15 **Abstract.** Bromine is a reactive trace element in the atmosphere, that destroys ozone, oxidizes mercury, modifies oxidative capacity and affects the lifetime of climate-active gases (e.g., methane). About 75% of tropospheric ozone and methane is destroyed in the tropics, primarily in the lower free troposphere, where bromine monoxide (BrO) radical measurements are generally scarce. The few available aircraft observations find BrO is variable, and measurements in different compartments of the atmosphere are not easily reconciled. While zenith-sky DOAS measurements provide long-term records of the stratospheric

20 O₃ and NO₂ abundances, autonomous MAX-DOAS placed at remote mountaintop observatories (MT-DOAS) provides cost effective and maximally sensitive access to probe the lower free troposphere, a climate-relevant yet understudied region of the atmosphere.

Here we describe and evaluate an innovative full-atmosphere BrO and formaldehyde (HCHO) profile retrieval algorithm using MT-DOAS measurements at Mauna Loa Observatory (19.536°N; 155.577°W; 3401m asl) during two case study days,

25 characterized by the absence (26 Apr 2017, base case) and presence of a Rossby Wave breaking double tropopause (29 Apr 2017, RW-DT case) above Big Island, Hawaii. The full atmosphere retrieval is based on time-dependent optimal estimation, and simultaneously inverts 190+ individual BrO (and formaldehyde, HCHO) SCDs (slant column densities, $SCD = dSCD + SCD_{Ref}$) from solar stray light spectra measured in the zenith and off-axis geometries at high and low solar zenith angle ($92^\circ > SZA > 30^\circ$) to derive BrO concentration profiles with 7.5 degrees of freedom (DoF) from 1.9 to 35 km altitude. Stratospheric

30 BrO vertical columns are near identical on both days ($VCD = (1.5 \pm 0.2) \times 10^{13}$ molec cm⁻²), and the stratospheric BrO profile peaks at a lower altitude during the Rossby wave breaking event (1.6 – 2.0 DoFs). Tropospheric BrO VCDs increase from $(0.70 \pm 0.14) \times 10^{13}$ molec cm⁻² (base case) to $(1.00 \pm 0.14) \times 10^{13}$ molec cm⁻² (RW-DT), owing to a tropospheric BrO profile re-distribution characterized by a three-fold increase in BrO located in the upper troposphere (1.7 – 1.9 DoF). BrO is found to be more variable in the lower free troposphere ($0.2 \text{ pptv} < \text{BrO} < 0.9 \text{ pptv}$) and characterized in three altitude layers (near,

35 above, below) MLO with added time resolution (~3.8 DoF). The BrO mixing ratio at MLO increases from $(0.23 \pm 0.03) \text{ pptv}$

(base case) to (0.46 ± 0.03) pptv BrO (RW-DT); while the maximum of (0.9 ± 0.1) pptv BrO is observed above MLO in the lower free troposphere in absence of the double tropopause.

We validate the retrieval using aircraft BrO profiles and in-situ HCHO measurements aboard the NSF/NCAR GV aircraft above MLO (11 Jan 2014) that establish BrO peaks around 2.4 pptv above 13 km in the UTLS during a similar RW-DT event
40 $(0.83 \times 10^{13} \text{ molec cm}^{-2}$ tropospheric BrO VCD above 2 km). The tropospheric BrO profile measured from MT-DOAS (RW-DT case) and the aircraft agree well (after averaging kernel smoothing). Furthermore, these tropospheric BrO profiles over the Central Pacific are found to closely resemble those over the Eastern Pacific Ocean (2-14 km); and contrast with the Western Pacific Ocean, where a C-shaped tropospheric BrO profile shape had been observed.

1 Introduction

45 Bromine has been of particular interest to atmospheric chemists since its role in the stratospheric ozone (O_3) hole prompted the Copenhagen Amendment to the Montreal Protocol. Gas-phase atmospheric bromine can be divided into organic species and inorganic species (Br_y). Br_y can be further divided into active bromine ($\text{BrO}_x \equiv \text{Br} + \text{BrO}$), reservoir species (HBr, HOBr, BrNO_2 , and BrONO_2), and photolabile compounds (Br_2 and BrCl). Atomic bromine (Br) and bromine monoxide (BrO) radicals rapidly interconvert, primarily by reaction with O_3 and photolysis. The atmospheric budget of BrO_x – and to a large extent Br_y
50 – is principally constrained by measurements of bromine monoxide (BrO) utilizing Differential Optical Absorption Spectroscopy (DOAS).

BrO_x impacts chemistry in the troposphere and stratosphere, by modifying (O_3) but also in other ways. First, the most direct impact on O_3 is direct catalytic photochemical destruction (von Glasow et al., 2004; Read et al., 2008; Saiz-Lopez and von Glasow, 2012; Simpson et al., 2015; Schmidt et al., 2016; Wang et al., 2015; Wofsy et al., 1975). Second, BrO_x modifies NO_x
55 ($\equiv \text{NO} + \text{NO}_2$) (Evans et al., 2003; Custard et al., 2015; Lary, 2005), increasing the ratio of NO_2/NO (Bloss et al., 2010), and as an overall sink of NO_x is suppressing O_3 production (Schmidt et al., 2016). Third, BrO_x adds radical species to oxidative capacity and exerts a number of competing effects on HO_x ($\equiv \text{OH} + \text{HO}_2$) (Stone et al., 2018). Fourth, bromine atoms are understood to be the primary oxidant of mercury in the atmosphere (Holmes et al., 2006; Coburn et al., 2016; Goodsite et al., 2004; Shah et al., 2021) and an important loss mechanism for dimethyl sulfide (Boucher et al., 2003). Fifth, the net-effect of
60 BrO_x impacts on O_3 , NO_x , and HO_x leads to an increase of the lifetime of CO, hydrocarbons, and climate-active gases such as methane (Lelieveld et al., 1998; Parrella et al., 2012; Saiz-Lopez and von Glasow, 2012; Sherwen et al., 2016; Wang et al., 2021).

Remote sensing of BrO by DOAS from the ground has previously been conducted near the poles (Kreher et al., 1997; Sinnhuber et al., 2002; Schofield et al., 2006; Hendrick et al., 2007), at mid-latitudes (Aliwell et al., 1997, 2002; Sinnhuber et al., 2002; Schofield et al., 2004), in the subtropics (Leser et al., 2003; Coburn et al., 2011, 2016), and in the tropics (Theys et al., 2007). There is also an extensive record of DOAS measurements of BrO from space (Chance, 1998; Wagner et al., 2001; Richter et al., 2002; Hendrick et al., 2009; Theys et al., 2011; Seo et al., 2019). DOAS measurements of BrO in free troposphere

and lower stratosphere from balloons (Fitzenberger et al., 2000; Pundt et al., 2002; Dorf et al., 2006, 2008) and from aircraft (Volkamer et al., 2015; Wang et al., 2015; Werner et al., 2017; Koenig et al., 2017) find that BrO is widespread in the free troposphere but highly variable. The sensitivity of ground-based and space-based measurements to BrO in the free troposphere was apparent even prior to the first profile studies (Harder et al., 1998; Frieß et al., 1999; Van Roozendaal et al., 2002). However, the quantification and location of BrO in the free troposphere from the ground and space requires accurate knowledge of the air mass factors (AMF), which the variability in tropospheric profiles continues to confound.

This work systematically explores the significant information content of MT-DOAS to profile tropospheric and stratospheric trace gases, which has potential to help overcome this limitation. Figure 1 illustrates the measurement concept: 1) ZS-DOAS measurements under twilight conditions exploit the sun motion to profile the stratosphere, while 2) Multi-AXis (MAX)-DOAS measurements during the day profile the troposphere. Section 2 introduces the hardware and software methods used; including the DOAS instrumentation (sect. 2.1), DOAS fit settings (sect. 2.2), radiative transfer models used to account for repartitioning of bromine during twilight (sect. 2.3); data taken from global models (sect. 2.4), and introduces the time-dependent Optimal Estimation approach (accounts for non-photochemical diurnal variability, sect. 2.5). Section 3 introduces the case studies (sect. 3.1) and discusses the results; including sensitivity studies in DOAS fitting that exploit recent advances in the knowledge of absorption cross-section spectra (sect. 3.2), the full atmosphere profile retrievals (sect. 3.3), and evaluation of the profiles using aircraft measurements (sect. 3.4); finally, the results are placed in context with previous aircraft campaigns (sect. 3.5). Section 4 presents conclusions and gives an outlook on opportunities for future work.

2 Instrumentation and Methods

Data reported herein were principally collected by a University of Colorado (CU) mountaintop (MT)-DOAS instrument at Mauna Loa Observatory (MLO) described in 2.1.1. References to the MT-DOAS hereafter refer to this instrument unless otherwise specified. Also included are data collected by the CU Airborne MAX-DOAS (AMAX-DOAS) described in 2.1.2 collected during the CONvective TRansport of Active Species in the Tropics (CONTRAST) field campaign.

90

2.1 DOAS Instrumentation

The MT-DOAS and AMAX-DOAS are broadly similar; solar scattered light enters a telescope and is transported by fiber optic cables to two diffraction spectrographs, which image and save spectra for analysis. The instruments are described below.

2.1.1 MLO MT-DOAS

The CU MT-DOAS at MLO (19.536°N 155.577°W 3401m a.s.l.) is a modified version of that previously deployed at Pensacola, Florida (Coburn et al., 2011). It is also a near-copy of an instrument which participated in the Cabauw Intercomparison of Nitrogen Dioxide Measuring Instruments-2 (CINDI-2) campaign (Kreher et al., 2020) matching apart from some precise points of the form factor and spectroscopy alignment. The system was deployed to MLO in February 2017 and

has operated near-continuously since then. The system will be described briefly with modifications since the Pensacola
100 deployment and particulars of the setup at MLO highlighted with further details in the supplement.

The telescope gathers light from a symmetric cone of $0.3^{\circ 2}$. The anodized aluminum telescope has been ruggedized for the
environment on MLO. The $\frac{1}{4}$ " baseplate has been replaced with 1" of cast aluminum to mitigate possible warping from
extended mechanical stress from mounting during long term deployments and to provide additional mass as a defense against
winds. In addition, a heating element was placed inside the telescope head to provide heating when the temperature dropped
105 below 0°C as indicated by a sensor also in the housing.

The primary viewing direction of the telescope is estimated to be along $-50\pm 2^{\circ}$. The telescope head rotates in a plane of
elevation angles (EA) defined relative to horizontal (positive up, negative down). The telescope has a free line of sight for EA
> -4.5° in the primary direction, below which major radiative effects from the reflective roof of the Chin Building are always
apparent, and EA $>7^{\circ}$ in the reverse direction (heading $130\pm 2^{\circ}$), below which the line of sight intercepts the ridge of Mauna
110 Loa.

The instrument includes two spectrometers: an Acton SP2356i spectrometer with a PIXIS 400B CCD detector equipped with
UV fluorescence coating (AP) covering 307.6 - 474.8 nm and an Ocean Optics QE65000 spectrometer (QE) covering 414.3 -
1119.7 nm. Atomic emission spectra from Hg and Kr are used to determine the spectral resolutions of 0.593 nm per full-width
at half-maximum (FWHM) and 1.45 nm for the AP and QE respectively. Spectra collected on the AP can be analyzed for
115 BrO, HCHO, NO₂ (360 nm and 450 nm), O₂-O₂ (360 nm; hereafter O₄), glyoxal (CHOCHO), and iodine oxide (IO) radicals.
Spectra on the QE can be analyzed for NO₂ (450 nm and 560 nm), O₄ (477 nm), CHOCHO, and H₂O. In this work only BrO,
HCHO, NO₂, and O₄ are presented.

