Abstract. Atmospheric evaporative demand is a key metric for monitoring agricultural drought. The existing ways of estimating evaporative demand in drought indices do not faithfully represent the constraints of land surface characteristics and become less accurate over non-uniform land surfaces. This study proposes incorporating surface vegetation characteristics, such as vegetation dynamics data, aerodynamic and physiological parameters, into existing potential evapotranspiration (PET) methods. This approach is implemented over the Continental United States (CONUS) for the period of 1981-2017 and is tested in a recently developed drought index the Standardized Precipitation Evapotranspiration Index (SPEI). We show that activating realistic maximum surface and aerodynamic conductance could improve prediction of soil moisture dynamics and drought impacts by 29% on average compared to the widely used simple methods, especially effective in the forests and humid regions. Surface characteristics that have a strong influence on the performance of the SPEI are mainly driven by leaf area index (LAI). Our approach only requires the minimum amount of ancillary data, while permitting both historical reconstruction and real-time forecast of drought. This offers a physically meaningful, yet easy-to-implement way to account for the vegetation control in drought indices.

1 Introduction

35 Drought is one of the most costly hydrological hazards (Wilhite, 2000; Ross & Lott, 2003), with devastating
impacts on croplands and pastures (Kogan, 1995), forests ecosystems (Clark et al., 2016), electricity
production, water quality, and soil fertility (Loon, 2015). Monitoring the changes in water availability is
critical for providing early warnings of drought and for risk management (Wilhite, Sivakumar, & Pulwarty,
2014). Many physical or probabilistic measures have been developed (Heim, 2002) to quantify drought, such
40 as Palmer Drought Severity Index (PDSI, Palmer, 1965), Standardized Precipitation Index (SPI, McKee,
Doesken, Kleist, & others, 1993), Vegetation Condition Index (VCI, Kogan, 1995), and multiple remote
sensing drought indices (Zhang, Jiao, Zhang, Huang, & Tong, 2017).

Atmospheric evaporative demand (AED) is a key input to drought indices because it is a measure of water
demand, namely, how thirsty the atmosphere is (Peng, Li, & Sheffield, 2018). AED typically reflects the
45 effect of temperature and humidity, and is considered a major driver of drought stress on vegetation and tree
mortality (Williams et al., 2012; McDowell et al., 2018). Among the drought indices, the recently developed
Standardized Precipitation Evapotranspiration Index (SPEI) (Vicente-Serrano, Beguería, & López-Moreno,
2010) factors in water demand (AED) in addition to water supply (precipitation). Compared to the SPI that
only considers precipitation, the SPEI is more suitable for quantifying the drought impacts on agriculture
50 (Potop, 2011; Potop, Možný, & Soukup, 2012), and ecosystems (Vicente-Serrano et al., 2012; Vicente-
Serrano et al., 2013; Barbeta, Ogaya, & Peñuelas, 2013). In addition, the SPEI is more flexible than the PDSI
because it is not sensitive to soil water field capacity and can be implemented on various time scales (Vicente-
Serrano, der Schrier, Beguería, Azorin-Molina, & Lopez-Moreno, 2015; Zhao et al., 2017). It has been widely
used for both drought reconstruction and monitoring (Paulo, Rosa, & Pereira, 2012; Beguería, Vicente-
55 Serrano, Reig, & Latorre, 2013).

The way of estimating AED in drought indices has a significant impact on drought quantification (Sheffield,
Wood, & Roderick, 2012; Trenberth et al., 2013; Yang, Roderick, Zhang, McVicar, & Donohue, 2018;
Dewes et al., 2017). AED is approximated by potential evapotranspiration (PET), the maximum rate of
evapotranspiration when surface water supply is unlimited. Previous work has used various PET formulations
60 for AED in the SPEI since it was first proposed in 2010 (Vicente-Serrano, Beguería, & López-Moreno, 2010;
Beguería, Vicente-Serrano, Reig, & Latorre, 2013). These conventional PET methods do not factor in the
effects of surface characteristics. The vegetation control on transpiration is often neglected, and therefore the
maximum surface conductance is overestimated and the PET rate during the onset and retreat of the growing
season is unrealistically high. Furthermore, by assuming an smooth reference surface, some methods do not
65 account for surface roughness, hence downplay aerodynamic conductance and suppress the PET estimate

(Peng et al., 2019). Even though the reference evapotranspiration (ET_0) method (Allen, Pereira, Raes, & Smith, 1998) considers the biophysical limitation of transpiration by assigning a surface resistance under well-watered condition, it does not account for vegetation phenology (Lorenz, Davin, Lawrence, Stöckli, & Seneviratne, 2013) and assumes a fixed reference height and a constant surface resistance for all vegetation
70 types. This approach is not physically meaningful for forests, where canopy height is relatively large and vegetation cover varies significantly.

We hypothesize that adding the surface vegetation characteristics to an existing drought quantification approach will improve the spatial and temporal accuracy of drought prediction. The goals of this study are to explore which surface features are the most useful for enhancing drought prediction, and which vegetation
75 types benefit most from incorporating these features. We propose incorporating realistic vegetation restrictions into existing PET methods, while not increasing much cost and uncertainty caused by additional data sources and complex formulations. Then we use independent soil moisture observations (Dai, Trenberth, & Qian, 2004) from satellite to evaluate the drought depictions by various forms of PET approaches across different temporal scales. The evaluation against observed soil moisture allows the direct diagnosis of the
80 most sensitive surface characteristics and the most effective approach for drought quantification (Vicente-Serrano et al., 2012).

In this study, we focus on the continental U.S. (CONUS) primarily because the drought events hitting this region have raised interest in variability, trends, and future risks of drought (Andreadis & Lettenmaier, 2006; Hobbins et al., 2012; Dewes et al., 2017). Several most severe droughts hit the western U.S. in the recent
85 decade, including the 2012 Great Plains drought (Hoerling et al., 2014) and the 2012-2016 California drought (Dong et al., 2019). The western U.S. has been experiencing the most severe drought period after the 1930s and 1950s (Andreadis, Clark, Wood, Hamlet, & Lettenmaier, 2005), and its vulnerability to drought continued to grow (Andreadis & Lettenmaier, 2006). Besides, high-quality meteorological datasets are available over the CONUS (Daly et al., 2008; Xia et al., 2012) and can help reduce the uncertainty of drought
90 prediction originating from input forcings.

2 Data

2.1 Meteorology

To calculate the SPEI, we use high-quality meteorology data from PRISM (Parameter-elevation Regressions
95 on Independent Slopes Model) that employs weather stations and digital elevation model (Daly, Neilson, &
Phillips, 1994; Daly et al., 2008). We acquire daily precipitation, daily mean, maximum, minimum, and dew
point temperature on a 4 km grid for the period of 1981-2017. Surface downward shortwave and net longwave
radiation, pressure, and wind speed are taken from the NLDAS-2 (North American Land Data Assimilation
System phase 2 (Xia et al., 2012). All data are spatially restricted to the continental United States (25–50°N,
100 67–125°W) and regridded to the 0.125° NLDAS-2 grid using the first-order conservative remapping tool
provided by Climate Data Operators (<https://code.zmaw.de/projects/cdo>).

