6

7 **Abstract.** Hypolimnetic oxygen depletion during summer stratification in lakes can lead to  
8 hypoxic and anoxic conditions. Hypolimnetic anoxia is a water quality issue with many  
9 consequences, including reduced habitat for cold-water fish species, reduced quality of  
10 drinking water, and increased nutrient and organic carbon (OC) release from sediments. Both  
11 allochthonous and autochthonous OC loads contribute to oxygen depletion by providing  
12 substrate for microbial respiration; however, their relative importance in depleting oxygen  
13 across diverse lake systems remains uncertain. Lake characteristics, such as trophic state,  
14 hydrology, and morphometry are also influential in carbon cycling processes and may impact  
15 oxygen depletion dynamics. To investigate the effects of carbon cycling on hypolimnetic  
16 oxygen depletion, we used a two-layer process-based lake model to simulate daily  
17 metabolism dynamics for six Wisconsin lakes over twenty years (1995-2014). Physical  
18 processes and internal metabolic processes were included in the model and were used to  
19 predict dissolved oxygen (DO), particulate OC (POC), and dissolved OC (DOC). In our  
20 study of oligotrophic, mesotrophic, and eutrophic lakes, we found autochthony to be far more  
21 important than allochthony to hypolimnetic oxygen depletion. Autochthonous POC  
22 respiration in the water column contributed the most towards hypolimnetic oxygen depletion  
23 in the eutrophic study lakes. POC water column respiration and sediment respiration had  
24 similar contributions in the mesotrophic and oligotrophic study lakes. **Differences in source**

1

25 ~~of respiration are discussed with consideration of lake productivity.~~ Differences in source of  
26 respiration are discussed with consideration of lake productivity and the processing and fates  
27 of organic carbon loads.

## 68 **1 Introduction**

69

70 ~~Hypolimnetic oxygen depletion impacts lake ecosystems through its influences on lake~~

71 ~~habitat and organic carbon (OC) cycling (Cole & Weihe 2016). In many lakes, oxygen~~

72 ~~depletion results in hypoxia and even anoxia (Nürnberg 1995). Hypolimnetic anoxia reduces~~

73 ~~habitat availability for cold-water fish species (Magee et al. 2019), reduces quality of~~

74 ~~drinking water (Bryant et al. 2011), and can lead to elevated nutrient and OC release from~~

75 ~~lake sediments (Hoffman et al. 2013, McClure et al. 2020). The formation of hypolimnetic~~

76 ~~anoxia is associated with many internal and external lake characteristics, such as trophic~~

77 ~~status (Rhodes et al., 2017; Rippey & McSorley, 2009), lake morphometry (Livingstone &~~

78 ~~Imboden, 1996), and hydrology (Nürnberg 2004). An increase in the prevalence of~~

79 ~~hypolimnetic anoxia and associated water quality degradation in temperate lakes indicates~~

80 ~~the need to better understand how lake ecological processes interact with external forcing to~~

81 ~~lead to the development of anoxia (Jane et al. 2021).~~

82

83 ~~Hypolimnetic anoxia can occur when water column and sediment microbial respiration rates~~

84 ~~exceed rates of oxygenation over an extended period. The conditions supporting oxygen~~

85 ~~depletion are the outcomes of complex ecosystem processes and the interactions of the lake~~

86 ~~with its climate and landscape settings (Jenny et al. 2016a, 2016b). Autochthonous OC~~

87 ~~inputs vary considerably across trophic gradients and are a labile substrate for microbial~~

88 ~~respiration that can contribute substantially to hypolimnetic anoxia (Müller et al. 2012,~~

89 ~~2019). Allochthonous OC sources have also been shown to impact dissolved oxygen (DO)~~