All spectra from the MT-DOAS used in the analysis are collected with one minute total integration time. The spectrometers
are operated synchronously. For $75^{\circ} < \text{SZA} < 110^{\circ}$ spectra were collected in a ZS geometry. For $\text{SZA} > 92.5^{\circ}$ insufficient
120 photons are collected for meaningful analysis on the AP and the data are excluded. For $\text{SZA} < 75^{\circ}$ spectra were collected in the
following standard sequence of angles where angles preceded by † are collected in the reverse direction: -4.5° , -3° , -2° , -1° , 0°
(four repeats), 1° , 2° , 3° , 5° , 8° , 12° , 20° , 30° (four repeats), 45° , 90° (four repeats), † 45° , † 30° (four repeats), † 20° , † 12° , † 8° .
Spectra in both directions were analyzed, however, representation of the radiative transfer in both viewing directions consistent
with measurements and with each other could not be accomplished and are not reported here.

125 For fixed reference analyses, spectra for both days were analyzed against a four-minute zenith acquisition collected shortly
before local noon on April 26 (Apr 26 21:18 UTC, EA = 90° , SZA = 15.92°), which is later in the morning than the data
presented here. Moving reference analyses, fixed reference analyses are adjusted by the fitted zenith spectra linearly
interpolated in time.

2.1.2 AMAX-DOAS

130 The CU AMAX-DOAS instrument has been deployed during field campaigns in urban air (Oetjen et al., 2013; Baidar et al., 2013), and over remote oceans (Dix et al., 2013; Volkamer et al., 2015), and is described in detail in these papers. The configuration employed during the CONTRAST field campaign is described in (Koenig et al., 2017).

Briefly, the CU AMAX-DOAS consists of a wing-mounted pylon containing a motion-stabilized telescope, and two spectrographs housed in the interior of the aircraft. One Acton SP2150/PIXIS400B CCD unit (AP1) covers the spectral range
135 from 330-470 nm with 0.7 nm full width half maximum (FWHM) optical resolution based on the 404.66 nm Hg line. The other (AP2) measures 440-700 nm at 1.2 nm FWHM resolution based on the 450.24 Kr line. Spectra collected on AP1 are used for the measurement of BrO, glyoxal, HCHO, H₂O, IO, NO₂ (360 nm and 450 nm), and O₄ (360 nm); spectra on AP2 are used for the measurement of NO₂ (560 nm) and O₄ (477 nm). In this work only BrO and O₄ (360 nm) results will be presented, using EA 0° spectra collected with 30 s integration times.

140 The data presented here were collected towards the end of research flight #1 (RF01; January 11, 2014) of the CONTRAST field campaign, when the aircraft conducted a deep vertical profile in the vicinity of MLO. For RF01 spectra were analyzed against a two-minute zenith acquisition collected during the period presented (Jan 12 00:47 UTC, 155.81°W, 20.12°N, 3.02 km a.s.l., EA = 90°, SZA = 53.28 °).

145 2.2 DOAS fitting

Trace gases were fit using the DOAS method (Platt and Stutz, 2008) using the QDOAS software package (Danckaert et al., 2012). Fit settings for the MT-DOAS are summarized in Table S1 and for the AMAX-DOAS in Table S2. The wavelength calibration for each spectrum is precisely determined by measuring the atomic emissions lines as described in Section 2.1. This slit function was further refined by fitting two wavelength dependent degrees of freedom, using the Kurucz spectrum as
150 reference (Chance and Kurucz, 2010; Kurucz et al., 1984). The slit function was fixed for final calibration of the instrument wavelength mapping. High resolution laboratory cross-sections (species and references given in Table S1) are convolved with the instrument function for analysis. Broadband extinction including Mie and Rayleigh scattering is accounted for by a polynomial. Trace gases with broad band absorption components such as O₃ and NO₂ are orthogonalized to this polynomial. A linear intensity offset is included to account for instrumental stray light and imperfect knowledge of the Grainger-Ring effect
155 (Grainger and Ring, 1962). Absorption by relevant species is fitted simultaneously using the non-linear Marquardt-Levenberg algorithm with full non-linear treatment reserved for shift, stretch, and intensity offset (Danckaert et al., 2012). This is done in finite wavelength windows targeting specific trace gases. The determination of optimized fit settings is a major product of this work, therefore relevant sensitivity studies and final fit settings are discussed in greater length Sect. 3.2 and 3.3 and presented in Fig. 3.

160 **2.3 Radiative Transfer**

Two radiative transfer codes were used for this study. For ZS-DOAS measurements, the principal program employed was Discrete Ordinate Method Radiative Transfer (DISORT). For off-axis measurements the principal program employed was the Monte Carlo Atmospheric Radiative Transfer Inversion Model (McArtim). Weighting functions used for the retrieval were calculated from both models using the same vertical grid, consisting of the following layers (given as altitude a.s.l.): 0 - 0.9
165 km, 0.5 km layers between 0.9 km to 3.4 km (instrument altitude), 0.5 km layers from 3.4 km to 7.4 km, 2 km layers from 7.4 to 53.4 km. Layers below the instrument (necessary for downward-looking angles) were not represented in DISORT, while longitudinal modeling of atmospheric change along the solar light path (necessary for high SZA) was not modeled in McArtim. For $SZA < 80^\circ$ and altitudes above ~ 7.4 km the results from both models agreed within 1.06% RMS difference.

2.3.1 DISORT

170 The principal forward model for stratospheric and ZS-DOAS measurements was the UVspec/DISORT package (Mayer and Kylling, 2005) which utilizes the discrete ordinate method in a pseudo-spherical geometry approximation. The application of the model to twilight measurements by ZS-DOAS is described in detail in Hendrick et al. (2004) and it has been utilized since for BrO (Hendrick et al., 2007; Theys et al., 2007, 2011).

The model was run in multiple scattering mode including Rayleigh and Mie scattering and molecular absorption. Pressure and
175 temperature profiles were based on those from the CAM-Chem model (see Sect. 2.4). Stratospheric aerosol were modeled to represent background conditions and tropospheric aerosol were derived from inversions reproducing the observed O_4 , in the course of which albedo was also optimized (see Supplement for details). UVspec/DISORT was run with the instrument at the surface, placed at 3.4 km altitude, with only the layers above this altitude treated in the model.

Rapid photochemical changes at twilight cause concentrations, particularly of BrO and NO_2 , to change along the light path
180 impacting radiative transfer (Sinnhuber et al., 2002). This is represented in UVspec/DISORT by introducing a second dimension with the different profiles along the light path populated using the stacked box photochemical model PSCBOX (Errera and Fonteyn, 2001; Hendrick et al., 2004). PSCBOX was run with 20 altitude levels between ~ 10 and ~ 55 km (altitudes below 10 km were assumed to have the same chemical partitioning as the lowest level) with chemical species from the SLIMCAT 3-D chemical transport model (Chipperfield, 2006; Hendrick et al., 2007). The model has been updated to reflect
185 the latest bromine chemistry taken from the JPL 2015 compilation (Burkholder et al., 2015).

2.3.2 McArtim

The principal forward model for MAX-DOAS measurements and aircraft measurements was McArtim (Deutschmann et al., 2011) in a 1D spherical atmosphere. The model includes Rayleigh and Mie scattering and molecular absorption. Pressure and temperature profiles were based on those from the CAM-Chem model (see Sect. 2.4). Tropospheric aerosol were assumed to
190 be marine for both MT-DOAS and AMAX-DOAS simulations: non-absorbing with aerosol phase function approximated by

the Henyey-Greenstein approximation with asymmetry parameter $g = 0.72$ above the boundary layer and $g = 0.77$ in the boundary layer. The surface was set at sea level with an albedo of 0.05 at 360 nm and 0.08 at 477 nm. For MT-DOAS, sensitivity studies were conducted for the surface altitude and albedo (see Supplement for details).

Aerosol extinction was based on reproducing O_4 signals measured by DOAS at 360 nm (Spinei et al., 2015; Volkamer et al., 2015) and utilized a layering approach. The aerosol extinction used for AMAX-DOAS retrievals is based on that used in (Baidar et al., 2013). In brief, aircraft limb measurements are collected on a 200 m grid with aerosol added to or removed from layers until the average difference between simulated and measured O_4 signals is within a specified tolerance. This procedure is repeated for each grid layer from the top of the profile down then iterated with decreasing tolerance. Clouds which are present are introduced based on camera imagery from the GV, assumed to have a constant optical density distribution the magnitude of which is adjusted manually to reproduce signals measured above and below the cloud. Pressure, temperature, humidity and major absorber (O_3 and NO_2) profiles were based on aircraft measurements below the aircraft ceiling altitude and based on CAM-Chem above this altitude.

For MT-DOAS retrievals, the atmosphere was initialized with a 200 m grid from the surface to 7.4 km altitude. Pressure, temperature, humidity and major absorber (O_3 and NO_2) profiles were based on those from the CAM-Chem model (see Sect. 2.4). The a priori aerosol profile used consisted of constant aerosol extinction below 2 km then exponentially decreasing with altitude with a scale height of 2 km. The difference between measured and modelled O_4 signals was computed for individual EA with the aerosol extinction in specific altitude ranges adjusted for each EA. This procedure was conducted independently for each scan. The retrieved extinction profile was used for all measurements in that scan. For morning twilight measurements, the aerosol profile from the first scan was used.

2.4 CAM-Chem

The 3-D chemistry climate model Community Atmospheric Model with Chemistry (CAM-Chem) is described in Lamarque et al. (2012). In the present configuration, meteorological analysis (from GEOS-5) specific to the observational periods are used to constrain the meteorological fields (horizontal wind components and temperature) in CAM-Chem. The horizontal resolution is $0.9^\circ \times 1.25^\circ$ and vertical resolution of 52 levels includes full coverage of the troposphere and stratosphere, with a full representation of tropospheric and stratospheric chemistry.

For bromine chemistry, the version used here includes geographically-distributed and time-dependent oceanic emissions of six bromocarbons ($CHBr_3$, CH_2Br_2 , CH_2BrCl , $CHBrCl_2$, $CHBr_2Cl$, CH_2IBr) as well as an additional source of inorganic bromine and chlorine in the lower troposphere due to sea-salt aerosol (SSA) dehalogenation (Ordóñez et al., 2012; Saiz-Lopez et al., 2012; Fernandez et al., 2014). It considers heterogeneous processes for halogen species on a variety of surfaces including uptake and recycling of HBr, HOBr, and $BrONO_2$ on ice-crystals and sulfate aerosols.

CAM-Chem fields for pressure, temperature, water vapor, O_3 , and NO_2 were used to constrain the atmosphere for MT-DOAS radiative transfer simulations, and above flight altitude for AMAX-DOAS radiative transfer simulations. For MT-DOAS measurements data was interpolated from the surrounding points horizontally then averaged from the 30-minute output over

the period of the included scans (the NO₂ field was still adjusted in spatiotemporally based on PSCBOX see Sect. 2.3.1). For
225 AMAX-DOAS, data was averaged from extracted curtains for the individual profiles. CAM-Chem profiles extracted for the
purposes of comparison with measurements were extracted the same way.

2.5 Retrieval Methods

The BrO profiles reported herein were retrieved using optimal estimation (Rodgers, 2000). In brief, the MT-DOAS
measurement vector, \mathbf{y} , consists of SCDs (= dSCD + SCD_{Ref}, Sect. 2.2 and 2.5.1.), where each measurement is a function of
230 the absorber profile \mathbf{x} and weighing functions \mathbf{K} (determined by RTM, Sect. 2.3) such that $\mathbf{y} = \mathbf{K} \mathbf{x}$. The solution to the inverse
problem consists in finding the maximum likelihood estimator of the profile $\hat{\mathbf{x}}$, given an a priori profile \mathbf{x}_a , the measurements
 \mathbf{y} , and their respective covariance matrices \mathbf{S}_a and \mathbf{S}_e . Because BrO is an optically thin absorber i.e. \mathbf{K} is independent of \mathbf{x} , and
for this linear case the solution is given by:

$$1) \quad \hat{\mathbf{x}} = \mathbf{x}_a + \mathbf{S}_a \mathbf{K}^T (\mathbf{K} \mathbf{S}_a \mathbf{K}^T + \mathbf{S}_e)^{-1} (\mathbf{y} - \mathbf{K} \mathbf{x}_a)$$

235 The MT-DOAS retrieval was developed for this work and includes a number of steps described in more detail below. The
AMAX-DOAS optimal estimation inversion was more straightforward. HCHO and BrO dSCDs were used with the DOAS fit
errors employed for the uncertainties. The three individual aircraft profiles (two descents and one ascent; Sect. 3.4) were
inverted separately.