2.2 Soil moisture

The European Space Agency Climate Change Initiative (ESA CCI) v4.3 surface soil moisture (SMsurf) is
used to evaluate the drought severity quantified by the SPEI time series (<https://www.esa-soilmoisture-cci.org/>). This dataset combines several active and passive microwave soil moisture products into a
105 harmonized surface layer soil moisture (2-5 cm) in $\text{m}^3 \text{m}^{-3}$ (Liu et al., 2012; Gruber et al., 2017; Gruber et
al., 2019). The version 4.3 provides soil moisture on a 0.25° grid at daily time step for the 1979-2017 period
and has been widely used in ET and drought studies (Dorigo et al., 2017; Martens et al., 2017).

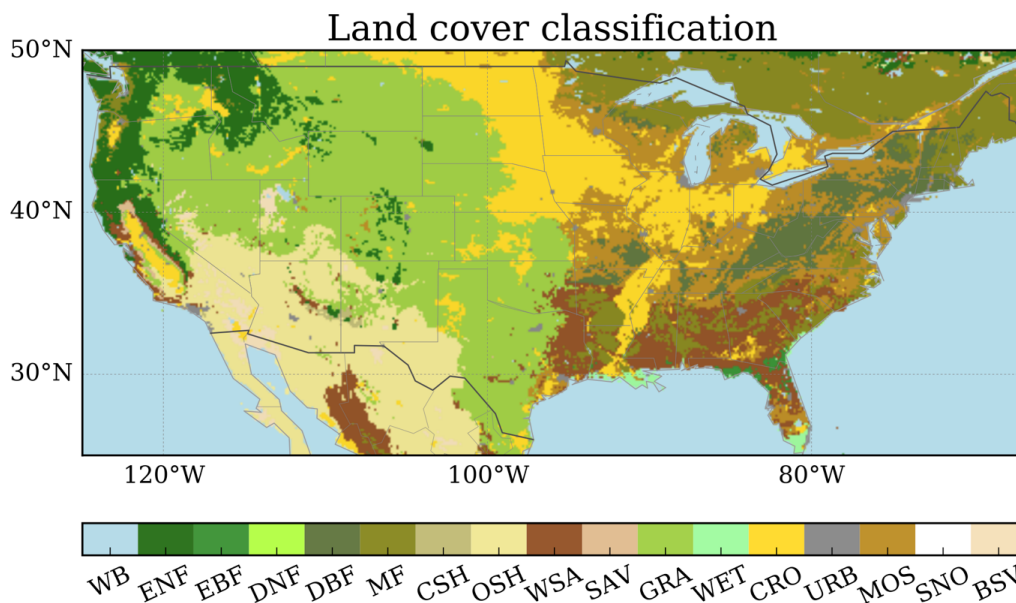

2.3 Land surface ancillary data

110 The land surface data used for deriving biophysical parameters include gridded land cover type, leaf area
index, and surface albedo. The land cover type is provided by the 0.5 km MODIS-based Global Land Cover
Climatology during the 2001-2010 period (Broxton, Zeng, Sulla-Menashe, & Troch, 2014,
https://archive.usgs.gov/archive/sites/landcover.usgs.gov/global_climatology.html). This dataset has 17 land
cover classes based on the International Geosphere - Biosphere Program (IGBP) classification. This land
115 cover climatology dataset is displayed in Fig. 1.

The monthly climatology of leaf area index is obtained from the 15-day, 1 km AVHRR GIMMS LAI3g
product that covers the period of 1982-2016 (Zhu et al., 2013). The monthly climatology of surface albedo
is derived from the 8-day, 0.05° GLASS (Global Land Surface Satellite) albedo product. This
GLASS02A05/06 product combines MODIS and AVHRR (Advanced Very-High-Resolution Radiometer)
120 to provide a gap-filled land surface shortwave black-sky and white-sky albedo (Qu et al., 2014; Liu et al.,

2013) that covers the period of 1982-2012. The canopy height data are obtained from a global tree height dataset at 1-km for 2005 using spaceborne lidar (Simard et al., 2011).

125 **Figure 1. The land cover classification over the Continental United States used for surface vegetation parameter inference. The classification is based on the satellite retrieval of land cover climatology during 2001-2010 (see Table 1 for a list of land cover full names).**

3 PET methods

3.1 Current PET methods

130 The Penman equation (Penman, 1948) is the most comprehensive physically-based method to estimate PET by combining the radiative and aerodynamic components:

$$PET_{Penman} = \frac{\Delta(R_n - G) + \rho_a C_p D G a}{\lambda(\Delta + \gamma)} \quad (1)$$

135 where PET is expressed as water mass fluxes ($\text{kg m}^{-2} \text{s}^{-1}$), R_n is the surface net radiation (W m^{-2}), G is the surface ground heat flux (W m^{-2}), Δ is the slope of the saturation vapor pressure curve at the temperature of interest (Pa K^{-1}), γ is the psychrometric constant (Pa K^{-1}), λ is the latent heat of vaporization (J kg^{-1}), ρ_a is the air density (kg m^{-3}), C_p is the specific heat of air ($\text{J kg}^{-1} \text{K}^{-1}$), D is the vapor pressure deficit (VPD, Pa), and $G a$ is the aerodynamic conductance (m s^{-1}).

The variants of the Penman equation have been widely used to estimate PET in hydrological and land surface modeling (Sellers et al., 1996; Liang et al., 1994; Ek et al., 2003; Peng, Li, & Sheffield, 2018; Peng et al., 2019; Yang et al., 2019). The open-water Penman (OW) equation is a simplified Penman equation to calculate
140 PET over an open water surface, re-parameterized by Shuttleworth (1993):

$$PET_{OW} = \frac{\Delta}{(\Delta + \gamma)} \frac{(R_n - G)}{\lambda} + \frac{\gamma}{\Delta + \gamma} \frac{6.43(1 + 0.536u_2)D}{\lambda} \quad (2)$$

where PET_{OW} is typically in mm d^{-1} ($\text{kg m}^{-2} \text{s}^{-1} = 86400 \text{ mm d}^{-1}$), $(R_n - G)$ is daily available energy ($\text{J m}^{-2} \text{d}^{-1}$), u_2 is the wind speed at 2-m height (m s^{-1}), λ is J kg^{-1} , and D is in kPa. Note that some of the variables have different units from Equation 1.

