (2020, red contour in Fig. 3d). In general, the average of the best sixteen simulations  
453 reproduces the overall ice extent of the North American ice sheet reasonably well; e.g. performances over the northern  
454 margin and the southern margin west of 110°W and east of 80°W are reasonable. Also the performance is much better  
455 compared to means of members that satisfies the GMST and the ice volume constraints but not the southern North American  
456 ice margin criterion (Fig. 3b, c). In contrast, the main differences between the best sixteen simulations and the reconstruction  
457 appear over the southern margin at 110°W - 80°W, where the model underestimates the area of the ice sheet. Another  
458 difference can be found over Alaska, where the model overestimates the ice sheet area and thickness (Fig. 3d). These  
459 features are commonly observed in ice sheet model simulations coupled to a low-resolution atmospheric model and will be  
460 discussed in section 4.1.

461

462 Away from the southern margin, the best performing FAMOUS-BISICLES simulations tend to lack sufficient ice at the  
463 eastern margin, where an ice shelf should exist (Fig. 3d). This is associated with the strong and uniform basal ice shelf  
464 melting applied in this study. The basal melting around the coastal area largely depends on the configuration of the  
465 continental shelf as well as the ambient ocean temperature, as shown by studies on the Antarctic ice sheet (e.g. Obase et al.  
466 2017). Future work could undertake additional sensitivity experiments changing the magnitudes and patterns of the basal  
467 melting to further explore this point.

### 468 3.3 Responses of the Greenland ice sheet

469 The Greenland ice sheet also shows various responses to modifications in the parameters in the ensemble of simulations,  
470 ranging from 8 m SLE to 15 m SLE (Fig. 9). The simulated range is similar to the range in the reconstructions suggesting  
471 9.3 m to 12.3 m SLE (7.3 m + 2~5 m SLE, Clark and Mix 2002, Lecavalier et al. 2014, Bradley et al. 2018, Tabone et al.  
472 2018), while the model overestimates the higher band.

473

474 Interestingly, the results show a different sensitivity to the model parameters we vary compared to the North American ice  
475 sheet (Fig. 9). The variations in the ice volume are mostly explained by changes in *beta*, where higher values increase the  
476 friction between the ice sheet and the bedrock at a cold ice base. This acts to increase the ice volume by reducing the amount  
477 of ice transported to its margin which then calves at the continental shelf, and hence by inducing thickening of the ice sheet  
478 interior.