2.5.1 Photochemical Langley Plot

240 For the MT-DOAS inversion, SCDs were used as the elements of \mathbf{y} , which required the determination of SCD_{Ref}. The primary
method of doing so was through use of a Langley plot of dSCDs against air mass factors (AMF). However, given that the BrO
profile changes rapidly during twilight both as a function of SZA and along the light path, a traditional Langley plot analysis
is not possible. We employ a method adapted from Hendrick et al. (2007) which normalizes the AMF to a single reference
SZA (70°) correcting for photochemical effects. Specifically we define $\text{AMF}_{70^\circ\text{SZA}}(\text{SZA}) = \text{SCD}_{\text{modeled}}(\text{SZA}) / \text{VCD}(70^\circ)$,
245 where $\text{SCD}_{\text{modeled}}(\text{SZA})$ is computed using DISORT and PSCBOX as described above in Sect. 2.3.1. This allows for an adapted
Langley equation to be defined, namely:

$$2) \quad \text{dSCD}(\text{SZA}) = \text{VCD}(70^\circ) \text{AMF}_{70^\circ\text{SZA}}(\text{SZA}) - \text{SCD}_{\text{Ref}}$$

Where the intercept of a fitted line determines SCD_{Ref}, and the slope determines VCD(70°). Significant deviations from
linearity would indicate that the time evolution of the BrO profile is not that assumed in the determination of SCD_{modeled}(SZA),
250 and thereby in AMF_{70°SZA}(SZA). The value for SCD_{Ref} determined by the Langley plot is compared and assessed using the
final retrieval results (see Sect. 3.3 for details).

2.5.2 Integrated Optimal Estimation

The integrated MT-DOAS retrieval required using weighting functions from DISORT and McArtim in tandem. As noted
above, to accomplish this DISORT was used for weighting functions for SZA > 70° (with McArtim used to extend these below

255 3.4 km) and McArtim was used for the weighting functions for $SZA < 70^\circ$. Both sets of weighting functions were adjusted to account for the photochemical change in a manner similar to that for AMFs described in Sect. 2.5.1. \mathbf{K} is elementwise multiplied by $(\mathbf{x}_{\text{mod}SZA}/\mathbf{x}_{\text{mod}70^\circ SZA})$, where $\mathbf{x}_{\text{mod}SZA}$ is the BrO profile at some SZA and $\mathbf{x}_{\text{mod}70^\circ SZA}$ is the profile at $SZA=70^\circ$. Note, because profile shape changes as a function of SZA this adjustment varies with altitude unlike that described for AMF. For each day, all measurements were considered simultaneously under the assumption of constant Br_y , i.e. that the changes in
260 the BrO profile are captured by the photochemical model and reflect only chemical repartitioning.
The MT-DOAS results reported herein used an a priori BrO profile composed of 0.5 pptv below 17.4 km, and set to 50% of the stratospheric climatology (Theys et al., 2011) above 17.4 km. For the measurement covariance \mathbf{S}_ϵ the uncertainties were assumed to be uncorrelated and equivalent to the DOAS fit errors. The a priori covariance \mathbf{S}_a , was computed as 100% of the a priori below 15.4 km and 50% above this altitude, with Gaussian correlation heights (Cl mer et al., 2010) of 1 km and 4 km
265 below and above 15.4 km altitude, respectively.

2.5.3 Time-Dependent Retrieval

The assumption of constant Br_y , with the only changes in BrO predicted by the photochemical model was ultimately found to be invalid for one day where dynamical changes in Br_y were observed, in addition to chemical repartitioning (see Sect. 3.3 and 3.4 for details). We addressed this by augmenting the optimal estimation with time-dependent variables. To our knowledge
270 such an approach has not been employed for DOAS optimal estimation before, so we describe it here in detail.
We define the time evolution of the BrO profile \mathbf{x} such that:

$$3) \quad \mathbf{x} = \mathbf{x}_0 \left(1 + f(t) \sum_L \mathbf{W}^L \mathbf{C}^L \right)$$

Where L are groups of atmospheric grid layers where Br_y is expected to evolve differently from other layers.
 $f(t) : t \rightarrow (-1, 1]$ is a time evolution function such that $f(t_0) = 0$. For convenience we choose t_0 to match $SZA = 70^\circ$ so that
275 photochemical and dynamical effects have a common zero. In principle, $f(t)$ could be indexed to the layers L and folded into the sum, but in this instance there was insufficient external information to constrain further choices. In practice, specific time evolution functions were chosen, but the choice of the codomain $(-1, 1]$ is important for reasons outlined below.
 $\mathbf{W}^L \rightarrow (0, 1]$ are altitude weights defining the atmospheric layers L constructed such that $\sum_L \mathbf{W}^L \leq 1$ for all altitudes. Final results reported herein fulfill the stricter condition that $\sum_L \mathbf{W}^L = 1$ for all altitudes.
280 Finally, \mathbf{C}^L are scaling factors describing the proportional change in the BrO profile within layer L , e.g. if an element of \mathbf{C}^L has a value of 1.1, BrO increased by 10% in that layer when $f(t) = 1$. We seek to retrieve \mathbf{C}^L in addition to \mathbf{x}_0 given a choice of $f(t)$ and \mathbf{W}^L .

First we define a time-augmented Jacobian H :

$$H(\mathbf{x}) = \mathbf{K}_0 \mathbf{x} = \mathbf{K}_0 \mathbf{x}_0 \left(1 + f(t) \sum_L \mathbf{C}^L \mathbf{W}^L \right)$$

285 4)

Taking the relevant partial derivatives:

$$5a) \quad \frac{\partial H}{\partial \mathbf{x}_0} = \mathbf{K}_0 \left(1 + f(t) \sum_L \mathbf{C}^L \mathbf{W}^L \right)$$

$$5b) \quad \frac{\partial H}{\partial \mathbf{C}^L} = \mathbf{K}_0 \mathbf{x}_0 f(t) \mathbf{W}^L$$

A close observer may notice a potential challenge posed by these equations; the weighting functions for \mathbf{x}_0 require knowledge of \mathbf{C}^L while the weighing functions for \mathbf{C}^L require knowledge of \mathbf{x}_0 . The extended definition for \mathbf{x}_0 still contains a term which is fully independent of \mathbf{C}^L and approaches the time-independent formulation as $t \rightarrow t_0$. We therefore seek to leverage the time-independent retrieval (already photochemically indexed to t_0) to gain imperfect knowledge of \mathbf{x}_0 . This retrieval already averages over the time dependence and should get us close to the true state. Furthermore, we can assess the effectiveness of this on the resolution set by the definitions of \mathbf{W}^L after the fact.

295 It remains to choose $f(t)$ and \mathbf{W}^L . Examination of Eq. 5a reveals the rationale for setting the codomain of $f(t)$ to $(-1, 1]$, for solutions in which the entire retrieved column entirely disappears or doubles (considered reasonable bounding cases) this bounds the time dependent term to $(-dim(\mathbf{W}^L), dim(\mathbf{W}^L)]$ which for the small values of $dim(\mathbf{W}^L)$ considered here is comparable to the time independent weight fixed at 1, hence ensuring the relative importance of measurements is at least partly preserved. In addition, by defining all $f(t)$ to have a maximum value of 1, the profile which is maximally different from that at t_0 is readily
300 computed and compared. For this work we considered only linear and ramp functions, ultimately using a ramp function defined with respect to 70° SZA (see Supplement for details). For \mathbf{W}^L logistic curves were chosen as the functional form with a logistic steepness in all cases of 2 km^{-1} . The atmosphere was first divided at the tropopause at 17.5 km. Then at 6 km and 10 km based on the results of retrievals using single scans and modeled behavior in CAM-chem (see Sect. 3.3 for details).

We supply the profile retrieved by the time-independent inversion as the a priori to the time-dependent inversion and reduce
305 the a priori covariance for the spatial components by a factor of ten.

The solutions to the inversion of the time-dependent retrieval were found to be highly sensitive to the a priori supplied for \mathbf{C}^L including non-physical results. This necessitated systematic sensitivity studies to find solutions which were physical as well as categorizing solutions based on minimizing any time-dependent trend in the a posteriori residuals. This methodology identified a family of solutions with similar values that met stringent criteria, from which the solution with lowest overall
310 residual was selected (see Sect. 3.3 for details).

3 Results and Discussion

3.1 Rossby Wave Breaking as a Natural Experiment

As outlined in the introduction there is a well-established record of measurements of BrO in the stratosphere by ZS-DOAS and near instrument altitude by MAX-DOAS. The sensitivity of an integrated retrieval to the region of limited information content in the upper troposphere can be tested when a change in BrO is expected in this region of the atmosphere. The much larger mixing ratios in the stratosphere (>5 pptv BrO) compared to those in the troposphere (0.5 – 1.0 pptv BrO) can result in high concentrations during Rossby wave breaking (RWB). Maua Loa is seasonally located near the subtropical jet where the tropopause — and associated BrO gradient — dramatically change altitude from ~17 km on the equatorward side to ~12 km on the poleward side. RWB events can transport BrO from the mid-latitude stratosphere into the tropical upper troposphere along isentropes. Such events are particularly frequent in the vicinity of the Hawaiian islands (Wernli and Sprenger, 2007; Funatsu and Waugh, 2008).

Routine and rapid processing of ZS-DOAS data for O₃ VCDs can readily identify RWBs as O₃ VCD enhancements. However, RWBs are found to be shortly preceded by large-scale convection, and indeed might have a causal link to it (Funatsu and Waugh, 2008; de Vries, 2021). This convection in turn leads to cloud conditions which challenge or preclude DOAS retrievals. Over the course of five years of observations only a limited number of unambiguous RWB have been observed (Fig. S1) and 29 April 2017 was an unusual instance when a RWB moved over MLO in such a manner as to allow significant periods of both ZS- and MAX-DOAS which was chosen for this study.

Fig. S2 highlights the natural experiment that the RWB provides as modeled by CAM-chem. Regional conditions on the morning of 26 April 2017 before the RWB show ordinary boreal spring conditions, stratospheric O₃ at 16 km is confined north of ~40°N poleward of the subtropical jet as indicated by strong zonal winds. On the morning of 29 April 2017 the RWB has streamed mid-latitude stratospheric air (as indicated by O₃) toward the equator at 12 – 17 km which is in the process of being cut off. Quantification and location of the BrO increase in this 12 – 17 km range will help characterize the capability of the integrated retrieval.

A further basis of assessment for the retrieval is the observation of another RWB in the vicinity of MLO during the CONTRAST RF01 by the AMAX-DOAS on board the NSF/NCAR GV aircraft. The lower panels of Fig. S2 show the broad similarity of the RWB observed on the afternoon of 11 January 2014 to that on 29 April 2017, with the former being smaller and more completely cut off when observed. The aircraft successfully profiled into the RWB allowing for greatly enhanced BrO information content and vertical resolution relative to the MT-DOAS retrievals. Unlike the 29 April 2017 RWB, the one observed during CONTRAST was impacted by clouds and required leveraging three separate profiles (see Sect. 3.4 for details).

3.2 Advances in Spectroscopy and DOAS fit settings

Fitting of BrO for the integrated tropospheric-stratospheric retrieval required leveraging recent advances in molecular spectroscopy – particularly of O₃ and O₄ – and managing the spectral cross-correlation of BrO and HCHO. For the levels of

BrO we aim to retrieve the optical density of BrO is typically an order of magnitude less than O₃ or O₄ across different observation geometries making even small changes to the cross-sections important for fitting BrO (Fig. S2). Early fitting windows for DOAS retrievals of BrO utilized narrower windows covering two or three BrO absorption bands at longer wavelengths (Aliwell et al., 2002) which minimizes spectral interferences by avoiding stronger absorptions by O₃ and HCHO. The development of methods accounting for non-linear terms in absorption fitting (Pukite and Wagner, 2016) has helped facilitate the use of wider windows with four bands (Coburn et al., 2016; Koenig et al., 2017; Seo et al., 2019) which are similar to HCHO retrieval windows (Pinardi et al., 2013). The use of wider windows with five BrO bands has been previously examined for BrO and HCHO (Pukite and Wagner, 2016; Pinardi et al., 2013) and even wider windows have been contemplated (Seo et al., 2019) but ultimately not adopted due to the strong impacts from O₃, HCHO, and SO₂. We have found that for the low optical densities of BrO (and HCHO) we encounter, rather than avoid these interferences we must characterize them accurately.