90 and carbon dynamics in lakes by providing a more consistent and recalcitrant substrate for  
91 respiration (Hanson et al. 2014, Solomon et al. 2015). Non-biological factors can be  
92 important as well, such as the watershed loading of allochthonous OC, which can influence  
93 the overall lability of OC in a lake and the rate of DO depletion (Hotchkiss et al. 2018).  
94 Physical factors, such as stratification onset, water column stability, and vertical mixing, can  
95 control the transport of DO from oxygen-rich upper layers to the lower layers of a lake, and  
96 can therefore limit oxygen availability in the hypolimnion (Snorheim et al. 2017, Ladwig et  
97 al. 2021). Lake morphometry can influence the spatial extents of stratified layers, which can  
98 have profound effects on hypolimnetic volume and its capacity to hold DO as well as the rate  
99 of sediment oxygen consumption, which can both influence anoxia onset in lakes  
100 (Livingstone & Imboden 1996). Thus, the sources and lability of OC, lake morphometry, and  
101 lake hydrodynamics all contribute to hypolimnetic oxygen depletion rates, making it an  
102 emergent ecosystem property with a plethora of causal relationships to other ecologically  
103 important variables.

104  
105 Although previous studies have investigated contributions of allochthonous and  
106 autochthonous OC to lake carbon cycling (Hanson et al. 2014, McCullough et al. 2018), the  
107 effects on formation of hypolimnetic anoxia deserves further exploration (Hanson et al.  
108 2015). The magnitude and relative balance of the sources of OC loads relates to hypolimnetic  
109 anoxia across trophic and hydrology gradients (Rhodes et al., 2017; Rippey and McSorley,  
110 2009, Hanson et al. 2014). These gradients affect the relative contributions of autochthony  
111 and allochthony in a lake, which further control the lability and fates (respiration, burial,

112 export) of OC. The lability of OC relates to its form and its source (Hotchkiss et al. 2018,  
113 Catalán et al. 2016). Autochthonous POC and DOC tend to be much more labile than  
114 allochthonous OC (Amon & Brenner 1996, Thorpe & Delong 2002), thus understanding both  
115 the forms of OC and their origins, in addition to their magnitudes, informs our understanding  
116 of the controls over lake respiration. Quantifying the contribution of these different factors to  
117 hypolimnetic anoxia is crucial to understanding its drivers across lakes and through time.

118

119 The availability of long-term observational data combined with process-based models  
120 provides an opportunity to investigate OC sources and their control over the dynamics of lake  
121 DO across multiple time scales. Long-term studies of lakes on regional and global scales  
122 highlight how environmental trends can influence metabolic processes in lakes, and how  
123 lakes can broaden our understanding of large-scale ecosystem processes (Richardson et al.  
124 2017, Kraemer et al. 2017, Williamson et al. 2008). For example, long-term studies allow us  
125 to investigate the impact that current and legacy conditions have on lake ecosystem function  
126 in a given year (Carpenter et al. 2007). Process-based modeling has been used to investigate  
127 metabolism dynamics and understand both lake carbon cycling (Hanson et al. 2004, Cardille  
128 et al. 2007) and formation of anoxia (Ladwig et al. 2022); however, explicitly tying lake  
129 carbon cycling and metabolism dynamics with long-term hypolimnetic DO depletion across a  
130 variety of lakes remains largely unexplored. The combination of process-based modeling  
131 with available long-term observational data, including exogenous driving data representative  
132 of climate variability, can be especially powerful for recreating representations of long-term  
133 lake metabolism dynamics (Staehr et al. 2010, Cardille et al. 2007).

134

135 ~~In this study, our goal is to investigate OC source contributions to lake carbon cycling and~~  
136 ~~hypolimnetic oxygen depletion. We are particularly interested in the relative loads of~~  
137 ~~autochthonous and allochthonous OC to lakes and how they contribute to hypolimnetic DO~~  
138 ~~depletion across seasonal to decadal scales. We use a process-based lake metabolism model,~~  
139 ~~combined with daily external driving data and long-term limnological data, to study six lakes~~  
140 ~~within the North Temperate Lakes Long-Term Ecological Research network (NTL-LTER)~~  
141 ~~over a twenty-year period (1995-2014). We address the following questions: (1) What are the~~  
142 ~~dominant sources of organic carbon that contribute to hypolimnetic oxygen depletion, and~~  
143 ~~how do their contributions differ across a group of diverse lakes over two decades? (2) How~~  
144 ~~do lake trophic state, hydrology, and morphometry influence the processing and fates of~~  
145 ~~organic carbon loads in ways that affect hypolimnetic dissolved oxygen?~~