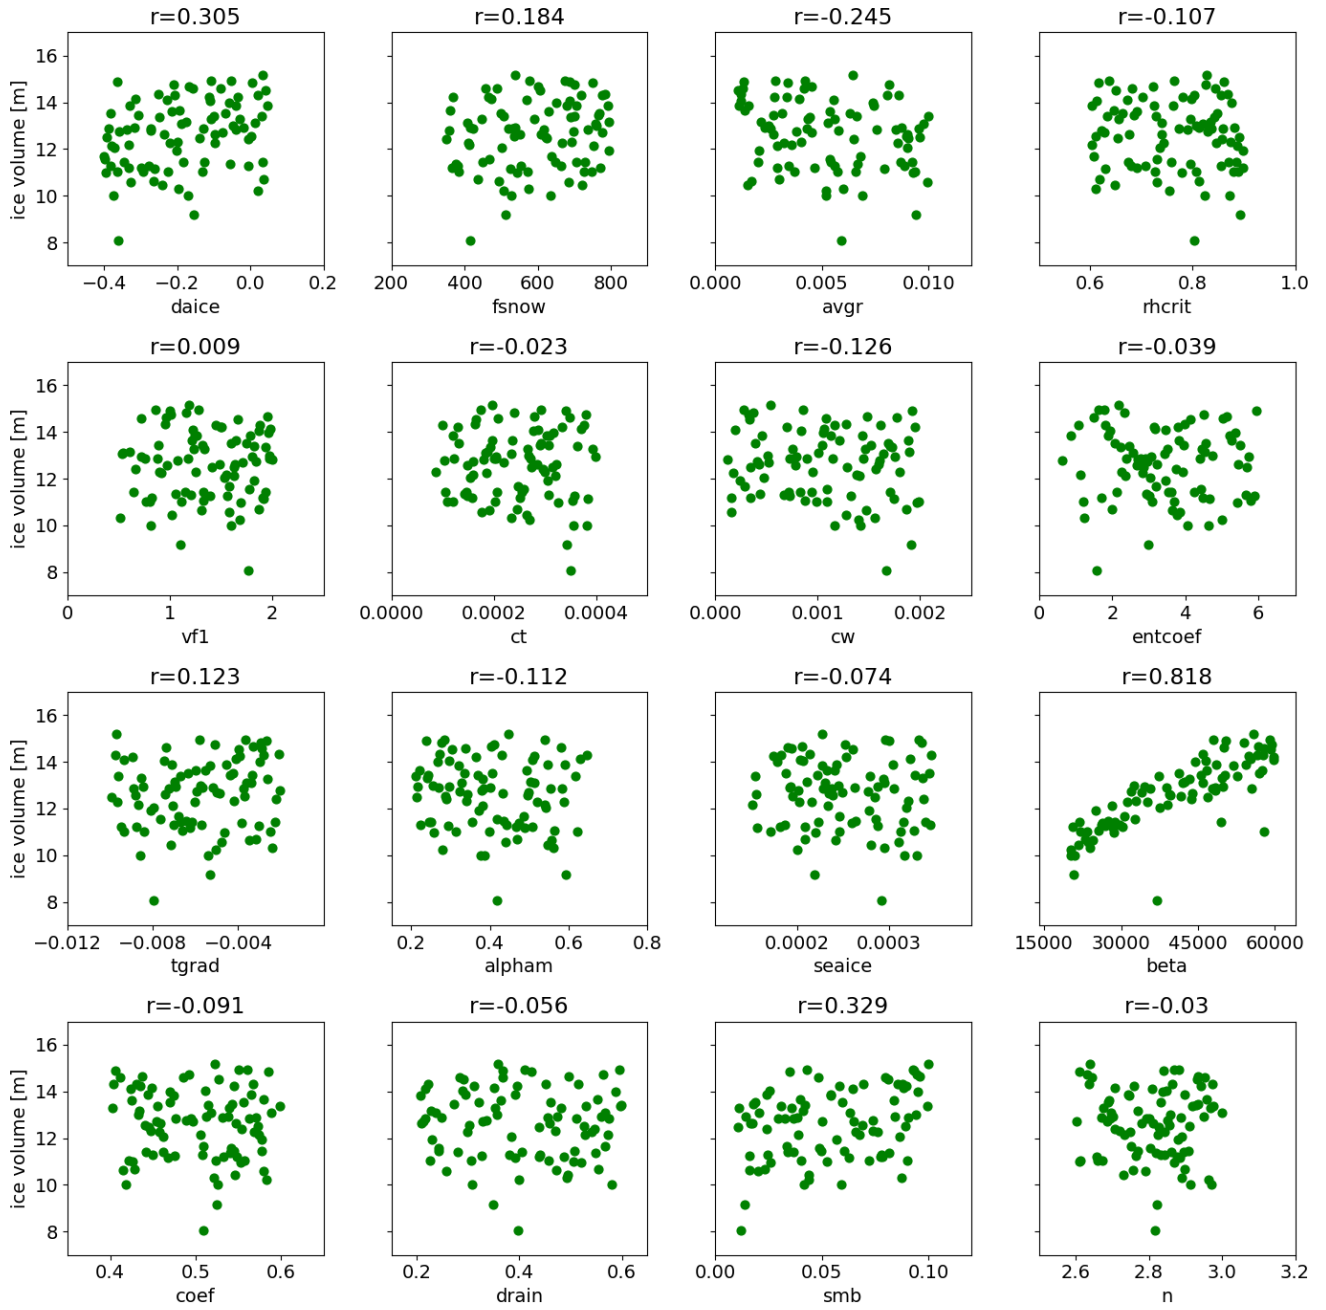

479

480 The lower sensitivity of the Greenland ice sheet to albedo parameters comes from different climatic conditions compared to  
481 North America. In North America, the large area is covered by negative surface mass balance (Fig. 3g) as the summer  
482 temperature can be close to freezing point in the simulations (Fig. 10). Hence, albedo parameters cause a drastic difference  
483 since they control the magnitude of the negative SMB over North America (Fig. 8). In contrast, the Greenland ice sheet is  
484 covered by colder conditions in summer (Fig. 10), hence most surface areas have positive surface mass balance (Fig. 9).  
485 Under this condition, the amount of the ice loss is determined by the amount of ice transported from the interior to its edge,  
486 which then calves. As a result, the ice volume is mainly driven by *beta* since it controls the transport of ice under the cold ice  
487 base.

488

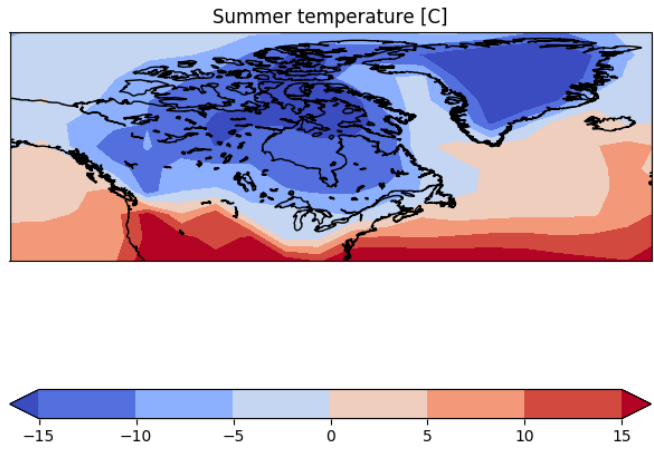

489 Previous studies have shown that basal melting of ice shelves by the underlying ocean is also important in controlling  
490 Greenland ice sheet volume at the LGM in their coupled ice shelf-ice sheet models (Bradley et al. 2018, Tabone et al. 2018).  
491 In this study, however, a constant value was given for the ice shelf basal melting. Conducting ensemble simulations with  
492 variations in the amount of ice shelf melting may enable us to explore the relative importance.