The choice of O₃ cross-section is critical as the difference between cross-sections has an optical density over an order of magnitude greater than that of BrO at twilight (Fig. S3). Comparison of empirical results reveals the benefits of advances in O₃ spectroscopy (Fig. 2). The narrow fit windows used by Aliwell et al., (2002) which specifically avoid strong spectral effects from O₃ are found to be generally insensitive as expected. For wider windows, however, significantly smaller BrO columns are measured on average, with large differences when using different O₃ cross-sections. Some variability in retrieved BrO as a function of fitting window is expected due to the different light paths sampled as a function of wavelength (Pukite and Wagner, 2016). Simulating this effect on different BrO bands for ZS observations at twilight finds that the effect is minor for SZA < 90° when accounting for photochemical changes except for the BrO band at ~325 nm (Fig. S4A). The cross-section reported by Serdyuchenko et al., (2014) yields the most consistent BrO across different windows with deviations from the modeled trend less than fit uncertainty for most windows apart from the widest. This cross-section is shifted by 3 picometer per the latest recommendations (Gorshlev et al., 2014; Siddans, 2023). Stability for even wider windows will likely require further measurements of O₃ cross-sections at the relevant wavelengths, or the application of higher-order corrections for non-linearity. Ultimately, the window starting at 328.5 nm was chosen (Table S1) despite deviating slightly from consistent O₃ for ZS data, this is on the basis of constraining O₄ and HCHO accurately.

For low elevation angles the choice of cross-section for O₂-O₂ collision-induced absorption (O₄) also changes optical density by more than ten times the total optical density of BrO. We utilize the recently published cross-section by (Finkenzeller and Volkamer, 2022) which significantly changes the O₄ band at 344 nm and adds the absorption band at 328 nm. During sensitivity tests for fitting it was found that O₄ plays a role in mediating the spectral cross-correlation between BrO and HCHO which we examine further below. This is consistent with previous findings (Pinardi et al., 2013). In order to capture O₄ accurately we first fit O₄ in an optimized fitting window (350 – 388 nm) then constrain the O₄ fit in the BrO fitting window to a scaled dSCD value. This method has been employed previously assuming a Rayleigh atmosphere for scaling (Koenig et al., 2017). For this work the scaling factor was determined empirically to be 0.80±0.01 by least-orthogonal-distance fitting of the correlation of the unconstrained fits (Fig. S4B). This value is similar to what one might expect for a Rayleigh comparison of the 360 nm and

344 nm bands $(344/360)^4 = 0.83$. To better represent the wavelength dependence of the scaling factor, the absorption bands at 344 nm and 328 nm were scaled by the empirical factor, but not that at 360 nm (to account for the wavelength dependent pathlength). Given that the constraint employed emerges empirically from unconstrained fits, one might question the need for it; the key impact of the O_4 constraint is to give more consistent fits, which are critical to further constraints discussed below. The NO_2 fits retrieved from the BrO fitting window were not consistent with those found in the visible, and indeed seemed non-physical. We suspect that this arises from intensity effects from the changes in illumination at different elevation angles as the fitted intensity offset and Ring cross-sections (which often compensate for such effects in DOAS) show similar patterns. The effect is too small to be relevant to stratospheric NO_2 retrievals, but is relevant to the small NO_2 signals measured in the free troposphere. Unlike O_4 which is sensitive to only light-path changes, NO_2 columns are also impacted by concentration changes which are more difficult to constrain. We first employed O_4 and NO_2 fits from a more sensitive window in the visible (411 – 490 nm) to invert tropospheric NO_2 profiles in the vicinity of instrument altitude. The results from NO_2 fitting and resultant profiles will be described in more detail elsewhere. We then used aerosol optical depth retrieved using the constrained O_4 fits described above to model NO_2 dSCDs in the BrO fitting window under the assumption of horizontal homogeneity. These NO_2 dSCDs were then specified and constrained for further fits of HCHO and BrO.

A major challenging factor in the retrieval of BrO in the troposphere is a remarkable (but coincidental) similarity of the absorption cross-sections of BrO and HCHO when observed at the optical resolutions typical of UV-Vis spectrometers. Characterization of this method-based anticorrelation is further confounded by chemical coupling which leads to an anticorrelation of BrO and HCHO via reactions of Br atom with HCHO and other aldehydes, which often correlate with the latter, suppressing BrO formation. After optimization of the fitting window we believe that this spectral cross-talk is handled by the DOAS fit with the exception of a fast-changing component identifiable as opposing changes in BrO and HCHO for replicate measurements, and a slow-changing signal visible as a “drift” in both HCHO and BrO signals. For periods on the order of one hour this “drift” in BrO and HCHO appears to correlate with the overall measured spectral fluxes and/or with small temperature variations of the spectrometer (<0.01 K), however we could not find a consistent correlating parameter nor a definite causal mechanism. As the SZA-dependent variation in HCHO dSCDs is relatively small and there is little prospect without more stable data of retrieving high-altitude HCHO columns, a moving reference analysis was employed for HCHO. The HCHO from the moving reference analysis was used as input to optimal estimation retrievals of HCHO profiles using differential AMFs (dAMFs) as described in Sect. 3.3.2. A posteriori HCHO profiles were then used to compute SCDs using AMFs (not dAMFs); as the information content in the HCHO retrievals is minimal above 7.4 km. HCHO profiles from CAM-Chem were substituted for these altitudes prior to computing SCDs. The SCD of the fixed reference was then subtracted to yield HCHO dSCDs which were used to constrain the BrO fit.

Examining Fig. 2A one might question why the 328.5 – 359 nm window was chosen given that even with the latest cross-sections it deviates from the expected consistency at twilight by more than measurement uncertainty. The benefit of the wider fitting window is to gain access to an additional HCHO absorption feature (Fig. 2B). The combined effect of the constraints on O_4 , NO_2 , and HCHO (resulting primarily from HCHO) is to slightly increase BrO dSCDs in general. Without the constraints

BrO dSCDs are frequently fit negative for $12^\circ \leq EA \leq 45^\circ$ relative to a zenith reference near noon. For smaller negative values this would indicate surprising profile shapes difficult to reconcile with ZS data; while larger negative values cannot be physically explained. For the 328.5 – 359 nm window application of the fitting constraints for O₄, NO₂, and HCHO yields positive or (within fit error) zero BrO dSCDs for almost all data, with marked benefits for robust physical dSCDs at the elevated
415 EA off-axis angles (Fig. S4). Leveraging the latest spectroscopy for O₃ and O₄ and applying constraints on O₄, NO₂, and HCHO determined from the same MT-DOAS yields robust BrO dSCDs as input to the further retrieval.

3.3 Mountaintop Profile Retrievals

The mountaintop BrO profile retrieval, including the DOAS fitting, is summarized in a flowchart in Fig. 3. Broadly, the retrieval proceeds from DOAS fitting to a time-independent profile retrieval, and finally to a time-dependent BrO retrieval. As
420 Fig. 3 makes clear, and as already outlined in Sect. 3.2, intermediate steps are taken. We first examine the aerosol and HCHO profiles retrieved for constraining the BrO DOAS fit on the mornings of 26 and 29 April 2017, then the determination of BrO SCD_{Ref} for the reference spectrum (on April 26, used on both days; see Sect. 2.2); discuss the time-average retrievals for both days and assess their self-consistency, and finally describe the time dependent profile retrievals for both mornings.

3.3.1 Aerosol Inversion

425 Aerosol extinction profiles were retrieved for each EA scan to reproduce the scaled O₄ dSCDs as described in Sect. 2.3.2. The retrieved aerosol profiles were then used for the HCHO inversion (Sect. 3.3.2) and BrO inversion (Sect. 3.3.3 – 3.3.5). In brief, there was very little aerosol near or above the instrument altitude, which owing to the altitude of MLO is close to a Rayleigh atmosphere. However, aerosols were detectably not zero when comparing O₄ dSCDs with Rayleigh simulations; this is in part owed to the sensitivity of O₄ dSCDs to detect even sub-Rayleigh aerosol extinction (Volkamer et al., 2015). More importantly,
430 aerosol below the instrument altitude enhances the signal from trace gases at lower altitudes in a manner similar to increased albedo (see Supplement for details). Retrieval of aerosol profiles especially when so close to Rayleigh conditions and including these complex effects from lower altitudes presently exceeds the data collection times by over an order of magnitude and is the greatest limitation in further application of this analysis.

3.3.2 HCHO profile inversions

435 As described above it was found to be necessary to constrain HCHO for the BrO DOAS fitting; HCHO profiles were therefore retrieved for each EA scan. Since a moving reference analysis is employed for HCHO, corresponding differential weighting functions (dWFs) were used for optimal estimation. The HCHO a priori profile is 600 pptv at the surface with mixing ratio decreasing exponentially with a folding height of 2 km, but not less than 50 pptv. This profile was chosen based on AMAX-DOAS and CAM-Chem (see Sect. 3.4 for details). The optimal estimation uses a 100% a priori covariance for diagonal terms
440 and 0.5 km correlation height for off-diagonal terms below 17.4 km, and 50% covariance and 4 km correlation height above 17.4 km. The retrieved profiles are then combined with WF (non-differential) to obtain HCHO dSCDs as BrO fit constraint.

The major effect of this constraint on HCHO can be seen in the top panels of Fig. S6, and is twofold: a general smoothing of the data and an elimination of the “drift”, most visible in scan 1 on Apr 26 and on Apr. 29. The effect of constraint eliminating the “drift” is generally to decrease HCHO, which given the spectral cross-correlation leads to an increase in BrO as shown in Fig. S5. In particular, the larger EA ($\geq 12^\circ$) are consistently pulled to non-negative, physically meaningful, values. In all instances, this is well within the range of uncertainty, nonetheless, this change is important to BrO as it acts on relatively small separations between these EA and the nearest zenith spectra. Reproducing the dSCDs retrieves independent HCHO profiles below ~6 km, but largely converging to the a priori above this altitude.

The DoF for the individual HCHO retrievals ranges from 2.24 to 2.61. This is roughly distributed as one DoF located between 1.9 km and 3.4 km, below the instrument; one DoF located between 3.4 km and 4.4 km near instrument altitude, and the remainder above instrument, with ~70% of the remaining information content below 6 km. Apart from scan 1 on Apr. 26, which has more HCHO, and the latter three scans on Apr. 29, which have decreasing HCHO concentrations, the retrieved HCHO concentration at instrument altitude varies by less than 10% from 2.73×10^9 molec. cm^{-3} (161 ppt). In contrast to this relative stability at instrument altitude, HCHO varies more below the instrument, without generally clear trends. Given there is a single DoF below the instrument the profile shape below the instrument should not be interpreted as significant. But the changes in partial columns remain significant. These perhaps reflect dynamic evolution of HCHO in the boundary layer below MLO from biogenic and/or anthropogenic primary and secondary sources. The retrieved HCHO concentrations above the instrument altitude tend to be greater than the 50 pptv a priori. Retrieved HCHO profiles and columns are further compared with aircraft data and other measurements and models in Sect. 3.5 and 3.6.