146 Hypolimnetic oxygen depletion is a persistent and global phenomenon that degrades lake  
147 ecosystems services (Nurnberg 1995; Cole & Weihe 2016; Jenny et al. 2016). In lakes where  
148 oxygen depletion results in hypoxia and even anoxia, habitat availability for cold-water fish  
149 species is eliminated (Magee et al. 2019), quality of drinking water is reduced (Bryant et al.  
150 2011), and nutrient and OC release from lake sediments becomes elevated (Hoffman et al.  
151 2013, McClure et al. 2020). An increase in the prevalence of hypolimnetic anoxia and  
152 associated water quality degradation in temperate lakes indicates the need to better  
153 understand how lake ecological processes interact with external forcings, such as hydrology  
154 and nutrient inputs, to control the development of anoxia (Jenny et al, 2016 a,b).

155

156 Allochthonous organic carbon (OC) loading to lakes that explains the prevalence of negative  
157 net ecosystem production (i.e., net heterotrophy) provides substrate for hypolimnetic oxygen  
158 depletion (Houser et al. 2003). Allochthonous OC sources have also been shown to influence  
159 dissolved oxygen (DO) and carbon dynamics in lakes by providing recalcitrant substrate for  
160 respiration (Cole et al. 2002; Hanson et al. 2014, Solomon et al. 2015). In lake surveys,  
161 dissolved allochthonous OC correlates positively with net heterotrophy ((Jansson et al.  
162 2000), indicating the importance of allochthony to both the carbon balance and dynamics of  
163 dissolved gases (Prairie et al. 2002; Hanson et al. 2003). However, the persistent and often  
164 stable concentration of allochthonous DOC in the water column of lakes also indicates its  
165 recalcitrant nature, raising the question of whether allochthony alone can support high  
166 oxygen demand in the sediments and deeper waters of lakes.

167  
168 The contributions of OC from autochthony to hypolimnetic oxygen depletion may be  
169 important as well, despite its low concentrations relative to that of allochthonous OC in many  
170 lakes (Cole et al. 2002). Autochthonous OC tends to be highly labile (Amon & Brenner 1996,  
171 Thorpe & Delong 2002), and spot samples from lake surveys may not detect autochthonous  
172 DOC, reducing its power as a correlate of ecosystem function. Positive correlation between  
173 anoxia and lake phosphorus concentrations suggests autochthony may contribute  
174 substantially to hypolimnetic oxygen demand (Rhodes et al. 2017; Rippey & McSorley,  
175 2009; Jenny et al. 2016a,b); however, the link between nutrient concentrations, autochthony,  
176 and hypolimnetic respiration is rarely quantified. Lakes with high autochthony can still be net  
177 heterotrophic (Staehr et al. 2010; Cole et al. 2000), however, it matters where in the lake  
178 autochthony is respired. Export of phytoplankton from the epilimnion to the hypolimnion and

179 sediments contributes to deep water oxygen demand (Müller et al. 2012; Rhodes et al. 2017;  
180 Beutel 2003), and the magnitude and timing of organic carbon inputs to deeper waters in  
181 lakes and the subsequent fate of that carbon deserves further exploration.

182  
183 Understanding the relative importance of autochthony and allochthony to hypolimnetic  
184 oxygen depletion requires consideration of a number of physical and biological processes  
185 controlling oxygen sources and sinks in lakes (Hanson et al. 2015). For dimictic north  
186 temperate lakes, the timing and dynamics of seasonal stratification determine the ambient  
187 temperature and light conditions for metabolism and the extent to which the hypolimnion is  
188 isolated from oxygen-rich surface waters (Snorheim et al. 2017, Ladwig et al. 2021). In  
189 many lakes, the hypolimnion is below the euphotic zone, but in very clear lakes, primary  
190 production within the hypolimnion may be an oxygen source (Houser et al. 2003). Lake  
191 morphometry influences the spatial extents of stratified layers, which determines the ratio of  
192 hypolimnetic volume to sediment surface area and the magnitude the sediment oxygen sink  
193 for the hypolimnetic oxygen budget (Livingstone & Imboden 1996). Thus, the sources and  
194 labilities of OC, lake morphometry, and lake hydrodynamics all contribute to hypolimnetic  
195 oxygen budgets, making it an emergent ecosystem property with a plethora of causal  
196 relationships to other ecologically important variables.