493  
494

495  
496  
497

Fig.9 Relation of ice volume of Greenland at 5000 ice years in FAMOUS-BISICLES and each parameter. Ensemble members satisfying the GMST constraint are used. Correlation values are displayed on the top of each panel.

498

499 Fig.10 Summer surface air temperature [ $^{\circ}\text{C}$ ] over North America and Greenland, averaged over all ensemble members  
500 satisfying the GMST constraint.

501 **3.4 Effects of global mean surface temperature (GMST) on ice sheet volume**

502 The sensitivity of the ice sheets to the reasonable LGM GMST range ( $2.7^{\circ}\text{C}$ - $14.7^{\circ}\text{C}$ ) is explored to see the relationship  
503 between them (Fig. 11). The results show a high correlation between the GMST and North American ice volume/southern  
504 extent; colder climates correspond to larger and more extensive ice sheets (Fig. 11a, b). This is not a surprise since a large  
505 uncertainty of  $\pm 6.0^{\circ}\text{C}$  is applied to the GMST. Reducing the uncertainty level to two sigma ( $8.7^{\circ}\text{C} \pm 4.0^{\circ}\text{C}$ , black dots in  
506 Fig. 11) weakens the correlation between the GMST and the North American ice volume/southern extent to -0.193 and -  
507 0.285, respectively. Nevertheless, the correlation analysis still shows some sensitivity of the southern extent of the North  
508 American ice sheet to GMST (Fig. 11b), where a colder global climate tends to produce a more extensive ice sheet in the  
509 south. In other words, it can also be said that it is hard to get an extensive southern North American ice sheet under warm  
510 LGM GMST (above  $12.0^{\circ}\text{C}$ ), irrespective of the albedo parameters, which demonstrates the value of constraining the upper  
511 band of real LGM temperatures for simulating the North American ice sheet well.

512

513 The Greenland ice sheet appears to be insensitive to the reasonable LGM GMST range ( $2.7^{\circ}\text{C}$ - $14.7^{\circ}\text{C}$ ), which is consistent  
514 with the dominant role of basal sliding in controlling the ice volume. Reducing the uncertainty level to two sigma ( $8.7^{\circ}\text{C} \pm$   
515  $4.0^{\circ}\text{C}$ , black dots in Fig. 11) increases the correlation value to 0.259 possibly associated with an increase in snow fall  
516 following the warming climate, however the effect is much weaker compared to the effect of basal sliding.

517

518 Fig. 11 Relationship between GMST [ $^{\circ}\text{C}$ ] and Ice sheet variables. (a) North American ice sheet volume [m], (b) Ratio of  
519 southern extent of the North American ice sheet compared to Dalton et al. (2020) and (c) Greenland ice sheet volume [m].  
520 Ensemble members that satisfy the GMST constraint and have run 5000 ice sheet years are used (87 members). Correlation

521 values are also shown in each figure. Black dots show results within the two sigma uncertainty in the LGM GMST ( $8.7^{\circ}\text{C} \pm$   
 522  $4.0^{\circ}\text{C}$ ).

523

524 **3.5 Localities in the effect of parameters**

525 The different sensitivities to parameters between the North American and Greenland ice sheets imply that similar variations  
 526 in sensitivity to parameters may exist between different local regions within the huge North American ice sheet. To explore  
 527 this point, we separate the North American ice sheet into seven different sectors (NW, SW, N, M, MS, NE, E) where a  
 528 substantial amount of ice remains in the ensemble mean of members satisfying the GMST constraint (Fig. 12). Results are  
 529 summarized in Table 2. While the albedo parameters remain the most important ones (*daice* and *avgr*) in each region, we  
 530 find that *beta* has an increased influence in SW and M. These areas either exhibit a mountainous bedrock topography or have  
 531 very thick ice, hence can be more affected by the basal sliding parameters. Additionally, we find that *ct* has a relatively  
 532 strong influence on the northern (N) and eastern (E) parts of the North American ice sheet. Our analysis indicates some  
 533 variation in regional sensitivities to climate and ice sheet parameters in different sectors of the ice sheet sectors. Further  
 534 analysis beyond the scope of this study would be required to explore this regional dependency in detail.

535

536 Fig. 12 Six different areas (NW, SW, N, M, NE and E) of the North American ice sheet used for the additional analysis  
 537 (black rectangle). Blue shades show the mean ice thickness [m, colour] of members satisfying the GMST constraint.