The Penman-Monteith (PM) equation (Monteith, 1965) is an extended version of the Penman equation to
145 estimate actual ET ($\text{kg m}^{-2} \text{s}^{-1}$), which introduces the surface conductance (G_s , m s^{-1}):

$$PET_{PM} = \frac{\Delta(R_n - G) + \rho_a C_p D G_a}{\lambda(\Delta + \gamma(1 + \frac{G_a}{G_s}))} \quad (3)$$

The reference crop evapotranspiration (PET_{RC}) recommended by the UN Food and Agricultural Organization (FAO) is a specific application of the Penman-Monteith equation (Allen, Pereira, Raes, & Smith, 1998). It is designed for calculating the maximum ET of reference crop under well-watered condition. The general formula is given by Allen et al. (2005):

$$PET_{RC} = \frac{0.408\Delta(R_n - G) + \frac{C_n u_2}{T_a + 273} \gamma D}{\Delta + \gamma(1 + C_d u_2)} \quad (4)$$

150 where PET_{RC} is also in mm d^{-1} , $(R_n - G)$ is daily available energy ($\text{MJ m}^{-2} \text{d}^{-1}$), Δ and γ are in $\text{kPa } ^\circ\text{C}^{-1}$, T_a is the air temperature at 2-m height ($^\circ\text{C}$), D is in kPa, C_n ($\text{K mm s}^3 \text{Mg}^{-1} \text{d}^{-1}$) is a constant describing the effect of aerodynamic conductance (G_a) that increases with canopy height. The denominator $\Delta + \gamma(1 + C_d u_2)$ is a special form of the denominator of the Penman-Monteith equation $\Delta + \gamma(1 + R_s/R_a)$. C_d ($\frac{R_s}{R_a u_2}$, s m^{-1}) is a constant that increases with the ratio of surface resistance ($R_s = 1/G_s$) to aerodynamic resistance ($R_a = 1/G_a$). There are two sets of C_n and C_d , tall crop ($C_n=1600$, $C_d=0.38$) and short crop ($C_n=900$, $C_d=0.34$).
155 The FAO short crop equation is used in the recent version of the SPEI calculation (Beguería, Vicente-Serrano, Reig, & Latorre, 2013).

The Priestley-Taylor (PT) equation is also a simplified form of the Penman equation, which describes evaporation from a well-watered surface based on the equilibrium evaporation under conditions of minimal advection (Priestley & Taylor, 1972):

$$PET_{PT} = 1.26 \frac{\Delta(R_n - G)}{\lambda(\Delta + \gamma)} \quad (5)$$

where PET_{PT} is in mm d^{-1} and $(R_n - G)$ is in $\text{J m}^{-2} \text{d}^{-1}$. The above methods require observations or estimates of surface net radiation, near-surface temperature, wind speed, or specific humidity. Empirically based methods can induce large uncertainty in the drought projection (Sheffield et al., 2012; Feng, Trnka, Hayes, & Zhang, 2017) and are therefore not considered in the study.

3.2 Surface characteristics

Classical PET definitions rely on surface meteorology and do not faithfully represent the vegetation conditions and biophysical constraints and become less accurate over non-uniform land surfaces (Moran et al., 1996). To understand the impact of surface characteristics on the AED estimate and drought quantification, three factors are explored: (i) aerodynamic conductance, (ii) surface conductance, and (iii) surface albedo. This section introduces the major equations and formulas for these factors.

3.2.1 Aerodynamic conductance

Aerodynamic conductance Ga in the OW and PT methods (Equations 2 and 5) are implicitly derived from a smooth surface with low roughness length, which can underestimate the Ga and PET values in the forests (Peng et al., 2019). Open water aerodynamic conductance Ga_{ow} can be obtained by inverting the open water Penman equation (Equation 2) to match the Penman equation (Equation 1), given by Peng et al. (2019):

$$Ga_{ow} = \frac{6.43(1 + 0.536u_2) \cdot P_s}{86.4\epsilon\lambda\rho_a} \quad (6)$$

where u_2 is converted from wind speed at 10-m to 2-m height following the wind profile relationship in Allen, Pereira, Raes, & Smith (1998). P_s is near-surface atmospheric pressure (Pa), ϵ is the ratio of molecular weight of water to dry air (= 0.622).

Short reference crop aerodynamic conductance $Ga_{RC-short}$ and $Ga_{RC-tall}$ is given by

$$Ga_{RC-short} = \frac{u_2}{208} \quad (7)$$

$$Ga_{RC-tall} = \frac{u_2}{110} \quad (8)$$

180 where u_2 is converted from wind speed at 10-m to 2-m height (m s^{-1}).

Instead of the low Ga in OW and the fixed Ga in RC, it is better to use canopy height to generate more realistic surface roughness (Brutsaert & Stricker, 1979; Allen, Pereira, Raes, & Smith, 1998; Shuttleworth, 1993):

$$Ga = \frac{k^2 u_z}{\ln\left(\frac{z_m - d_0}{z_{0m}}\right) \ln\left(\frac{z_h - d_0}{z_{0h}}\right)} \quad (9)$$

185 where z_m is the measurement height (m) for wind speed, z_h is the measurement height (m) for temperature and humidity, u_z is the wind speed at measurement height (m s^{-1}), k is the von Karman constant, d_0 is the zero-plane displacement height (m), z_{0m} and z_{0h} are the roughness lengths for momentum and heat (m). d_0 and z_{0m} can be estimated from canopy height (h) following $d_0 = 2h/3$ and $z_{0m} = h/8$ (Brutsaert, 1982). When estimating z_{0h} , instead of assuming $z_{0h} = 0.1z_{0m}$ as in Allen, Pereira, Raes, & Smith (1998), it is common to introduce a concept of excess resistance (Verma, 1989) and characterize the relationship between z_{0h} and
190 z_{0m} :

$$z_{0h} = \frac{z_{0m}}{\exp(kB^{-1})} \quad (10)$$

The $\ln(z_{0m}/z_{0h})$ term, also known as kB^{-1} , depends on the roughness Reynold's number Re^* or frictional velocity (u^*), LAI (Yang & Friedl, 2003), and land cover type (Rigden, Li, & Salvucci, 2018).

195 Given that NLDAS-2 provides wind speed at a 10 m level, we used a measurement height = 10 m for both wind speed and temperature because the variation in the vertical temperature profile (2-10 m) is negligible compared to that of wind speed. As canopy height and frictional velocity are rarely measured continuously for each grid, we use a simple look-up table approach to provide roughness parameters, z_{0m} , d_0 , kB^{-1} , based on land cover type (Fig. 1), summarized in Table 1. z_{0h} is then estimated based on land cover specific z_{0m} and kB^{-1} (Equation 10). For z_{0m} , we apply the typical values for different land cover types, and estimated d_0 from z_{0m} ($d_0 \approx 16z_{0m}/3$).

200 For kB^{-1} , we adopt estimates from a collection of literature as below. The forests generally have lower kB^{-1} values ($kB^{-1} = 1$ for needleleaf or mixed forest, $kB^{-1} = 0.5$ for broadleaf) than shrublands ($kB^{-1} = 3.75$) and croplands ($kB^{-1} = 1.75$), based on the values of Rigden et al. (2018) for the medium emissivity case ($\epsilon = 0.96$). For grasslands, $kB^{-1} = 2.25$ is computed as the average of short grass ($kB^{-1} = 2.0$) and medium-length grass ($kB^{-1} = 2.5$), based on Brutsaert (1982). For barren or bare soil, we estimate $kB^{-1} = 3$ by taking
205 the average of all observed kB^{-1} in Yang et al. (2008). Nadeau et al. (2009) suggested $kB^{-1} = 6$ for the

urban area. For water body, wetlands, and snow, we adopt the widely-used $kB^{-1} = 2$, as Zilitinkevich et al. (2001) showed that kB^{-1} over the water surface is within the 0~4 range. There are large variations in the observed kB^{-1} for savannas. Troufleau et al. (1997) reported $kB^{-1} = 7.9$ for fallow savanna; Kustas et al. (1989) provided a range of 1 to 11; Stewart et al. (1994) found an average value of $kB^{-1} = 5.8$, similar to the study by Lhomme et al. (1997) that reported $kB^{-1} = 5.9$ for Sahelian vegetation; Verhoef et al. (1997) suggested a high value of $kB^{-1} = 12.4$. We choose $kB^{-1} = 7$ as most of these observed values fall into the range of 6-8.