197  
198 The availability of long-term observational data combined with process-based models  
199 provides an opportunity to investigate OC sources and their control over the dynamics of lake  
200 DO across multiple time scales. Long-term studies of lakes on regional and global scales  
201 highlight how environmental trends can influence metabolic processes in lakes, and how

202 lakes can broaden our understanding of large-scale ecosystem processes (Richardson et al.  
203 2017, Kraemer et al. 2017, Williamson et al. 2008). For example, long-term studies allow us  
204 to investigate the impact that current and legacy conditions have on lake ecosystem function  
205 in a given year (Carpenter et al. 2007). Process-based modeling has been used to investigate  
206 metabolism dynamics and understand both lake carbon cycling (Hanson et al. 2004, Cardille  
207 et al. 2007) and formation of anoxia (Ladwig et al. 2022); however, explicitly tying lake  
208 carbon cycling and metabolism dynamics with long-term hypolimnetic DO depletion across a  
209 variety of lakes remains largely unexplored. The combination of process-based modeling  
210 with available long-term observational data, including exogenous driving data representative  
211 of climate variability, can be especially powerful for recreating representations of long-term  
212 lake metabolism dynamics (Staeher et al. 2010, Cardille et al. 2007).

213  
214 In this study, our goal is to investigate OC source contributions to lake carbon cycling and  
215 hypolimnetic oxygen depletion. We are particularly interested in the relative loads of  
216 autochthonous and allochthonous OC to lakes and how they contribute to hypolimnetic DO  
217 depletion across seasonal to decadal scales. We use a process-based lake metabolism model,  
218 combined with daily external driving data and long-term limnological data, to study six lakes  
219 within the North Temperate Lakes Long-Term Ecological Research network (NTL LTER)  
220 over a twenty-year period (1995-2014). We address the following questions: (1) What are the  
221 dominant sources of organic carbon that contribute to hypolimnetic oxygen depletion, and  
222 how do their contributions differ across a group of diverse lakes over two decades? (2) How  
223 does lake trophic state influence the processing and fates of organic carbon loads in ways that  
224 affect hypolimnetic dissolved oxygen?

225

## 226 **2 Methods**

### 227 **2.1 Study Site**

228 This study includes six Wisconsin lakes from the NTL-LTER program (Magnuson et al.  
229 2006). Trout Lake (TR), Big Muskellunge Lake (BM), Sparkling Lake (SP), and Allequash  
230 Lake (AL) are in the Northern Highlands Lake District of Wisconsin and have been regularly  
231 sampled since 1981 (Magnuson et al. 2006). Lake Mendota (ME) and Lake Monona (MO)  
232 are in southern Wisconsin and have been regularly sampled by the NTL-LTER since 1995  
233 (NTL-LTER, Magnuson et al. 2006). The NTL-LTER provides a detailed description of each  
234 lake (Magnuson et al. 2006). The six lakes span gradients in size, morphometry, landscape  
235 setting, and hydrology, which creates diverse carbon cycling characteristics and processes  
236 across these systems. TR and AL are drainage lakes with high allochthonous carbon inputs  
237 from surface water, while BM and SP are groundwater seepage systems with allochthony  
238 dominated by aerial OC inputs from the surrounding landscape (Hanson et al. 2014). All four  
239 northern lakes (TR, AL, BM, SP) are surrounded by a forested landscape. ME and MO are  
240 both eutrophic drainage lakes surrounded by an urban and agricultural landscape. [Although](#)  
241 [the full range of DOC concentrations for lakes in northern Wisconsin varies from about 2 to](#)  
242 [>30 mg L<sup>-1</sup> \(Hanson et al. 2007\), DOC concentrations among our study lakes covered a](#)  
243 [relatively narrow range typical of non-dystrophic lakes in Wisconsin \(Hanson et al. 2007\)](#)  
244 [and are near the global averages previously estimated, i.e., 3.88 mg/L \(Toming et al. 2020\)](#)  
245 [and 5.71 mg/L \(Sobek et al. 2007\), respectively.](#) Morphometry, hydrology, and other  
246 information can be found in Table 1.