538

539 Table 2 Four most influential parameters on ice volumes at different regions. Values in the bracket show the correlation. For  
 540 the Southern Extent, results from Fig. S4 are used.

Region	1	2	3	4
NW	<i>avgr</i> (-0.48)	<i>fsnow</i> (0.47)	<i>daice</i> (0.4)	<i>ct</i> (-0.25)
SW	<i>fsnow</i> (0.42)	<i>daice</i> (0.4)	<i>beta</i> (0.39)	<i>avgr</i> (-0.35)
N	<i>avgr</i> (-0.44)	<i>daice</i> (0.37)	<i>ct</i> (-0.36)	<i>fsnow</i> (0.28)
M	<i>daice</i> (0.53)	<i>avgr</i> (-0.49)	<i>beta</i> (0.29)	<i>ct</i> (-0.25)
MS	<i>avgr</i> (-0.58)	<i>daice</i> (0.47)	<i>fsnow</i> (0.39)	<i>ct</i> (-0.30)

NE	<i>avgr</i> (-0.52)	<i>daice</i> (0.49)	<i>smb</i> (0.30)	<i>fsnow</i> (0.26)
E	<i>avgr</i> (-0.48)	<i>daice</i> (0.43)	<i>fsnow</i> (0.33)	<i>ct</i> (-0.30)
Southern Extent	<i>avgr</i> (-0.52)	<i>daice</i> (0.41)	<i>fsnow</i> (0.36)	<i>ct</i> (-0.33)

541

### 542 3.6 Sensitivity of influential parameters to individual constraints

543 Applying our three simulation constraints simultaneously may be hiding relationships that exist between model parameters  
544 and simulation behaviour. We perform additional analyses to explore how each constraint individually affects the  
545 relationship between our model parameters and North American ice sheet volume. In the case of no-constraints (139  
546 members), the albedo parameters are important, but the influence from *ct* becomes more important (Table 3). This is due to  
547 the increased range of GMST allowed by varying *ct* (Fig. 5). Having a much colder or warmer climate allows the ice sheets  
548 to grow or melt, and the resulting feedback further enhances the role of *ct*. In contrast, most members with extremely warm  
549 climates crashed during the 5000 year simulation. This means that, *entcoef* does not appear to have so large an effect on ice  
550 sheet volume directly, unlike its importance in setting the GMST.

551

552 In the case of applying only the ice sheet volume constraint (73 members), *avgr* and *fsnow* still show relatively high  
553 correlations with ice sheet volume. However their influence is less than when GMST constraint alone is applied (Table 3).  
554 The ice volume constraint alone results in a preferred selection of members exhibiting colder climates (46 members have a  
555 GMST below 4 °C). As a result, the members are less sensitive to albedo related parameters.

556

557 When the southern extent constraint alone is applied, 33 members remain. Similar to above, members satisfying this  
558 condition tend to have very cold climates, where 24 members have GMST colder than 4°C and 14 members colder than  
559 0.63°C. In this case, *avgr* and *beta* appear to be most influential. This may imply that snow albedo and basal conditions play  
560 an important role in maintaining an extensive ice sheet once the climate allows the ice sheet to reach this size. Further  
561 discussion on the maintenance of the southern margin of the North American ice sheet is in subsection 4.1.

562

563 Table 3 Effects of constraints on the relation of parameters and North American ice sheet volume at year 5000. The four  
564 most influential parameters on ice volumes are shown.

Constraint applied	1	2	3	4
No Constraint (139 members)	<i>daice</i> (0.51)	<i>avgr</i> (-0.45)	<i>ct</i> (0.45)	<i>fsnow</i> (0.35)
GMST alone (87 members)	<i>avgr</i> (-0.56)	<i>daice</i> (0.48)	<i>fsnow</i> (0.37)	<i>ct</i> (-0.33)
Min Ice volume alone (73 members)	<i>avgr</i> (-0.39)	<i>fsnow</i> (0.33)	<i>smb</i> (0.33)	<i>daice</i> (0.24)
Southern Extent alone (33 members)	<i>avgr</i> (-0.71)	<i>beta</i> (0.51)	<i>smb</i> (0.44)	<i>fsnow</i> (0.39)

565

566

567

## 568 4. Discussion

#### 569 4.1 How could FAMOUS-BISICLES be made to reproduce the southern extent of the North American ice sheet?

570 A recent study by Gandy et al. (2023) performed a similar ensemble simulation with FAMOUS-Ice, but with fixed SSTs and  
571 with the simpler Glimmer ice sheet model rather than BISICLES. Our findings here are consistent with theirs in that the ice  
572 extent is sensitive to choices of parameters in the snow and ice albedo scheme and that both models underestimate the  
573 southern extent of the North American ice sheet, especially the so-called ‘lobe’ characteristics. To investigate the possibility  
574 of the model being able to reproduce the full extent of the southern margin of the North American ice sheet, we analyse in  
575 detail the ensemble member that has the most extensive southern margin, disregarding our imposed climate plausibility  
576 constraints (Fig. 3e). In this simulation, the performance of the southern extent of the North American ice sheet is closer to  
577 the reconstructed area due to the very cold climate simulated, whose absolute GMST is  $-7.4^{\circ}\text{C}$ . Yet even in this very cold  
578 simulation, the model cannot maintain the ‘lobe’ characteristics of the North American ice extent as far south as the  
579 reconstructions.