3.3.3 Determination of BrO SCD_{Ref}

Previous studies have highlighted the impact that SCD_{Ref} can have on BrO retrievals, particularly in regions of low sensitivity. These prior studies had found a need to optimize the distribution of BrO based on a modified Langley plot (Hendrick et al., 2007; Theys et al., 2007) or by iteration until a self-consistent result is obtained (Coburn et al., 2016). A consistent feature of these previous studies has been the connection between upper tropospheric BrO and the BrO SCD_{Ref} . In Hendrick et al., (2007) inclusion of the tropospheric BrO column is necessary to retrieve consistent BrO VCDs and thereby a photochemical Langley plot. In Coburn et al., (2016) optimal estimation retrievals with and without SCD_{Ref} were both assessed, with SCD_{Ref} providing additional information content in a broad peak in the upper troposphere. While Theys et al. (2007) examined the connection between SCD_{Ref} and BrO in the upper troposphere less directly, tropospheric AMFs are folded into the parameterization used to derive SCD_{Ref} ; furthermore, the authors note that the lack of BrO signals near instrument altitude and differences between their retrieved tropospheric BrO VCDs and unpublished results over Nairobi both indicate the tropospheric BrO is likely located at higher altitudes in the troposphere. We adopt a similar approach, assessing different values of SCD_{Ref} .

To assess values of SCD_{Ref} we employ photochemical Langley plots as described in Sect. 2.5.1; results from this are summarized in Fig. S7. Because the retrieved profile itself impacts the photochemical AMFs we conduct the time-independent retrieval for various values of SCD_{Ref} . This is a fast process because as a trace absorber BrO does not change the WF used for

475 its own retrieval. It is found that $SCD_{Ref} = 2.00 \times 10^{13}$ molec. cm^{-2} recovers itself within uncertainty ($2.01 \pm 0.09 \times 10^{13}$ molec.
480 cm^{-2}) and has a high R^2 value (0.984). While the R^2 value (0.982) and apparent linearity for $SCD_{Ref} = 1.50 \times 10^{13}$ molec. cm^{-2}
are similar, it is not self-consistent in that it retrieves a value for SCD_{Ref} which is $>3.5\sigma$ different ($1.85 \pm 0.09 \times 10^{13}$ molec. cm^{-2}).
Using $SCD_{Ref} = 2.50 \times 10^{13}$ molec. cm^{-2} , the photochemical Langley plot is visibly non-linear which is also reflected in a
lower R^2 value (0.901), and can more readily rejected on this basis. However, the retrieved value ($2.58 \pm 0.09 \times 10^{13}$ molec. cm^{-2})
is not significantly different from the previous value, and it might be considered self-consistent. Furthermore, Coburn et al.,
(2016) employed an iterative approach for SCD_{Ref} using an a posteriori SCD_{Ref} as the a priori which assumes that SCD_{Ref} will
tend to converge, however, the retrieved SCD_{Ref} in this instance diverges further from the optimized value of 2.00×10^{13} molec.
 cm^{-2} which is used. We find that iterative approaches and goodness-of-fit metrics are not sufficient alone to identify accurate
values of SCD_{Ref} rather different values should be surveyed and assessed based on self-consistency and apparent linearity in
tandem.

3.3.4 Integrated Time-Independent BrO Retrieval

A difference between the twilight BrO SCDs between April 26 and April 29 is apparent by simple examination. On April 26
BrO SCDs are observed to decrease monotonically as the sun rises from values starting from almost 2.5×10^{14} molec. cm^{-2} ,
whereas on April 29 they at first increase from lower values of $\sim 1.7 \times 10^{14}$ molec. cm^{-2} before an umkehr around $SZA = 90^\circ$
490 then decreasing by less to a relatively high BrO SCD at $SZA = 75^\circ$ (Fig. 4). These differences together indicate additional BrO
above the site on April 29 relative to April 26 located below the mean scattering altitude for $SZA \geq 90^\circ$ (~ 30 km). Zenith SCDs
at lower SZA , however, are similar on both days necessitating additional differences; these are ultimately determined to be
dynamics-driven profile changes over the course of the measurement period on April 29. On both days intermediate angles (3
 $- 30^\circ$ EA) are often elevated relative to lower elevation angles, suggesting BrO is not enhanced at instrument altitude, but aloft
495 in the free troposphere. The residuals of the time-independent retrieval on April 26 are within 2% of the mean slant column fit
uncertainties and typically are smaller Comparing the residuals (Fig. 4) to these mean uncertainties for April 26: the overall
comparison is very slightly larger for all observations 6.2 vs 6.1×10^{12} molec. cm^{-2} , but smaller (8.1 vs 8.3×10^{12} molec. cm^{-2})
for ZS data, and (3.6 vs 4.1×10^{12} molec. cm^{-2}) for MAX data. For April 29, by contrast, the comparison for ZS data is even
better, 7.9 vs 9.1×10^{12} molec. cm^{-2} ; while MAX data compare less favorably, but still within 60% (7.1 vs 4.4×10^{12} molec. cm^{-2})
500 2) in turn driving poorer performance overall (7.1 vs 6.6×10^{12} molec. cm^{-2}). Examination of the time series of the retrieval
residuals from the time-independent retrieval (black symbols Fig. 4d background) reveals a clear pattern: for ZS data residuals
scatter around zero, increasingly converging as more photons improve signal to noise, rather suddenly at $SZA=75^\circ$ residuals
are systematically positive across EA, then decrease approximately linearly to be systematically negative at $SZA=40^\circ$. This is
indicative of changes in BrO above those MAX measurements are most sensitive to but below those ZS measurements are
505 most sensitive; potentially consistent with an evolving RWB event. While it is clear the retrieval, especially on April 29, can
be further improved (as is done below in Sect. 3.3.5) the magnitude of residuals indicates the results of the time-independent
retrieval are sufficiently accurate to examine.

Examination of the retrieved time-independent profiles and the associated AVKs (Fig. 5) can better quantify the major differences in the BrO profile brought about by RWB. Examination of the AVKs and column sensitivities reveals the two regions of high information content at the bottom and top of the profile. Below ~ 7.4 km, the retrieval has three DoF with reasonable precision of altitude: 1.9 – 3.4 km (1.1 DoF), 3.4 – 4.4 km (1.1 DoF), and 4.4 – 7.4 km (1.0 DoF). A local minimum in BrO is observed near instrument altitude on both days, however, the altitude regions each possess a single DoF in aggregate; considering this, the BrO at instrument altitude is not significantly less than below the instrument on April 29. The more striking difference between the two days is above the instrument, in the 4.4 – 7.4 km range, which on April 26 peaks at over twice the concentration at instrument altitude. While on April 29 the BrO concentration decreases on average broadly in line with air density (see also Fig. 5). There is no obvious connection between a RWB event and this altitude range, suggesting the observed differences are coincidental, or that something more subtle in the atmospheric dynamics or retrieval is responsible. The column sensitivity (Fig. 4) reveals the other region of significant information content (1.5 DoF) from ZS data concentration in the stratosphere above 17.4 km. The retrieved stratospheric BrO profile on April 26 is broadly consistent with those previously measured by balloons in the tropics (Pundt et al., 2002; Dorf et al., 2008), peaking between 20 and 25 km at 1.2 ± 0.1 molec. cm^{-3} . The effect of the RWB on the 29th is immediately apparent as the stratospheric BrO profile is shifted to lower altitude, and with a larger total column, both better resembling midlatitudes. It is notable, that the decrease in BrO concentration is greater than the decrease of air density above 25 km, which would indicate a BrO concentration decrease which we do not believe has been previously observed. However, as the AVK reveal, information content in the stratosphere is imprecise for the attribution of altitude to BrO signal and information content is especially limited at these highest altitudes; therefore we suspect that this decrease in mixing ratio is likely false, and the BrO peak at lower altitude is slightly overestimated in a manner consistent with the AVK and that sensitivity above ~ 30 km is limited though better signal to noise for $\text{SZA} > 90^\circ$ could address this.

Below ~ 1.9 km the sensitivity of the MT-DOAS is not only limited but negligible (< 0.1 DoF) and constitutes a null space for retrieval. This leaves one region of the atmosphere between the lower troposphere (1.9 – 7.4 km; 3.2 DoF) and the stratosphere (> 17.4 km; 1.5 DoF): the upper troposphere (7.4 – 17.4 km) is not readily retrieved using MAX or ZS data alone, a local but nonzero minimum in column sensitivity in the upper troposphere. The joint leverage of ZA and MAX data allows 0.85 – 0.97 DoF to be retrieved between 7.4 – 10.4 km, clearly revealing the impact of the RWB even on the BrO concentration in the upper troposphere. On April 26, the BrO profile decreases with altitude to a minimum, not significantly different from zero, at 11.4 – 13.4 km. The increase above this altitude while still in the troposphere is consistent with previous profiles on mobile platforms (Pundt et al., 2002; Dorf et al., 2008; Koenig et al., 2017) During the RWB event on April 29, however, there is instead a BrO maximum in the upper troposphere presumably resulting from the injection of air from the stratosphere with a much higher BrO mixing ratio. This stratospheric intrusion on April 29 is captured with an independent DoF from the synergy of ZS and MAX observation indicating it is independently significant and not the result of other differences in the profile.

540 3.3.5 Time-Dependent BrO Retrieval

The SCD retrieval residuals on April 29 show a clear temporal pattern, particularly for MAX data (Fig. 4); as noted in Sect. 3.3.4 these are the only subset of data for which the retrieved residuals exceed the average fitting uncertainties. Given that the photochemical variation in Br_y partitioning is already reflected in the air mass factor calculations, we attribute this to additional time dependent changes in BrO (and possibly Br_y). The set up of the time-dependent retrieval is given in Sect. 2.5.3. Sensitivity studies used to determine the values ultimately used are described in the supplement. In brief, in Eq. 3, $f(t)$ was set to be a ramp function with value zero for SZA < 70° increasing linearly with time to a value of one for remaining data based on time dependent O₃ VCD retrieval for ZS data (Fig. S8). Four atmospheric layers (W^L) for the lower, middle, and upper troposphere, and for the stratosphere based on CAM-Chem modelling for Apr. 29 (Fig. S9). The retrieval was found to be highly sensitive to the choice of a priori values for C^L which were chosen based on consistent results when varying the BrO a priori profile (x_0 a priori) and for small changes in the C^L a priori (Fig. S11). Settings optimized for April 29 were also applied to April 26, which was found to be less sensitive to the choice of a priori. 1.7 and 2.1 time-dependent DoF were retrieved for April 26 and April 29 respectively.

RW-DT events involve the movements of mid-latitude air toward the tropics which might be expected to increase the BrO VCD, however, the difference in BrO VCD is not significant (base case $(2.2 \text{ to } 2.3 \pm 0.2) \times 10^{13}$ molec. cm⁻² vs RW-DT $(2.6 \text{ to } 2.4 \pm 0.3) \times 10^{13}$ molec. cm⁻²). The stratospheric BrO VCD varies by 5 – 10% between the two days, $(1.46 \text{ to } 1.47 \pm 0.08) \times 10^{13}$ molec. cm⁻² on April 26, and $(1.61 \text{ to } 1.55 \pm 0.08) \times 10^{13}$ molec. cm⁻² on April 29 (Fig. 6), broadly consistent with the 7% difference in the O₃ VCDs for SZA < 70° (Fig. S8). Given the observed increase in O₃ VCDs on April 29, it could be expected that the observed decrease in stratospheric BrO VCDs on April 29 must be compensated by a tropospheric increase resulting from the RW-DT, however BrO SCDs are actually lower than expected (Fig. 4); consistent with this the tropospheric BrO VCD decreases from $(1.01 \pm 0.14) \times 10^{13}$ molec. cm⁻² to $(0.85 \pm 0.17) \times 10^{13}$ molec. cm⁻². Counterintuitively, tropospheric BrO increases slightly, $(0.13 \pm 0.16) \times 10^{13}$ molec. cm⁻² increase on $(7.00 \pm 0.14) \times 10^{13}$ in the base case, while for the RW-DT case the change $(0.15 \pm 0.17) \times 10^{13}$ molec. cm⁻² decrease on $(1.01 \pm 0.14) \times 10^{13}$ molec. cm⁻² is in the mid to lower-FT (>80% of the change), the altitudes furthest from the stratosphere. The small to negligible change in the stratosphere and upper FT for the RW-DT has 0.86 total DoF. This suggests that while the O₃ VCD provides a reasonable estimate of the change in stratospheric BrO VCDs between the two days, it does not readily predict changes during the RW event. Nonetheless, the time evolution of the O₃ VCDs has been found to roughly correspond to changes in BrO, suggesting there is some connection between the changes. On both days the largest changes are observed in the lower atmosphere (< 7.4 km). On April 26 the change is primarily in the 4.4 – 7.4 km range where BrO increases from 0.7 ± 0.1 pptv to 0.9 ± 0.1 pptv which is very slightly compensated by minor increases at lower altitudes. Changes on April 29 are roughly the opposite (0.5 ± 0.1 pptv to 0.3 ± 0.1 pptv) and more consistent with the changes at lower altitudes (0.46 ± 0.03 pptv to 0.29 ± 0.04 pptv at 3.4 – 4.4 km; and 0.32 ± 0.06 pptv to 0.20 ± 0.07 pptv at 1.9 – 3.4 km). Even if the observed increase in O₃ is in or near the stratosphere, it would be expected to slightly lower J_{BrO} via increased UV absorption increasing the BrO:Br ratio holding other chemical conditions constant. The observed decrease

in BrO in the lower FT therefore points to either a decrease in Br_y or chemical changes lowering the BrO:Br_y ratio, which have some link to the changes in O₃ VCDs.