Table 1. G_a and G_s parameters by IGBP land cover*.

(1995), ^kZhou et al. (2006).

3.2.2 Surface conductance

The maximum surface conductance $G_{s,max}$ can be obtained by scaling the maximum stomatal conductance (Gst_{max}) with the LAI satellite data (Yan et al., 2012):

$$G_{S_{max}} = G_{st_{max}} \cdot LAI \quad (11)$$

The FAO approach only uses a fixed LAI throughout the growing season. However, LAI plays a dominant role in determining the canopy-atmosphere coupling and ET partitioning (Peng et al, 2019; Wei et al., 2017; Forzieri et al., 2020). In this study, we overcome this limiting assumption by introducing the seasonal cycle of LAI. Kelliher, Leuning, Raupach, & Schulze (1995) found that $G_{S_{max}}$ estimates are at most three times of the $G_{st_{max}}$ estimates, therefore we set a maximum limit for $LAI = 4$. For $G_{st_{max}}$, the measured values are ranging from 9 mm/s for natural vegetation to 12 mm/s for crops (Kelliher, Leuning, Raupach, & Schulze, 1995), listed in Table 1.

We also used an alternative formula for $G_{S_{max}}$ from Zhou et al. (2006):

$$G_{S_{max}} = \frac{LAI_e}{R_{st_{min}}} \quad (12)$$

where LAI_e is the effective LAI, which is equal to $LAI/2$ when LAI is greater than 4. $R_{st_{min}}$ is the minimum stomatal resistance, obtained by the land cover types listed in Table 1 from Zhou et al. (2006).

3.2.3 Albedo

Previous approaches use a fixed grass albedo (0.23) regardless of the underlying land cover type (Allen, Pereira, Raes, & Smith, 1998). In this study, we choose the albedo consistent with the land cover type and explore the option of introducing seasonal cycle of albedo from satellite observations.

3.3 Two source model: separating canopy and soil

The above-mentioned equations in 3.1 and 3.2 treat the surface vegetation as a “big leaf” by considering the canopy resistance and soil resistance together as the bulk surface resistance, and therefore require fewer parameters and less computational costs. One challenge of the big-leaf assumption is to infer bulk surface resistance from canopy resistance when the surface is not fully covered by vegetation (Leuning et al., 2008). Therefore, additionally, we compare the big leaf models with the Shuttle-Wallace (SW) two source model (Shuttleworth and Wallace, 1985; Zhou et al., 2006), incorporating vegetation cover and separating ET into the sum of transpiration and soil evaporation:

$$PET_{SW} = C_c PET_{PMc} + C_s PET_{PMs} \quad (13)$$

where PET_{PMc} , PET_{PMs} , C_c , and C_s are given by Equations 12-18 in Shuttleworth and Wallace (1985). We adopt the same parameterizations detailed in Zhou et al. (2006).

4 Drought quantification

Given the substantial divergence in the PET magnitudes among different models (Peng et al., 2019), a direct comparison of the absolute values among methods is not meaningful. However, the performance in representing drought between PET methods should be comparable. We hypothesize that incorporating the parameters or model structures in Section 3 into the existing methods will increase the accuracy of drought quantification. To test the hypotheses, we use the PM algorithm for big leaf methods, so that we can easily control a specific set of parameters that represents a process option.

We integrate the PET methods into the SPEI drought index across 1-, 3-, 6-, and 12-month time scales over the CONUS. The SPEI is based on the climatological water balance (water supply – atmospheric evaporative demand) cumulated over multiple time scales (e.g., 1, 3, 6, 12 months) following a similar procedure as in the SPI computation (Vicente-Serrano, Beguería, & López-Moreno, 2010). The accumulated water balances are fit using the log-logistic distribution and the probability distribution function is normalized to a standardized variable with mean = 0 and standard deviation = 1, termed as 1-, 3-, 6-, 12-month SPEI, respectively. We calculate the monthly SPEI with the SPEI R package (<https://cran.r-project.org/web/packages/SPEI/>) using daily meteorological data. We choose the SPEI driven by zero PET as a control scenario to showcase the net effect of introducing existing PET methods into traditional SPI drought index. We choose the SPEI driven by the Open Water (OW) method as the baseline, because the OW approach is the simplest scenario with minimal surface characteristics.

Soil moisture is a direct measure of drought severity. Therefore, we use the correlation between SPEI and soil moisture observations to quantify the skill of PET methods. We aggregated the daily ESA CCI surface soil moisture (SMsurf, $\text{m}^3 \text{m}^{-3}$) to monthly averages between 1981-2017 over the CONUS. To match the SPEI on multiple time scales, we calculated the moving average of SMsurf for 1, 3, 6, 12-month periods, respectively. Our analysis focuses on the growing season (April-September), because PET is close to zero during the cold season (not shown). Given the monthly SPEI and SMsurf series during the growing season, Pearson correlation coefficient (R) is calculated for each pair of the SPEI and SMsurf monthly series in each grid cell of the CONUS on the time scale of 1, 3, 6, and 12 months. Then we calculate the change of correlation for each method from the control scenario or the baseline. This change can identify whether a PET method causes an improvement in drought quantification relative to the baseline approach.

275

5 Results

5.1 Overall evaluation of the PET parameterizations

We conducted a pilot analysis to identify the relative importance of different surface characteristics. We selected four existing PET methods and seven testing methods (see Table A1 and Fig. A1 in Appendix A). Note that many methods in these experiments (Table A1) are unrealistic due to the inconsistencies of the surface conditions. Our attention is to include as many combinations as possible for a preliminary analysis. We then compare the CONUS averaged R values between the pairs of PET methods that share the same surface characteristics except for one of the features (Fig. 2).

285 **Figure 2. Differences in correlation (ΔR) of pairs of PET methods that share the same surface characteristics except for one of the surface features: surface roughness, canopy conductance, albedo, and overall consistency among the above features.**

Interestingly, activating realistic surface roughness does not necessarily increase, but may even decrease the correlation (ΔR ranging from -0.01 to 0.01 for all time scales). Canopy conductance stands out to be the most important feature for enhancing the skill of drought index ($\Delta R = 0.015$ -0.03), meaning that adding the plant phenology driven by LAI can largely improve the seasonal variations of drought index and hence the correlation with SMSurf. We compare ΔR of four pairs with an inconsistent surface (e.g., a combination of open water G_a and seasonal G_c) subtracting from a consistent surface and find that methods with consistent surface features have higher correlations with SMSurf. Surprisingly, seasonal and constant albedo showed no significant difference on the correlations, possibly because of the little variation of albedo during the growing season. The differences in the spatial pattern between constant and seasonal albedo are almost negligible

(Fig. A1). In subsequent sections, we default to using the seasonal albedo in our PET methods to fully represent the surface characteristics.