580

581 So, how might we reproduce the southern margin of the North American ice sheet in our simulations? There are several  
582 possibilities:

- 583 • Finer horizontal resolution in the climate model: during the simulations, FAMOUS-BISICLES loses the thin ice  
584 sheet at the south margin abruptly in the first 1000 ice sheet years due to the very large negative SMB simulated in  
585 the atmospheric model (e.g. Fig. 13b). Applying a high-resolution atmospheric model might be better able to sustain  
586 a more southerly ice margin through a stronger stationary wave effect that cools the area (Abe-Ouchi et al. 2007).
- 587 • Representation of clouds: Gregory et al. (2012) pointed out the importance of changes in cloud cover over the  
588 southern margin of the North American ice sheet on its SMB during the glacial inception. Having a larger cloud  
589 cover at the southern margin may help to maintain the ice sheet by reducing the very large negative SMB, although  
590 a careful analysis on the physical plausibility of creating this feature would need to be done.
- 591 • Improvements in the downscaling scheme: including the effect of strongly stratified boundary layer on the surface  
592 temperature during the downscaling may allow a colder surface temperature over ice, which can help sustain the ice  
593 sheet at its margin. Incorporation of downscaling of accumulation in FAMOUS-BISICLES can increase the snow  
594 fall at the southern margin, which increases the SMB and surface albedo and may help to sustain the ice sheet at the  
595 southern margin (e.g. Yamagishi and Abe-Ouchi 2005).
- 596 • Higher initial surface elevation: the simulation could be started with a higher initial surface elevation which can be  
597 obtained by giving a thicker ice or a higher bedrock topography at the southern margin, allowing for lower surface  
598 temperatures due to the higher elevation, although this may not be physically plausible.
- 599 • Palaeo-vegetation: the choice of vegetation type for the unglaciated region near to the ice sheet may be relevant.  
600 The modern vegetation distribution used in this study may tend to give a warmer condition in this area, unlike  
601 tundra, which grows under cold climates and causes a surface cooling (O’ishi and Abe-Ouchi 2013).
- 602 • Bedrock conditions: creating a slippery bedrock condition would enhance ice flow from the ice sheet interior  
603 towards the margin, and so may be instrumental in redistributing ice outwards. In this regard, adding a scheme that  
604 allows the generation of proglacial lakes and increases ice flow at the southern margin would help advance the lobe  
605 (Hinck et al. 2022).
- 606 • Longer integration of the model: extending the integration of FAMOUS-BISICLES may help to redistribute the  
607 thick ice in the interior to the southern margin. In fact, some of the members, which have been extended for  
608 additional 5000 years show some southward expansion (Fig. S2).

609 It is also possible that the concept of the southern margin being in a quasi-equilibrium state with the LGM forcing may not  
610 be valid, and that may instead be several transient ice advance events that occurred during the recent glacial period (and