575 3.4 Aircraft Profile Retrievals of HCHO and BrO

Aircraft observations of a second RWB event in the vicinity of MLO by the CU-AMAX-DOAS provide an opportunity to assess the retrieval leveraging the greater sensitivity and precision of altitude available aboard a mobile platform. As has been previously noted, RWB are often accompanied by widespread and complex cloud fields presenting challenges for DOAS retrievals due to the radiation fields; this was the case on January 11, 2014, however, two descents and an ascent over Hawaii
580 together provide a near complete profile sampled twice with clear line of sight. The relevant flight path is summarized in Fig. 7. BrO profiles from the CONTRAST campaign have been previously reported in (Koenig et al., 2017). After conducting sensitivity studies we have made some minor adjustments to the BrO fit settings to better match those used for MLO in this work summarized in Table 1, with further details in the supplement.

The retrieved BrO and HCHO profiles are summarized in Fig. 8. In the boundary layer below ~2 km altitude significant
585 heterogeneity is observed. The rapid changes in observed signals around the missed approach at KOA airport present challenges for the optimal estimation leading to strikingly different concentrations at neighboring altitudes and between RF01-06 and RF01-07 (Fig. S13 and S14). Comparison with the interpolated BrO profile from CAM-Chem shows that the model underestimates the local concentrations, however, the shading showing the range of concentrations over the Hawaiian Islands shows that the model does include instances of high BrO concentrations in the MBL, and is only missing the precise location
590 of these in the vicinity of KOA airport. A number of points retrieved in the HCHO profile for RF01-07 in the boundary layer – but not for RF01-06 – are outside the measured range of in-situ observations by ISAF indicating there might have been very low HCHO air somewhere in the vicinity but not along the flight track, although the large propagated uncertainty in the optimal estimation indicates limitations of the retrieval also likely play a role. Retrieved BrO mixing ratios in the FT from 2 km to 9.5 km oscillate around ~0.5 ppt with a minor local maximum around 5 – 6 km captured in all profiles (see also Fig. S13). CAM-
595 Chem generally captures the broad picture of BrO in the FT, but appears to misplace the vertical extent of RWB stratospheric intrusion down as low as 8 km, which is not observed. Instead, the stratospheric intrusion is observed to start at 10 – 12 km where BrO is observed to increase to over 2 ppt with the intensity again mildly underestimated by the model. In the lower FT, both the ISAF and AMAX-DOAS find that HCHO mixing ratios are not only higher than predicted by CAM-Chem, but outside the regional range in the model up to roughly the altitude of MLO. Through the altitude range of 4 – 8 km the measurements
600 remain in general agreement, with the ISAF possessing greater precision, the model is within uncertainty over this range but still systematically slightly low. The measurements again depart from CAM-Chem predictions in the stratospheric intrusion where the model predicts <50 ppt HCHO, but both instruments observe ≥100 ppt. This discrepancy was not generally observed by ISAF during flights over the central Pacific but is more typical of the western Pacific (Anderson et al., 2017).

3.5 Retrieved Profiles in Context

605 The CONTRAST RF01 profiles offer only a limited snapshot over the central Pacific, but nonetheless offer an opportunity to compare to prior aircraft measurements over the western and eastern Pacific. Examining the profiles over the altitude range the MT is sensitive to (Fig. 9), the RF01 retrieved profile is broadly consistent with the eastern Pacific in the lower FT. This is particularly notable because, as noted above, BrO was observed in the MBL similar to the western Pacific, but this is not found to propagate up to the lower FT as it does there. This might reflect lower convective intensity relative to the western Pacific, but might also be a reflection of limited sampling and statistics. Through the range of 4 – 9 km all three regional profiles are approximately 0.5 ppt BrO, indicating this might reflect a broadly applicable Pacific background with some uncertainty. Above this altitude, the RF01 profile is again in general agreement with the average profile observed over the eastern Pacific. Keeping in mind that the observed profile is during a RWB, this suggests that such events, and isentropic transport from the stratosphere more generally which are common in the region (Wernli and Sprenger, 2007; Funatsu and Waugh, 2008), are likely contributors to the observed increase in BrO in the upper FT observed over the eastern Pacific. Intriguingly, the decrease in BrO lower in the FT observed at the same time may reflect the effects of dynamics which are broadly coupled to RWB (Funatsu and Waugh, 2008; de Vries, 2021) and it is possible these dynamics can also contribute to the relatively low BrO concentrations at lower altitudes observed over the eastern Pacific.

610 Comparing the MT and aircraft profiles from this work (Fig. 9), BrO is consistently ~ 0.5 ppt, again generally suggesting this might be a regional average within some bounds of altitude. Interestingly, the maximum of ~1.0 ppt BrO observed around 6 km altitude on Apr. 26 is broadly similar to the upper range of a local maximum observed over the western Pacific, suggesting it might arise from similar processes over the western Pacific. The low BrO observed above 9 km on Apr. 26 is also broadly consistent with the western Pacific although again more marked than average. In contrast to the RWB impacted profiles, Apr. 26 more closely resembles the western Pacific. This suggests that variability in BrO profiles, over the central Pacific and perhaps more broadly, might be partly driven by meteorological conditions which occur and are sampled with different frequency regionally. Intriguingly, the aircraft profile observes a similar BrO minimum between 6 km and 9 km as on Apr. 29. As previously noted this altitude range does not obviously connect to the RWB events observed. With only two samples it is possible this is merely coincidental, and it should be noted that applying the AVK for Apr. 29 to the aircraft profile eliminates this feature. However, we posit that local maximum in BrO observed on Apr. 26 and over the western Pacific, and this minimum might have their origins in convective transport (and perhaps the lack thereof) which is known to be systematically perturbed prior to and during RWB. Examining the stratospheric intrusion above ~12 km associated with the RWB, the two profiles are remarkably similar when accounting for the AVK. Consistent with the model prediction that the RWB on Apr. 29, 2017 is greater in intensity than on Jan 11, 2014 (Fig. S2) more BrO is observed in the upper FT from the MT when accounting for AVK. This demonstrates that the MT DOAS is sensitive to BrO in the upper FT and can detect the impact of a RWB with AVK likely accurately capturing the limitations of the retrieval. These limitations as represented by the AVK should be considered when interpreting the data as the comparison with the aircraft profile demonstrates the limited altitude precision of

620
625
630
635

the MT retrieval. It is likely that BrO enhancements are more limited in vertical extent than captured by MT-DOAS, but correspondingly more intense.

3.6 Prospects for Further Development and Application

640 The RTM calculations limit the systematic analysis of long-term data records using this retrieval. Especially since RTM
calculations also feed through the dSCD constraints for HCHO and NO₂ in the DOAS fit of BrO dSCDs. Furthermore, multiple
different RTM codes are used for the ZS and MAX parts of MT-DOAS data interpretation. The development of RTM with a
full set of capabilities (which can handle twilight, longitudinal scattering in the stratosphere, and EA viewing geometries above
and below the detector) would aid to simplify and streamline the retrieval. Aerosol-albedo relation also deserves further
645 attention in this context. Look up tables may also be an option for the generally low AOD conditions on mountaintops.
This initial application of the full atmosphere integrated retrieval of BrO was chosen, because there is BrO in both the
troposphere (probed primarily by MAX) and stratosphere (ZS), and the partial VCDs in these compartments are comparable
(i.e., less than 1:2 ratio either way). Future applications for NO₂ are likely to succeed. The implementation for urban NO₂ is
most similar to the BrO case, in that the boundary layer- and stratospheric NO₂ partial VCDs often are within the 1:2 ratio
650 (either way). Placement of the sensor above the pollution layer is desirable; and regions with significant NO₂ in the lower FT,
or high-altitude cities could be interesting candidate sites. Remote atmosphere NO₂ is more challenging, but the small number
ratio of tropospheric to stratospheric partial VCDs (~1:6) is in principle helpful. A further advantage of NO₂ is that the DOAS
fit can in principle leverage multiple wavelengths, and ranging especially at low AOD (Ortega et al., 2015; Dimitropoulou et
al., 2022). A different multispectral approach might allow for the retrieval of tropospheric O₃ using the relative atmospheric
655 transparency of the Chappuis bands to retrieve a stratospheric profile and the high signal to noise of the Huggins bands for
tropospheric O₃.

4 Conclusions and Outlook

MT-DOAS is well suited for measuring trace gas profiles up to 35 km altitude, i.e. not limited to the lower free troposphere.
660 The sensitivity is highest near instrument altitude, and in the stratosphere. Moreover, sensitivity remains significant (3-5 km
vertical resolution) also in the upper troposphere, and is demonstrated here suitable to track changes in BrO radical
concentrations in the UTLS that are induced by RW-DT events above Hawaii. In the absence of clouds, MT-DOAS has many
advantages: it provides a clear view into the lower and upper free troposphere and stratosphere that is maximally sensitive,
unobstructed by aerosols, and the extended spatial scale probed inherently minimizes influences from a local boundary layer.
665 Furthermore, MT-DOAS is inherently calibrated, has minimal need for consumables, and lends itself to autonomous long-term
observations.

670 The spectral cross-correlation between BrO and HCHO (Pinardi et al., 2013; Pukite and Wagner, 2016; Seo et al., 2019) was actively managed through the use of wide DOAS spectral fitting windows (here: 6 band BrO analysis, 4 band HCHO analysis), and by imposing external constraints for overlapping species (i.e., NO₂, O₂-O₂ and HCHO). Pre-requisite for our full atmosphere retrieval are recent advances in the molecular spectroscopy of O₃, and O₂-O₂ collision induced absorption (Serdyuchenko et al., 2014; Finkenzeller and Volkamer, 2022) that facilitate the consistent spectral fitting of BrO and HCHO dSCDs from solar stray light spectra measured in the ZS and MAX geometries at high and low solar zenith angle ($92^\circ > \text{SZA} > 30^\circ$).

675 The information content of MT-DOAS profile retrieval increases, if the solution to the inverse problem is defined as a time dependent optimal estimation solution (~7.5 DoF) rather than a time-independent (static) solution (~5.5 DoF). The time dependent retrieval is needed to accommodate atmospheric variability in BrO concentrations over the course of 2 - 4 hours during the RW-DT event. It further is found to reduce residuals between measured and predicted BrO SCDs during days when BrO (and/or Br_y) is subject to temporal variability resulting from dynamical activity in the FT and UTLS. In absence of RW-DT activity, the time-independent retrieval is adequate, and gave equivalent results to the time dependent retrieval (which still has higher DoF). The similarity of fine scale BrO vertical structure probed by MT-DOAS and AMAX-DOAS during RW-DT events three years apart suggests that rapid changes in the BrO profile on the scale of hours are a consistent feature of RW-DT induced dynamical changes in atmospheric composition of the FT that require a time-dependent retrieval.