300 We further compare different parameterizations for G_a and G_s . Here we establish a control scenario where PET is not considered in the SPEI, equivalent to the traditional SPI. The selected PET methods include three traditional methods: OW, RC-short, and RC-tall, four big leaf models and a two source model. We calculated ΔR between each PET method and the control scenario (set PET to zero). Fig. 3 shows ΔR for all grids, forested grids, and nonforested grids using 1-month SPEI. The big leaf methods are grouped by the
 305 parameterization of G_a and G_s (Fig. 3 left table).

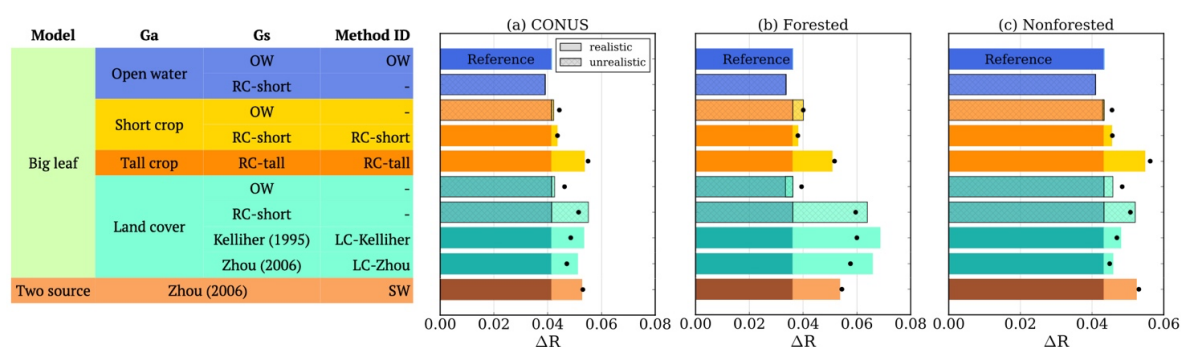

Figure 3. Differences in correlations (ΔR) for selected PET methods versus the control scenario (PET = 0). Correlations were computed between the 1-month SPEI and SMSurf series across: (a) CONUS, (b) forested grids, and (c) nonforested grids. The bars represent the mean ΔR and the black dots represent the median ΔR . The top blue bars show ΔR in the OW approach versus PET = 0 as a reference. For each bar, the darker shade indicates the reference ΔR and the lighter shade represents any improvement (or decline) relative to the reference. Methods with unrealistic surface conditions are highlighted with a hatch pattern, without any specific Method ID.

315 Incorporating the benchmark OW method into the SPEI increases R by 0.042, shown by the top horizontal bars. Among the conventional PET methods, the tall reference crop (RC-tall) method stands out. Over the CONUS, it improved ΔR relative to control scenario by 29% more than the OW method (0.054 versus 0.042). The short reference crop (RC-short) method has an identical averaged R with the OW method. Although the RC-tall algorithm (Allen et al., 2005) is less known than the widely used RC-short algorithm (Allen, Pereira, Raes, & Smith, 1998), our results suggest that the SPEI driven by RC-tall correlates better with the SMSurf
 320 dynamics.

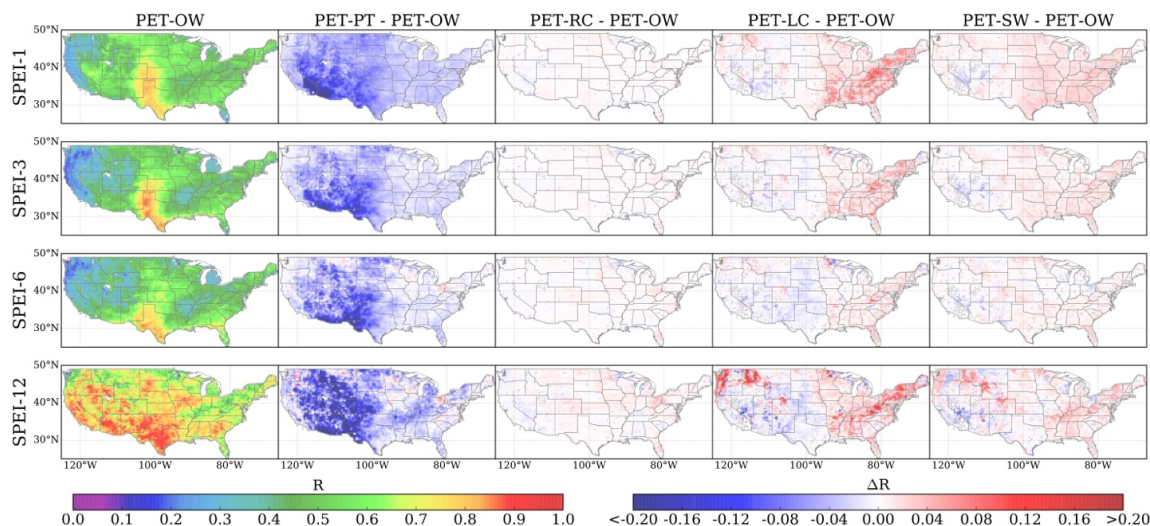

One encouraging outcome is the performance improvement seen in the two big leaf algorithms incorporating realistic surface conductance. Activating both surface roughness and seasonal G_s produces high correlations of SPEI with SMsurf. These algorithms improve the OW method ($\Delta R = 0.042$) by 24-29% (ΔR is 0.052-
325 0.054). Methods where G_a is determined by land cover (the cyan bars in Fig. 3a) especially improve the correlations with SMsurf (Fig. 3a). It confirms our hypothesis that incorporating realistic vegetation information in atmospheric evaporative demand can enhance drought characterization. Finally, the two source Shuttleworth-Wallace (SW) method outperforms the OW method as expected. However, the SW method produces a similar R as the LC-Kelliher method. This suggests that the simple big leaf model in
330 combination with the land cover details can achieve the same efficacy of the more complicated two source model. While we evaluated several unrealistic methods (see hatch patterns) with inconsistent surface assumptions, most did not outperform the OW method. One exception is the pairing of land cover-specific G_a with the RC-short G_a , which yields a high R .

Over the CONUS, RC-tall, LC-Kelliher, and SW are the top three methods with similar average R . However,
335 when we evaluate the performance in the forested areas (Fig. 3b), LC-Kelliher exhibits the most significant enhancement in ΔR to control scenario, with an increase of 89% over OW's improvement (0.068 relative to 0.036). RC-tall and SW improve ΔR to control scenario by 39% (0.05) and 50% (0.054), respectively. In nonforested areas (Fig. 3c), RC-tall has the best performance, followed by SW. The SW method, designed for sparse vegetation, naturally demonstrates strong performance in these regions. However, it is surprising
340 to see that the simple parametrized RC-tall can outperform SW. Conversely, LC-Kelliher only exhibits a moderate improvement in ΔR . This suggests that, particularly in the sparsely vegetated areas, RC-tall can serve as a strong candidate for PET estimates and drought characterization.