247  
248  
249  
250  
251  
252

**Table 1.** Physical and biogeochemical characteristics of the study lakes. The table includes lake area (Area), maximum depth (Zmax), hydrologic residence time (RT), mean annual temperature (Temp), mean annual surface total phosphorus concentration (Mean TP), and mean annual surface DOC (Mean DOC).

Lake	Area (ha)	Zmax (m)	RT <sup>3,4</sup> (years)	Temp <sup>2</sup> (°C)	Mean TP <sup>1</sup> (µg/L)	Mean DOC <sup>1</sup> (mg/L)
Allequash Lake (AL)	168.4	8	0.73	10.5	14	3.9
Big Muskellunge (BM)	396.3	21.3	5.1	10.5	7	3.8
Sparkling Lake (SP)	64	20	8.88	10.6	5	3.12
Trout Lake (TR)	1607.9	35.7	5.28	9.8	5	2.8
Mendota (ME)	3961	25.3	4.3	12.5	50	5.6
Monona (MO)	1324	22.5	0.7	13.8	47	5.8

260

## 261 2.2 Driving Data and Limnological Data

262 Most driving data for the model is provided by the “Process-based predictions of water  
263 temperature in the Midwest US” USGS data product (Read et al. 2021). This includes lake  
264 characteristic information such as lake area and hypsometry, daily modeled temperature  
265 profiles, ice flags, meteorology data, and solar radiation for the six study lakes. Derived  
266 hydrology data is used in calculating daily OC loading and outflow for the study lakes.  
267 Hydrology for the northern lakes is taken from Hunt & Walker (2017), which was estimated  
268 using a surface and groundwater hydrodynamic model. Hydrology for ME is taken from  
269 Hanson et al. (2020), which used the Penn State Integrated Hydrologic Model (Qu & Duffy  
270 2007). We assume for ME and MO that evaporation from the lake surface is approximately  
271 equal to precipitation on the lake surface and that groundwater inputs and outputs to the lake  
272 are a small part of the hydrologic budgets (Lathrop & Carpenter 2014). Therefore, ME  
273 outflow is assumed to be equal to ME inflow. ME is the predominant hydrologic source for  
274 MO (Lathrop & Carpenter 2014), thus, MO inflow is assumed to be equal to ME outflow,  
275 and MO outflow is assumed to be equal to MO inflow. We found that the derived discharge  
276 data for ME, TR, AL, and SP was approximately 20-50% higher than previously reported  
277 values (Hunt et al. 2013, Webster et al. 1996), depending on the lake, while hydrology in BM  
278 was approximately 25% too low (Hunt et al. 2013). To accommodate this issue, we adjusted  
279 total annual hydrological inputs to match published water residence times for each lake  
280 (Table 1), while retaining temporal hydrological patterns. NTL-LTER observational data are  
281 interpolated to estimate daily nutrient concentration values, which are used in calculating  
282 daily primary production in the model (Magnuson et al. 2020).

283

284 The NTL-LTER observational data used to calibrate and validate the model for the six lakes  
285 include DO, DOC, and Secchi depth (Magnuson et al. 2020, Magnuson et al. 2022).  
286 Saturation values for DO and gas exchange velocity used in calculating atmospheric  
287 exchange for DO are calculated using the “o2.at.sat.base” and using the Cole and Caraco gas  
288 exchange method from the “K600.2.KGAS.base” function within the USGS  
289 “LakeMetabolizer” package in R (Winslow et al. 2016).