685 In the future, the retrieval can be extended to other trace gases (e.g., IO, CHOCHO, NO₂, others), and lays the foundation for tracking the temporal (daily and seasonal) variability of trace-gas profiles in the troposphere and stratosphere from long-term time series measurements of MT-DOAS. Further evaluations of MT-DOAS integrated troposphere/stratosphere observing strategy, by time-synchronous aircraft observations or other unanticipated methods are desirable. Furthermore, our instrument located at 3.4 km altitude is found to have a null-space below 1.9 km. This gap can in principle be filled by coordinated MT-DOAS and MAX-DOAS observations inside the boundary layer. Our finding, that BrO profiles in the FT over the Central and Eastern Pacific Ocean are similar (during a RW-DT event) but differ from the C-shaped profiles over the Western Pacific Ocean, has implications for cloud slicing of satellite data as a tool to derive global maps of tropospheric BrO vertical profiles. Satellite cloud slicing needs to consider this longitudinal variability of BrO profiles.

695 *Data Availability.* MT-DOAS data and associated RTM data products are archived at <https://doi.org/10.5281/zenodo.8337857>. The AMAX-DOAS BrO data are available from the CONTRAST data archive: http://data.eol.ucar.edu/master_list/?project=CONTRAST. The CONTRAST data set is open for use by the public, subject to the data policy: <https://www.eol.ucar.edu/content/contrast-data-policy>.

Table 1. Retrieved Degrees of Freedom Summary

Time-independent Layers (km)	Apr. 26 DoF	Apr. 29 DoF	Time-dependent Layers (km)	Apr. 26 DoF	Apr. 29 DoF	Total DoF Apr. 26	Total DoF Apr. 29
1.9 – 3.4	1.12	1.22	0 – 6	0.59	0.62	1.32	1.43
3.4 – 4.4	1.06	1.18				1.26	1.39
4.4 – 7.4	0.98	0.79				1.17	0.99
7.4 – 17.4	0.97	0.85	6 – 10	0.91	0.61	1.92	1.73
			10 – 17.5	0.04	0.27		
17.4 +	1.47	1.39	17.5 +	0.14	0.59	1.61	2.00
Total	5.60	5.42	Total	1.68	2.09	7.28	7.51

Figure 1: Principals and components of integrated BrO retrieval.

1000 From left to right. At twilight, high solar zenith angle (SZA), measurements are taken in a zenith-sky (ZS) geometry and must
 account for the rapid photochemical changes to bromine in both time and along the light-path. BrO mixing ratios are shown for the
 1005 stratosphere (solid line), western Pacific (long dashes), and eastern Pacific (fine dashes) next to the box air mass factors (boxAMF)
 showing which altitudes measurements at different SZA (matching color to left) are sensitive to (red SZA=92°, pink SZA=88°, orange
 SZA=84°). These peak strongly in the stratosphere and more mildly in the tropical transition layer (TTL) and upper free troposphere
 (uFT). When SZA < 75° the instrument varies the elevation angle (EA) viewing geometries relative to the horizon (MAX). The
 1010 differential boxAMF relative to a ZS measurement at the same times is shown for different EA (orange -3°, red 0°, green 30°). These
 peak below the instrument in the transition layer (TL), at instrument altitude (lower FT to TL) and lower FT. Combining these
 sensitivities allows for 5.5-6 independent measurements conceptually shows as averaging kernels (AVK) on the right. Far above the
 instrument almost three independent partial columns are retrieved, almost two in the stratosphere (primarily from ZS-DOAS data),
 and one in the upper FT and TTL through ZS-DOAS and MAX-DOAS synergy. Near instrument altitude there is relatively fine
 vertical resolution (from MAX-DOAS) and three mixing ratios are retrieved.

1010

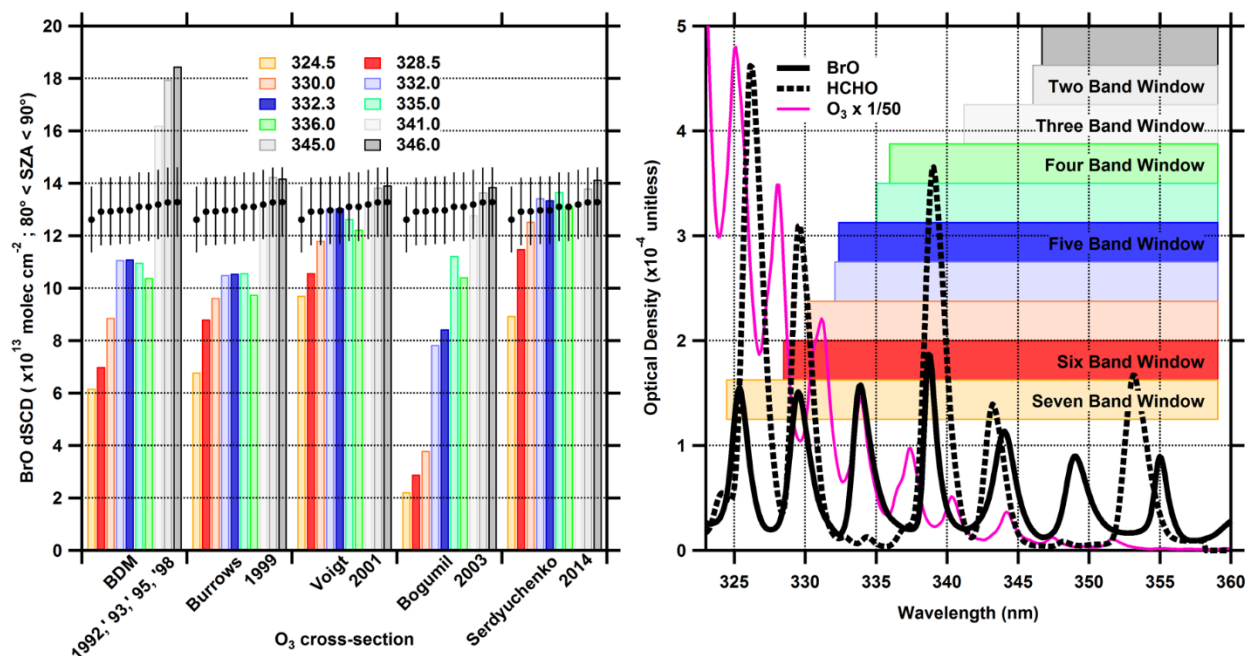

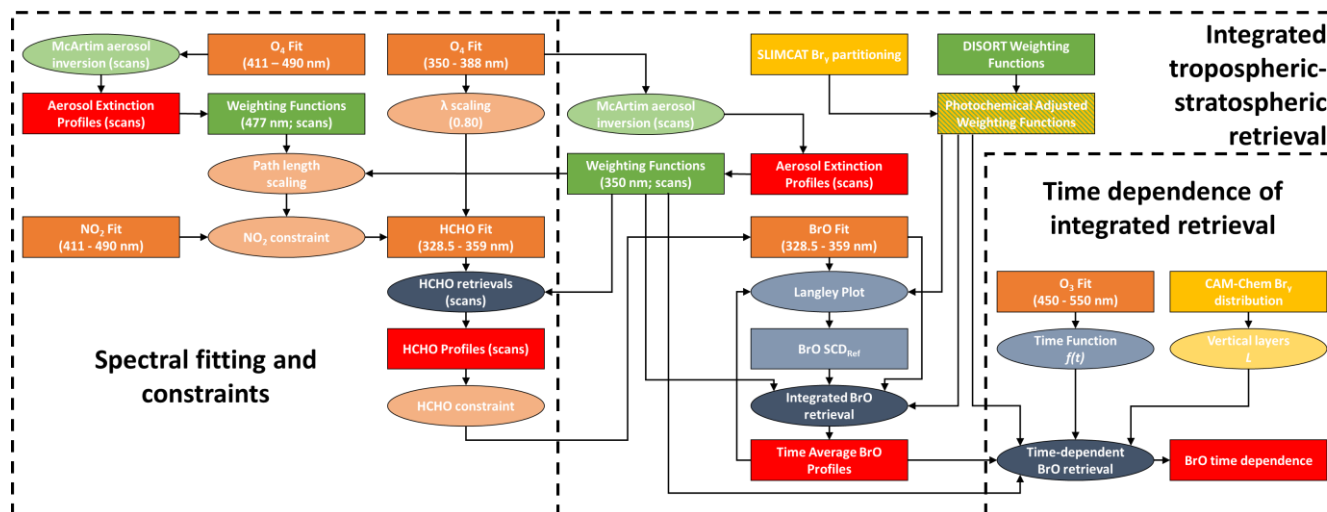

Figure 2: Advances in O₃ molecular spectroscopy, and the effect on a robust BrO fit.

Left: average BrO dSCD fits for twilight data in different spectral fitting windows when using different O₃ cross-sections. Right: representative optical densities as observed at MLO for SZA=70° and EA=0°. Colored bars indicate DOAS fitting windows for which the short wavelength edges are given in the legend (the long wavelength edge is always 359 nm) and graphically shown on the right to indicate the number of BrO bands included. Bars on the left compare the average measured BrO dSCD (80° < SZA < 90°) with that expected due to changes in light-paths for the different windows (due primarily to O₃; black circles are scaled to match the average from windows with five BrO bands or fewer), error bars indicate the average DOAS fit uncertainty in the same SZA range.

Figure 3: Summary of MT-DOAS BrO retrieval methods

Rectangles identify data products while ellipses indicate processing tools. In orange spectral fitting processes and products, in green radiative transfer modelling tools and products, in yellow chemical data products and tools, in blue optimal estimation and other retrieval methods, in data products reported in this work.