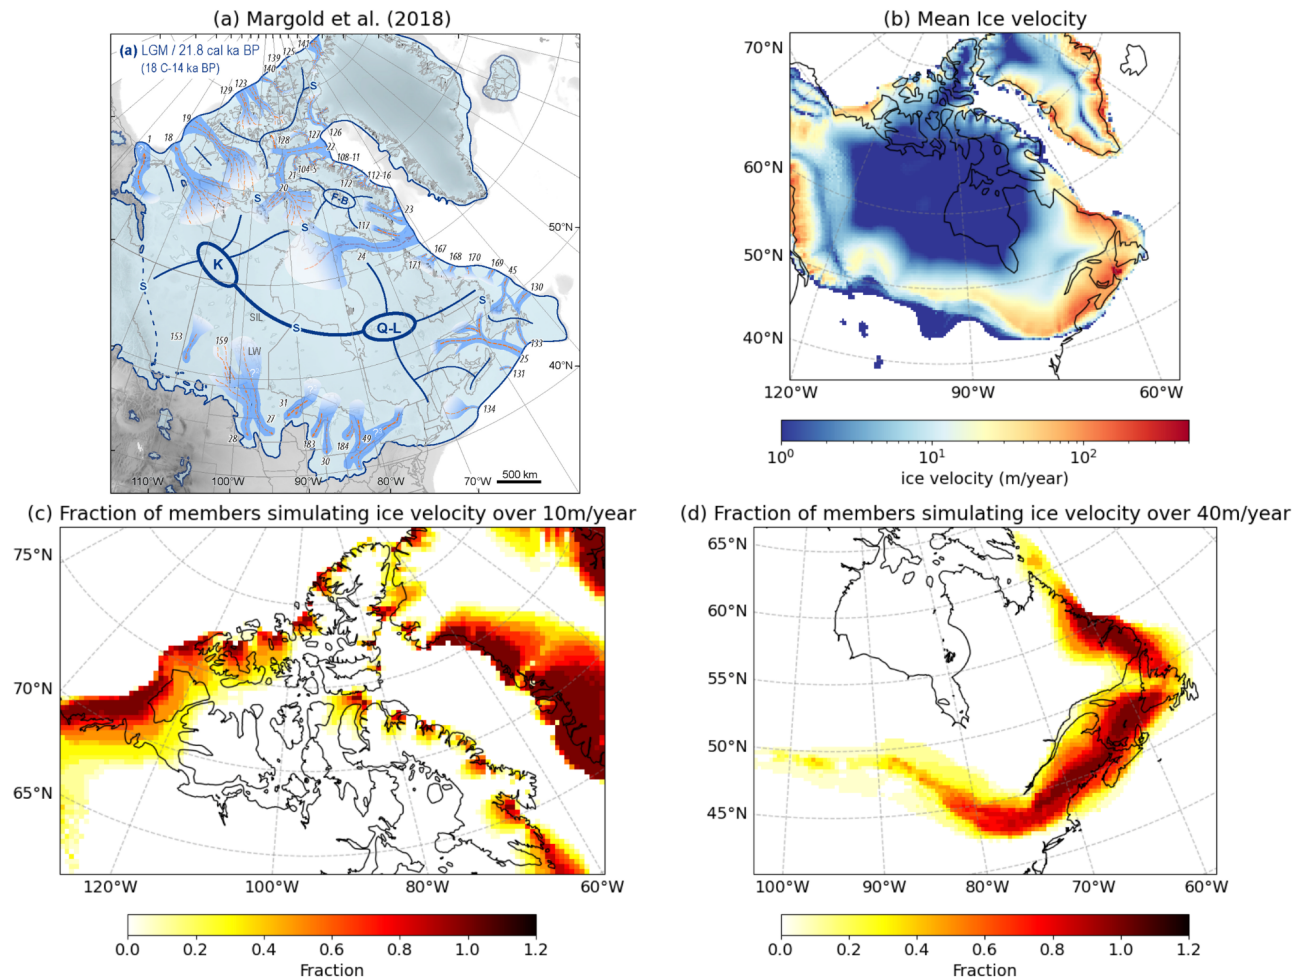

611 preceding the LGM)(e.g. Pico et al. 2017, Gowan et al. 2021, Bradley et al. 2024). We speculate that such earlier southward  
612 ice advance may allow a more expansive southern ice sheet to establish, before rebalancing with the insolation forcing. In  
613 this case, running a long transient simulation, rather than performing equilibrium-type LGM simulations, may be essential  
614 for achieving the target southern margin extent.

#### 615 **4.2 Performances of ice streams**

616 The positions of our simulated ice streams in the best sixteen ensemble members are evaluated against the reconstruction by  
617 Margold et al. (2018) (Fig. 13 and Fig. S5). The figure depicts that BISICLES shows regions of relatively high ice velocities  
618 (or ice streams) at various sites, despite the relatively low resolution of the model (16 km at finest grid) and the relatively  
619 short integration period. Specifically, most members reproduce high ice velocities at the margin over the Baffin Bay area. In  
620 addition, the simulation of ice streams facing the Arctic Ocean is encouraging (Fig. 13, S5). However, once again the  
621 southern margin is tricky to get right, and our ice stream behaviour there is somewhat diffuse, not picking up the  
622 characteristic ‘lobe’ structure of the reconstructions (Margold et al. 2018). Over the Eastern North American ice sheet, the  
623 model captures some large glaciers such as Laurentian Channel (25), Placentia Bay-Halibut Channel (133) and Hopedale  
624 Saddle (168), while none of the best sixteen ensemble members simulate the large ice stream that flows to the Labrador Sea  
625 from the present-day Hudson Bay area. These poorly represented ice stream features may be caused by low resolution of the  
626 smallest ice sheet refinement (16 km, e.g. Gandy et al. 2019), too-short integration and misrepresentation of the surface type  
627 of till (Gowan et al. 2019). With the last point, the amount of till water calculated prognostically in the simulations appears  
628 small, hence most areas use the Weertman sliding law. An increase in the basal melting, a choice of a smaller value for  
629 *drain* or incorporating a spatially variable Weertman coefficient map based on geological evidence may help to improve the  
630 performance of the ice streams. Nevertheless, the model does show some reasonable potential in simulating North American  
631 ice streams considering the relatively low resolution as well as the explicit calculation of basal drag.