5.2 Spatial patterns analysis

In the subsequent sections, we compare the LC-Kelliher (referred to as LC) method with the three widely
345 used methods: OW, PT, RC-short (simply referred to as RC), and the two source SW method. The time series of these PET methods as well as the SMsurf time series are shown in the Fig. B1. The OW approach serves as the baseline. The highest R is observed for long-term drought (12-month, average $R = 0.73$) and the lowest is found in medium-term drought (3- and 6-month, average $R = 0.48$). This suggests that the meteorology-driven SPEI can generally reproduce soil moisture dynamics, especially on an annual time scale.

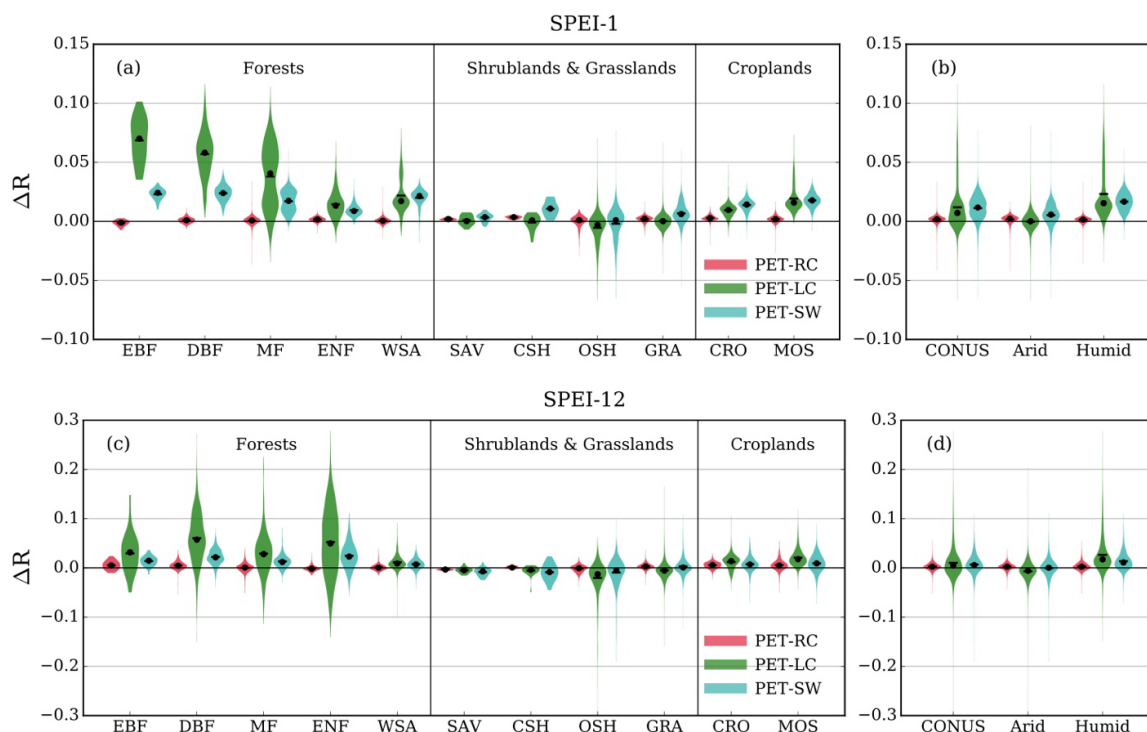

350

Figure 4. The first column displays the correlations between SPEI driven by OW and SMSurf. The four columns on the right show the differences in correlations (ΔR) of PT, RC, LC, and SW relative to OW.

355

Figure 4 displays the spatial distribution of correlations between SPEI driven by OW and SMSurf, along with the differences in correlations of PT, RC-short, LC, and SW compared to OW. PT consistently exhibits lower correlations than OW over most regions, with an average decrease of 0.04, and has especially weak correlations in the southwest U.S. (lower by 0.15). Interestingly, the widely used RC method for SPEI presents little improvement over OW with minimal increases in correlation. LC shows substantial improvements in some areas, with ΔR exceeding 0.16, notably in the eastern and pacific western U.S.. The enhancements of LC are prominent but can be diluted when averaged across CONUS, with ΔR relative to the control scenario 0.012 higher than OW (Fig. 3a). This is especially true when considering LC's less favorable performance in the wouthwest and midwest U.S.. SW also exhibits notable improvements in the eastern and pacific western U.S., with a magnitude of improvement falling between LC and RC. It is encouraging to see that LC outperforms SW in many eastern US grid cells ($\Delta R = 0.15$ versus $\Delta R = 0.05$), given LC's much simpler parameterization. Though it is worth noting that both LC and SW experience performance declines in the Southwest, with LC slightly worse than SW. On the other hand, RC robustly displays improvements in this particular area.

365

370 **Figure 5. Violin plots of differences in correlations of three PET methods relative to OW, grouped by**
vegetation types and aridity.

We further delve into the relative performance of these methods summarized by major vegetation types and by aridity (Fig. 5). LC increases R significantly in forests, especially in evergreen broadleaf, deciduous
 375 broadleaf, and mixed forests, where the largest ΔR exceeds 0.1, and the average ΔR hovers around or above 0.05 for 1-month scale (Fig. 5a). Notable improvements in evergreen needleleaf forest, woody savanna, and croplands compared to the OW are also observed.

For the time scale of 12-month (Fig. 5c), OW has an already high the average R of 0.73 across the CONUS. LC's performance is outstanding in forests, with an average ΔR of about 0.05 and the largest ΔR even
 380 exceeding 0.25. In evergreen needleleaf forests, LC's performance is significantly higher than that of the 1-month time scale. In humid regions, LC's improvements over SW becomes even more apparent compared to the 1-month time scale (Fig. 5d).

In contrast, the average performance of LC in grasslands, shrublands, and savannas (Fig. 5a and c), which are the dominant vegetation types in the western CONUS, are equivalent to OW (except for open shrubland
385 where LC slightly underperforms OW). The magnitude of averaged ΔR of LC is slightly smaller than SW, mainly due to LC's weaker performance in the arid shrublands and grasslands, which cover large portions of the CONUS. Both LC and SW show less advantage or even worse performance than RC and OW in nonforested and arid grid cells (Fig. 5c-d).

390 6 Discussion

6.1 Interaction between surface features

Figure 2 provides important insights into the SPEI sensitivity to different surface features. Introducing G_s with seasonal vegetation dynamics accounts for most of the total improvement of PET algorithm. This confirms that the FAO approaches are more favored than the OW approach due to its constraints on G_s . This highlights the importance of leaf area index (LAI) as a vegetation feature for drought depiction. LAI is a scaling factor to upscale $G_{st_{max}}$ to maximum canopy conductance. This is different from the drought index based on the normalized difference vegetation index (NDVI) or LAI, which requires the real-time dynamics of satellite data. This approach only requires the climatology of LAI, which can be easily implemented for drought forecasting where real-time or near-future data are not available.