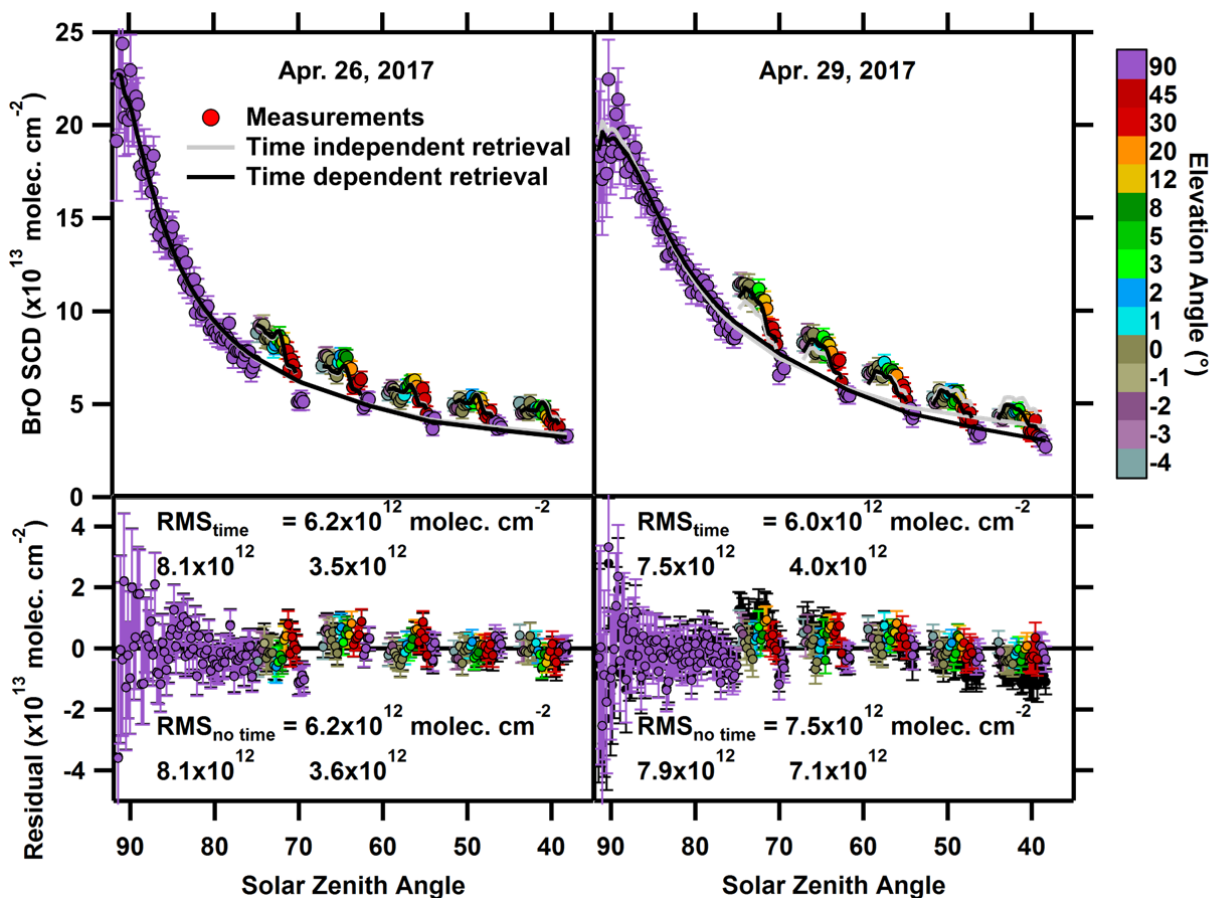

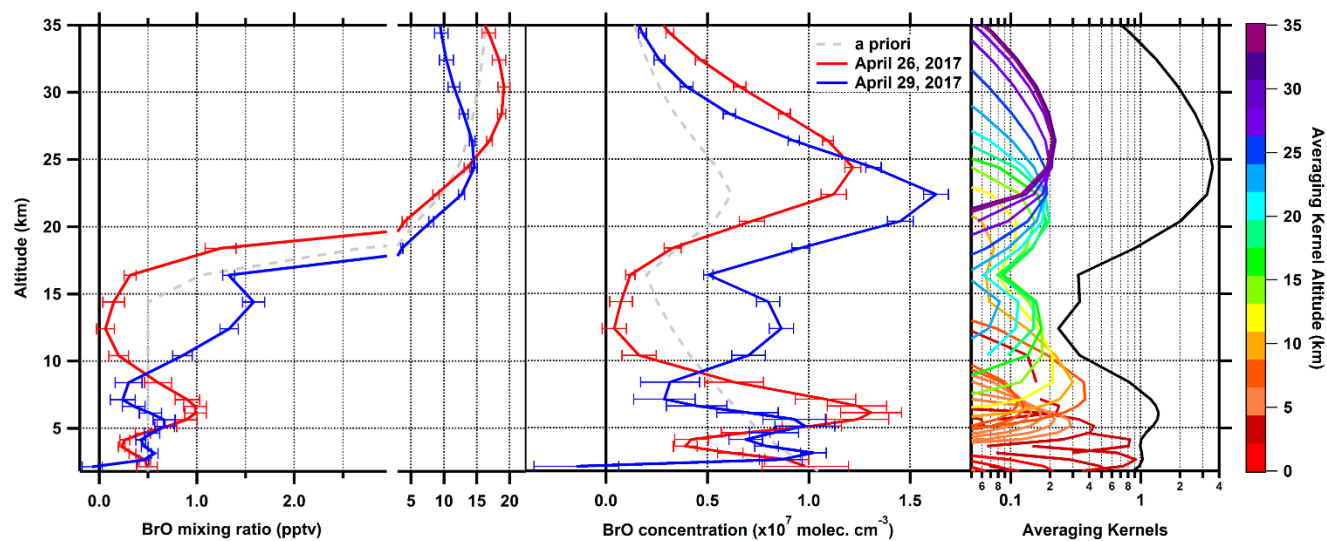

Figure 4: Comparison of measured and retrieved BrO SCDs.

1030 Top: Retrieved reproduction of measured BrO SCDs for the mornings of April 26 (left) and 29 (right), 2017. Measurements are color coded by EA with error bars showing the DOAS fitting error (the SCDRef = 2.0×10^{13} molec. cm^{-2} is included) against SZA (sunrise is on the left of each window). The grey lines show the retrieval for the zenith data, and for each EA scan normalized to SZA 70° without time dependence accounted for. The black line shows the retrieval allowing for a time dependence of the BrO profile (the difference is almost imperceptible for April 26). The residuals (= retrieved – measured) are shown on the bottom for the time independent retrieval (solid black) and the time dependent retrieval (color coded). Also listed are the root-mean-square (RMS) of the residuals for each retrieval, as well as for subranges of SZA > 75° and SZA < 75°. The primary benefit of including the time dependence is to eliminate the slope apparent in the residuals for SZA < 75° on April 29.

1035

1040 **Figure 5: The integrated BrO profile retrieval.**

1045 Left: BrO mixing ratio profiles at $\text{SZA}=70^\circ$ for the mornings of April 26 and April 29, 2017, utilizing the default a priori (grey dashed line). Middle: The corresponding BrO concentration profiles at $\text{SZA}=70^\circ$. Right: Averaging Kernels (for April 26) at the kernel altitude (color coded), and the column sensitivity (black line, the sum of all kernels at a given altitude). The vertical resolution is best near instrument altitude, and decreases in the uFT and stratosphere; the column sensitivity drops as low as ~ 0.3 in the altitude range of 10-17 km, but does not drop lower.

Figure 6: Retrieved BrO columns and mixing ratios and time evolution.

Top: the total, stratospheric (17.4 – 53.4 km), and tropospheric (1.9 – 17.4 km) BrO VCD, the error bars indicate the total uncertainty; middle: the tropospheric BrO VCD (repeated) is broken into upper FT (7.4 – 17.4 km) and lower FT (1.9 – 7.4 km). Bottom: three mixing ratios retrieved in the lower FT are averaged above the instrument (3.9 – 7.4 km), near the instrument (3.4 – 3.9 km), and below the instrument (1.9 – 3.4 km).

1050

1055 **Figure 7: Overview of CONTRAST RF01 aircraft case study in the vicinity of Mauna Loa Observatory (MLO) on January 11, 2014.**

Approaching from the east, the GV aircraft descended to a missed approach at Kona (descent is denoted RF01-06) then ascended spiraling (RF01-07) into the stratospheric intrusion (not observed on the RF01-06 to the east), finally spiraling descended (RF01-08) out of the intrusion to land in Honolulu. Color coded arrows indicate the viewing direction and approximate maximum horizontal distance sampled by the MT-DOAS near instrument altitude under typical low aerosol conditions at the wavelengths indicated. BrO observed at MLO may be transported from but is not located over the ocean.

1060

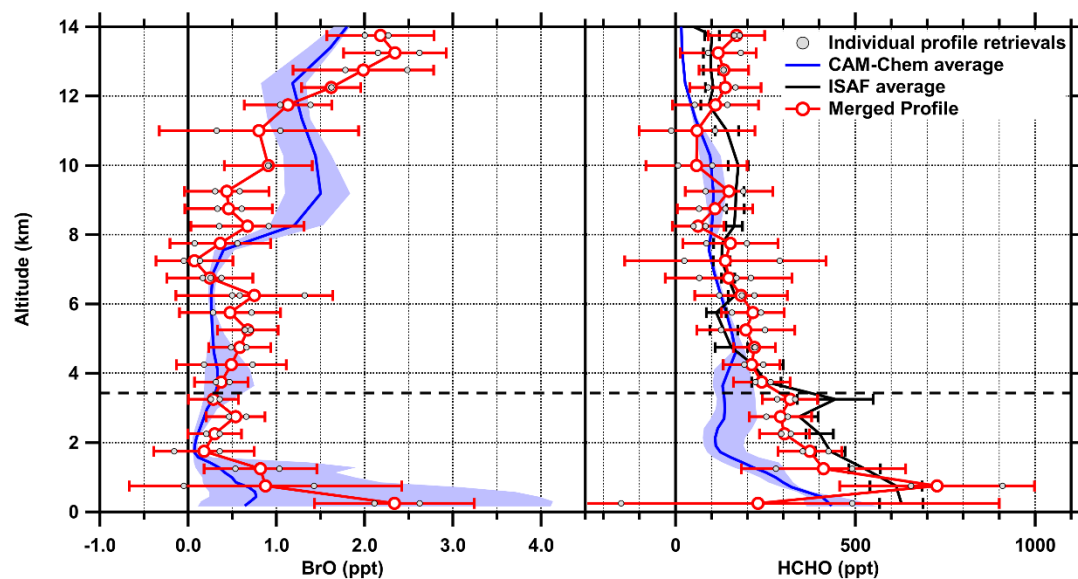

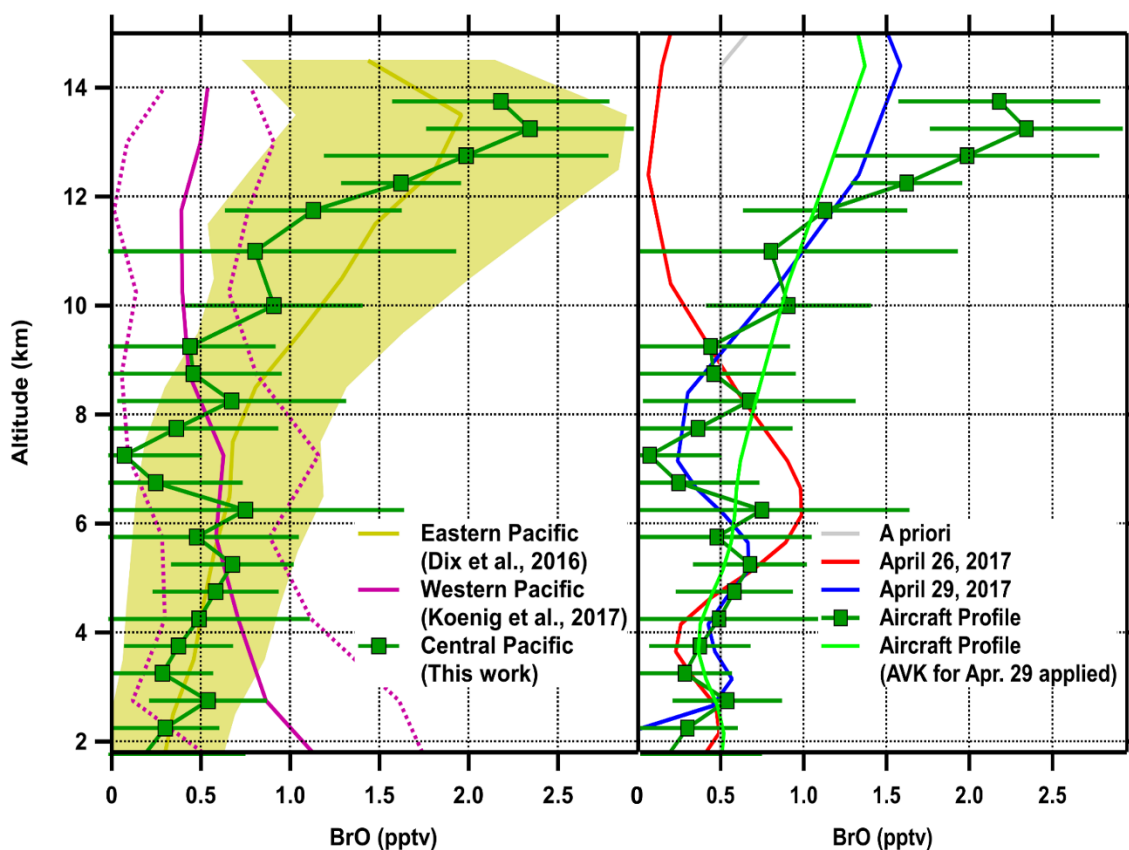

Figure 8: Retrieved BrO and HCHO columns compared with modeled profiles from CAM-Chem and measured by ISAF.

1065

Individual component profiles are shown as small gray points the combined profile is a weighted average. See text for details on averaging and CAM-Chem and ISAF profiles.

1070 **Figure 9: Comparison of MT-DOAS retrieved tropospheric BrO profiles with AMAX-DOAS profiles.**

1075 **Left:** BrO over the Central Pacific Ocean is compared with BrO profiles previously measured over the Eastern Pacific Ocean (Dix et al., 2016) and Western Pacific Ocean (Koenig et al., 2017). All profiles are measured in January and February. **Right:** comparison of the AMAX-DOAS and MT DOAS retrieved profiles reported here. Mountaintop profiles are shown for SZA=70°. Despite measurements occurred three years apart, and utilized different geometries, the BrO profiles for the RW-DT conditions are remarkably similar through most of the troposphere. Applying the MT-AVK to the aircraft profile resolves apparent discrepancies in the uFT.