632

633

634

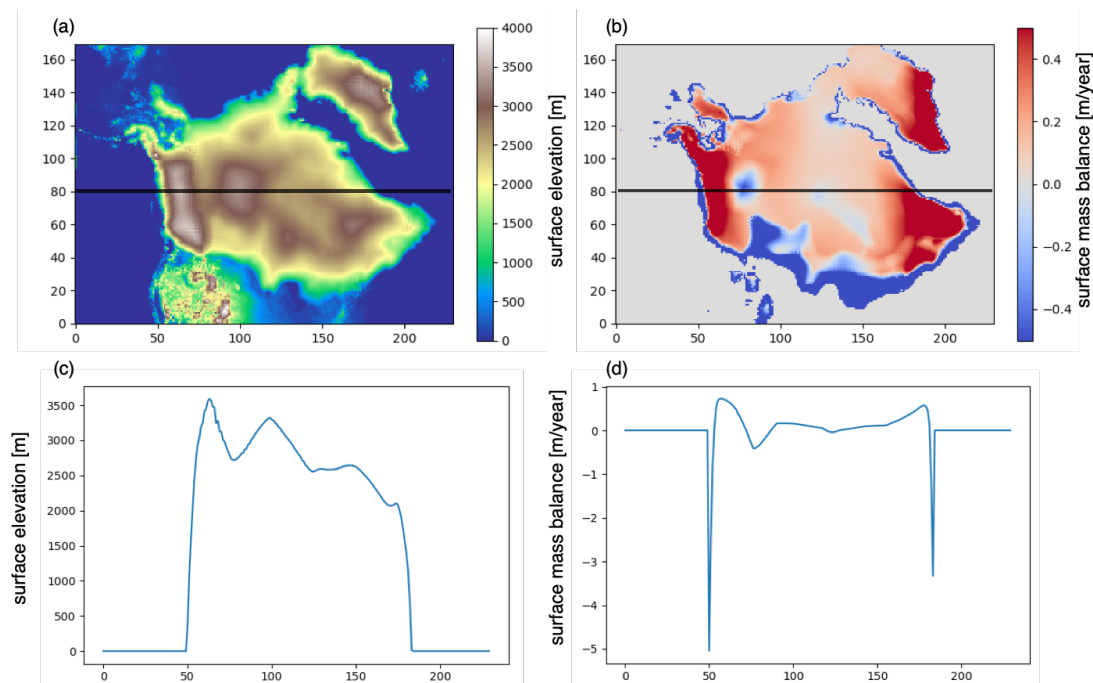

635 Fig.13 Comparison of ice velocity [m/year, colour] between (a) Reconstruction (Margold et al. 2018, adapted from Fig. 5 of  
 636 Margold et al. 2018) and (b) the mean of best sixteen members. (c) and (d) show the fraction of numbers of members  
 637 simulating ice velocity beyond 10m/year for (c) and 40m/year for (d), respectively. Fraction of 1.0 means all the sixteen  
 638 members simulate ice velocities of those values.

### 639 4.3 Effects of biases in the simulated climate

640 Some of the simulations in the ensemble exhibit a local melting of the ice sheet from parts of the interior outwards, which is  
 641 unusual, as ice sheets usually melt from their margins, where the surface temperature is close to the freezing point (e.g. Figs  
 642 3c and 14). This phenomenon is caused by biases in the atmospheric model, which are amplified by the downscaling method  
 643 and a positive feedback from the coupling. In these simulations, the model has a warm summer temperature bias over the ice  
 644 sheet interior. As a result, large parts of the central North American ice sheet have a temperature above  $-10^{\circ}\text{C}$  despite the  
 645 surface elevation exceeding 2000 m (Fig. 10). A similar feature was pointed out by Smith et al. (2021) using the same model  
 646 under the modern Greenland ice sheet, which produced a higher ELA (around 2 km high in places) compared to a high  
 647 resolution regional atmospheric model (at about 1 km high). Second, because the downscaling of SMB strongly depends on  
 648 the elevation, a local change in surface elevation can induce a local negative surface mass balance if the surface temperature  
 649 calculated in the FAMOUS grid points are close to the freezing point. This example is shown in Fig. 14, where a negative  
 650 SMB can be found at the local minima of surface elevation, despite the elevation exceeding 2000 m. The initial negative  
 651 SMB then kicks in a strong positive feedback where melting of snow reduces the albedo and results in more energy  
 652 absorption. As a result, the ice elevation starts to decrease and causes additional positive feedback similar to saddle node  
 653 collapse (Gregoire et al. 2012). The strong dependence of SMB on temperature and altitude implied by this way of

654 downscaling the climate model output works well for modern Greenland, especially at low elevation where the SMB is  
 655 observed to have a very strong elevation dependence. However, at the higher altitudes achieved by the LGM North  
 656 American ice sheet, SMB may be more greatly affected by other factors such as wind speeds, as suggested by studies on  
 657 Antarctica (Van Liefferinge et al. 2021). Hence, further improvements in the downscaling method at higher elevation could  
 658 help to reduce the impact of the climate biases.