400 Using realistic surface roughness does not necessarily improve the overall performance of the SPEI. In fact, the consistency between aerodynamic conductance and surface conductance is more critical for the skill of PET method. Previous study by Peng et al. (2019) explains the linkage between the ratio of actual ET to PET and the ratio of G_a to G_s . When G_a/G_s is large, the ratio of actual ET to PET becomes smaller. Although our study focused on the maximum evapotranspiration given the realistic vegetation condition, such a relationship remains valid. Thus, a large $G_a/G_{st_{max}}$ ratio should better limit PET with realistic surface constraints. In fact, the LC approach activates surface roughness and increases G_a , while constraining $G_{st_{max}}$ and reducing G_s . Altogether these factors increase the G_a/G_s ratio and result in significant improvement in capturing the temporal evolution of SMSurf.

6.2 Surface characteristics matter in the forests

410 Our analysis concludes that incorporating surface features can largely improve the accuracy of drought monitoring in the forests. There are two vegetation groups with significantly improved correlation after incorporating the realistic surface characteristics. Forests over the eastern and pacific western U.S., such as evergreen broadleaf and deciduous broadleaf forests, the LC method exhibits large ΔR compared to OW (up to 0.12 for 1-month and up to 0.25 for 12-month, Fig. 5a, c). While OW has a ΔR at about 0.04 compared to the zero PET control scenario (Fig. 3b), LC has an average ΔR of 0.05 relative to OW in these forests (Fig. 5a). This means the improvement of LC over control scenario is more than doubling of OW. LC also displays a significant increase in R at about 0.025 in woody savanna. The enhancements in the forests or woody savannas are the most predominant since LAI in forests is relatively variable, and surface roughness is also the strongest. Although the southeastern U.S. has a humid subtropic climate, this region also suffered from periodic droughts in 1986–1988, 1998–2002 and 2006–2009 (Seager, Tzanova, & Nakamura, 2009; Pederson

et al., 2012), which is consistent with the increased forest drought severity from 1987-2013 (Peters, Iverson, & Matthews, 2014; Clark et al., 2016). Drought monitoring in these regions is also critical and can benefit from our approach that significantly improve the spatial and temporal accuracy in the forests.

In contrast, the short-grass regions (grasslands, shrublands, and savannas) located in the western U.S. exhibit zero to small improvements for LC. These regions have sparse vegetation cover, and thus LAI plays a less effective role in determining the seasonal dynamics of PET.

6.3 Strategies for PET method selection

We recommend the use of the LC parameterization for drought monitoring in the forests, in which the roughness and surface conductance parameters vary with realistic vegetation conditions. LC is superior than OW or RC-short because of better performance, and compared to SW, it is both better performing and a simpler approach in the forested areas.

For shrublands and grasslands, we recommend the use of RC-tall to replace the more widely used RC-short for drought monitoring. We found that the RC-tall approach has a higher skill than the RC-short approach that is more widely used. The main difference between these two methods is the C_n constant that describes the effect of aerodynamic conductance (Allen et al, 2005). The implementation of tall reference ($C_n = 1600$) seems to work better than the short reference ($C_n = 900$) over the CONUS. It is worth noting, however, that the FAO approaches assume a universal C_n regardless of actual vegetation type. The better skill of RC-tall will not always hold, which may overestimate PET in semi-arid non-vegetated regions.

For sparse vegetation, since the responses of the components of evapotranspiration to the environmental drivers are different (Katul, Oren, Manzoni, Higgins, & Parlange, 2012; Or & Lehmann, 2019), the partitioning between canopy and soil can also play a role in determining AED. The SW model significantly improves the SPEI skill driven by the OW approach. It outperforms LC in the shrublands and grasslands. Despite its complexity, it is a good choice for drought monitoring in these vegetation types.

For croplands, we recommend choosing between RC-tall versus RC-short based on the actual crop canopy height. The more realistic approach is to use RC-tall for higher crops. Lastly, the PT method has the poorest correlation with soil moisture and is unlikely to capture drought dynamics.

6.4 Bridging gaps in drought prediction

Motivated by the question of whether incorporating surface characteristics can improve drought prediction, we overcome several limitations of previous drought quantification methods. Firstly, our study presents a different approach whereby we focus on the maximum possible evapotranspiration for a given vegetation

condition. This concept allows a physically meaningful definition of evaporative demand for the non-uniform land surfaces.

Secondly, the ultimate goal of PET calculation is to simulate ET and to quantify drought. Despite the simplicity of calculating PET using the existing Penman-type methods, the biggest challenge for assessing these methods is validation. Since the real evaporative demand rate is unattainable from observations, it is challenging to validate which PET method is superior directly. Even using ET observations for PET validation can be problematic because biased PET estimates and wrong surface biophysical parameters can still produce accurate ET estimates for locations with ET measurements (Peng et al., 2019). Our study evaluates the PET methods by comparing drought index with independently observed soil moisture (Vicente-Serrano et al., 2012). This approach helps diagnose the most appropriate PET approach for drought quantification directly while avoiding the complexity and divergence caused by various PET definitions.

Finally, our approach bridges the gap between the two methodologies for quantifying soil-moisture drought, which is of most relevance to agriculture (Seneviratne, 2012). Since soil moisture observations are limited by inadequate measurement networks, drought indices such as the SPEI are often used to quantify drought. In hydrology, a drought index is a simple water balance model driven by surface meteorology without the use of any surface characteristics. Its shortcomings are the neglect of seasonally varying vegetation cover and the incapability to capture the vegetation control on transpiration. An alternative is to use land surface models to estimate large-scale soil moisture (Sheffield, & Wood, 2007). This approach often builds in vegetation dynamics and can provide temporally consistent soil moisture simulations, but it also requires substantial efforts to prepare meteorological forcings at high temporal resolution, set up the domain, spin up, and calibrate. Our approach is a compromise between the above two types of models, which is more realistic and process-based than the commonly used drought index while being easy-to-implement and less data-intensive than a land surface model.

475

7 Conclusions

To understand whether incorporating surface characteristics can improve drought prediction, we revise current PET methods in a newly developed drought index (SPEI), using the concept of maximum ET for any given vegetation condition. We use a simple look-up table approach combining in situ measurements and large-scale data fusion products for the key surface and aerodynamic parameters,. This study also presents a novel application of independent soil moisture observations to diagnose the most appropriate PET approach for drought quantification. Our approach is proved to be more effective than widely used big leaf methods and two source model in accurately predicting soil moisture spatiotemporal dynamics in the forests and humid regions. LAI has a particularly important influence on the skill of the SPEI. This new yet simple approach strikes a balance between a meteorology-driven water balance model and a complex land surface model for drought prediction. It could improve the accuracy of the drought reconstruction in forests and displays great potential to improve real-time drought forecast.