659

660

661 Fig.14 An example of local ice melting in the interior of the ice sheet; ensemble member xplji, which has a GMST of 9.9°C  
 662 and North American ice sheet volume of 88.4m SLE. (a) Surface topography [m] and (b) Surface mass balance [m/year].  
 663 Height zonal cross-section of (c) surface topography and (d) surface mass balance at y=80 are shown.

## 664 5. Conclusion

665 In this paper, we have presented a large ensemble of simulations of the North American and Greenland ice sheets and  
 666 climate of the LGM, performed with a coupled atmosphere-ice sheet-slab ocean model FAMOUS-BISICLES, a version of  
 667 the FAMOUS-Ice model developed by Smith et al. (2021). The experiment consists of a 200-member perturbed parameter  
 668 ensemble, where the values of 16 parameters associated with climate and ice dynamics were varied using a Latin-hypercube  
 669 sampling method. The simulated results are evaluated against the LGM GMST, the North American ice volume and the  
 670 southern extent of the North American ice sheet. In the ensemble, the GMST is controlled by a combination of precipitation  
 671 efficiency in the large-scale condensation and entrainment rate in the cumulus convection, consistent with previous  
 672 FAMOUS simulations of modern climate (Joshi et al. 2010). Under reasonable LGM GMST conditions, we find that the  
 673 surface albedo exerts the strongest control on North American ice volume. In contrast, the ice volume of Greenland is found  
 674 to be mainly controlled by the Weertman coefficient in the basal sliding law. The different sensitivity of these ice sheets to  
 675 the model's physical parameter values mainly comes from different climatic conditions; the North American ice sheet being  
 676 generally warmer hence has a larger area of negative SMB, which is affected by the albedo. In contrast, most parts of the  
 677 Greenland ice sheet are covered by a very cold atmosphere, hence the ice sheet volume is more affected by the calving at its  
 678 margin, the total amount of which is controlled by the magnitude of the basal sliding law that affects the amount of ice  
 679 transported to the margins. These differences between the North American and Greenland ice sheets provide an important  
 680 take-home message on model performance, suggesting that for best flexibility (i.e., the ability to simulate conditions very

681 different from today), simulators should be calibrated under a range of climate and ice sheet conditions and tested out-of-  
682 sample.

683

684 Analysis of the relationship between the North American southern ice extent and GMST with the uncertainty level of two  
685 sigmas ( $8.7^{\circ}\text{C} \pm 4.0^{\circ}\text{C}$ ) shows a slightly weak relation. Nevertheless, we find that it is hard to get an extensive southern  
686 North American ice sheet under warm LGM global temperature (above  $12.0^{\circ}\text{C}$ ), irrespective of the albedo parameters in our  
687 model. This demonstrates the value of constraining the upper band of real LGM temperatures for simulating the North  
688 American ice sheet well.

689

690 Based on our plausibility constraints, the model produces sixteen ‘acceptable’ simulations with reasonable GMST and North  
691 American ice sheet. These simulations show the most extensive southern margin under reasonable LGM temperature and ice  
692 volume, but, like LGM ice sheet simulations by other authors, they overestimate ice volume in Alaska, and do not expand far  
693 enough at the southern margin (even after 5000 years, with the absolute global temperature as cold as  $-7.4^{\circ}\text{C}$ ). Both of  
694 these features are likely attributable to the underestimation of the stationary wave effect (Roe and Lindzen 2001, Abe-Ouchi  
695 et al. 2007), which might be improved upon/overcome by increasing the climate model resolution. It is also possible that  
696 more accurate representation of the palaeo vegetation, different treatments of ice sheet sliding and downscaling method of  
697 the SMB, or a different spin-up procedure could improve the simulated southward ice sheet extension.

698

699 Our results show that warm summer temperature biases in the interior of the ice sheet as well as the downscaling method of  
700 SMB based on elevation can cause strong local melting of the ice sheet from the interior outwards. More complex treatment  
701 of the atmospheric conditions and surface mass balance in the ice sheet interior could improve this, and may be especially  
702 important when applying the model to the Antarctic ice sheet.

703

704 Lastly, the strong sensitivities of the North American ice sheet to albedo at the LGM may imply a potential constraint on the  
705 future Greenland ice sheet by constraining the formulation and behaviour of albedo schemes for climate and ice sheet models  
706 under relatively warm climates. Running similar ensemble simulations with a directly comparable version of this model for  
707 the modern and future Greenland ice sheet will provide an important data set to directly connect the simulations of past  
708 climates and ice sheets to those of the modern and future. Using such data, we will be able to explore how simulations of  
709 past climate-ice sheet conditions can more tightly constrain or increase confidence in projections of future sea level rise.

## 710 **Code and data availability**

711 The simulation data of FAMOUS-BISICLES used in this study will be available in a public database.