Appendix A. Initial examination of PET methods and parameterizations

490 We conduct a preliminary analysis to identify the importance of surface characteristics. Each of the above
 processes are regarded as different options: (i) using active surface roughness or open water surface, (ii)
 495 seasonally varying or fixed surface conductance, and (iii) seasonally varying or fixed surface albedo.

Table A1 provides the PET methods and the parameters in the preliminary analysis. The first set of methods
 (a-d) are the existing physically-based PET approaches: the open-water Penman equation (OW), the FAO
 495 reference crop evapotranspiration for tall crop and short crop, and the Priestley-Taylor equation (PT).

Table A1. Summary of the PET methods with their ID, name and abbreviation code, and details about surface characteristics.

		G_a		G_{Smax}			Albedo (α)	
ID	Method (Code)	Open Water	Rough surface	Infinite	Constant	Seasonal	Constant	Seasonal
a	Open Water (OW)	X		X			X	
b	FAO Tall reference crop (RC-tall)		X		X		X	
c	FAO Short reference crop (RC-short)		X		X		X	
d	Priestley-Taylor (PT)						X	
e	Open Water G_a / Infinite G_c / Seasonal α (GAow GSinf ALBs)	X		X				X
f	Open Water G_a / Seasonal G_c / Constant α (GAow GSs ALBc)	X				X	X	
g	Open Water G_a / Seasonal G_c / Seasonal α (GAow GSs ALBs)	X				X		X
h	Rough G_a / Seasonal G_s / Seasonal α (GAR GSs ALBs)		X			X		X
i	Rough G_a / Infinite G_c / Constant α (GAR GSinf ALBc)		X	X			X	
j	Rough G_a / Infinite G_c / Seasonal α (GAR GSinf ALBs)		X	X				X
k	Rough G_a / Seasonal G_c / Constant α (GAR GSs ALBc)		X			X	X	

We examine seven algorithms (e-k) to isolate the effects of surface characteristics on PET. First, in methods
500 (e), (f), (g), the aerodynamic conductance module is not active as we set Ga to the open water Ga_{ow} ,
indicating a smooth surface with low roughness (Equation 6). In methods (h), (i), (j), (k), we activate
aerodynamic conductance using realistic surface roughness (Equation 9). Second, in methods (e), (i), (j), the
surface conductance parameter is unconstrained as we set Gst_{max} to infinity. In methods (f), (g), (h), (k), we
activate surface conductance using seasonal LAI dynamics and Gst_{max} from Kelliher et al. (1995). Lastly,
505 in methods (f), (i), (k), the albedo parameter is not active as we set α to a constant (grass: 0.23, water: 0.08).
In methods (e), (g), (h), (j), we activate albedo parameter using seasonal albedo dynamics.

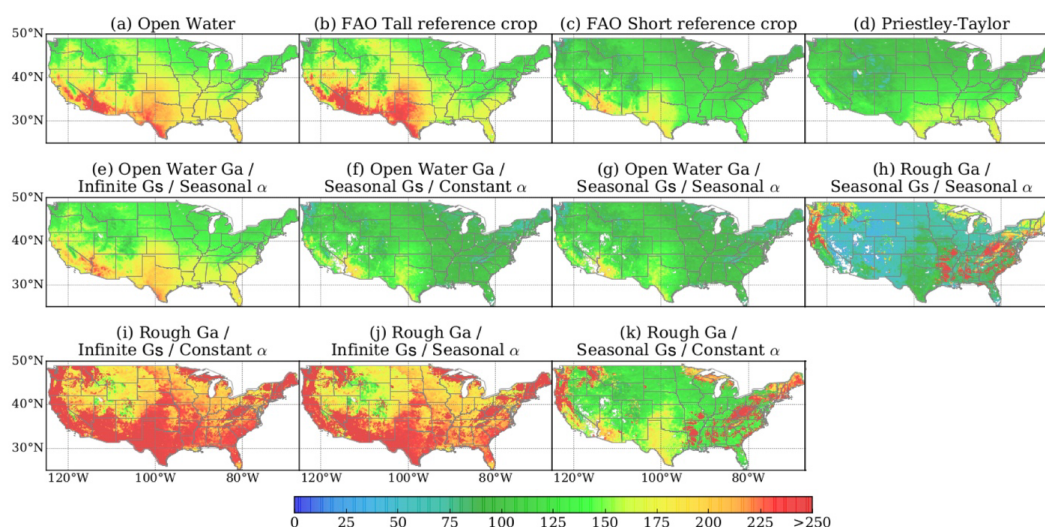

Figure A1. Growing season averages of AED derived from four PET methods and seven testing algorithms over the CONUS. Details and ID for each method are listed in Table A1.

510

Figure A1 displays the spatial patterns of growing season averages of these methods. For the classical Penman/Penman-Monteith methods (Fig. A1a-c), the highest mean growing season AED values are found in southern California, Arizona, and Texas, while the PT method (Fig. A1d) predicts the largest AED values in Texas and Florida. The spatial patterns of PET based on the rough surface (Fig. A1h-l, Rough Ga) are very different from those methods that assume a universal reference height (Fig. A1b-c, reference crop) or open water surface (Fig. A1a, e-g). Specifically, the regions which exhibit large PET estimates (> 250 mm/mon, Fig. A1h-k) are forests, such as ENF in the Pacific Northwest, DBF in the Northeast, and MF in the southeastern U.S.. Interestingly, although the methods using constant albedo ($\alpha=0.08$) have generally larger
515

AED values than those using seasonal albedo, the differences in the spatial pattern between the two are almost negligible (Fig. A1a vs. A1e, Fig. A1i vs. A1j, Fig. A1k vs. A1h).

The combination of the rough aerodynamic and unconstrained surface conductance, represented by (i) $G_{Ar_GSinf_ALBc}$ and (j) $G_{Ar_GSinf_ALBs}$, produces extremely high monthly PET values with means at 330 to 340 mm/mon. The remaining methods also predict a wide range of mean monthly totals. On average, the big-leaf method $G_{Ar_GSs_ALBs}$ (Fig. A1h) provides the smallest PET estimates.

Assessing the change between pairs of the above methods can identify whether adding/removing a surface feature eventually causes an improvement in drought quantification (Fig. 2). The first feature surface roughness is determined by the way G_a is estimated. We compare the parameter set between rough and the open water surface by calculating the differences (Rough - Open Water) for the following pairs of experiments: (i) $G_{Ar_GSinf_ALBc}$ - (a) OW, (j) $G_{Ar_GSinf_ALBs}$ - (e) $G_{Aow_GSinf_ALBs}$, and (k) $G_{Ar_GSs_ALBc}$ - (f) $G_{Aow_GSs_ALBc}$. In terms of the canopy conductance, we calculate the differences between seasonal and infinite $G_{s_{max}}$ (Seasonal - Infinite) for the following pairs of experiments: (f) $G_{Aow_GSs_ALBc}$ - (a) OW, (g) $G_{Aow_GSs_ALBs}$ - (e) $G_{Aow_GSinf_ALBs}$, and (k) $G_{Ar_GSs_ALBc}$ - (i) $G_{Ar_GSinf_ALBc}$.