290

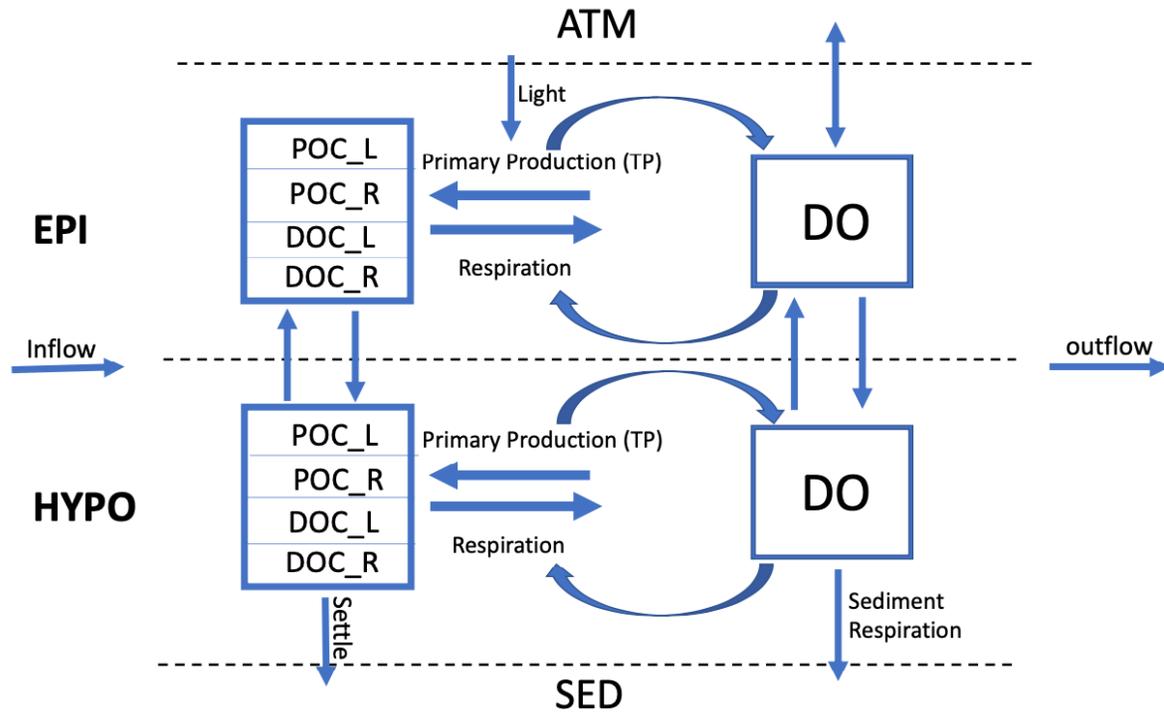

### 291 **2.3 The Model**

292 The goal of our model is to use important physical and metabolic processes involved in the  
293 lake ecosystem carbon cycle to best predict DO, DOC, and POC, while keeping the model  
294 design simple in comparison with more comprehensive water quality models (e.g., Hipsey et  
295 al. 2019 2022). We ran our model with a daily time step over a twenty-year period (1995-  
296 2014) for each lake and included seasonal physical dynamics, such as lake mixing,  
297 stratification, and ice cover from Read et al. 2021. Throughout each year, the model tracks  
298 state variables and fluxes in the lake for each day (Fig. 1). These state variables include DO  
299 and the labile and recalcitrant components of particulate organic carbon (POC) and dissolved  
300 organic carbon (DOC). Initial conditions for each state variable are based on literature  
301 values or lake observational data (SI Table 5). The model is initialized on January 1st of the  
302 first year, so we set the initial labile POC mass to zero under the assumption that the  
303 concentration is low in the middle of winter. The initial DO value is set to the saturation  
304 value based on the conditions of the initial model run day and is calculated using the  
305 LakeMetabolizer R package (Winslow et al. 2016). During stratified periods, the state

306 variables and fluxes for the epilimnion and hypolimnion are tracked independently.

307 Atmosphere, sediments, and hydrologic inputs and outputs are boundary conditions.

308

309

310 **Figure 1.** Conceptual lake model showing state variables (boxes) and fluxes (arrows). The  
311 model has two thermal layers under stratified conditions, as shown here, and tracks state  
312 variables separately for each layer. The sediment (SED), atmosphere (ATM), inflow and  
313 outflow are system boundaries. The state variables included are DO (dissolved oxygen),  
314 DOC\_L (labile dissolved organic carbon), DOC\_R (recalcitrant dissolved organic carbon),  
315 POC\_L (labile particulate organic carbon), and POC\_R (recalcitrant particulate organic  
316 carbon). ~~Inorganic carbon (IC) is not tracked in the model and is assumed to be a non-~~  
317 ~~limiting substrate to primary production.~~ Observed total phosphorus (TP) is used as a driving  
318 variable for primary production in the model.

319

320 The model is built specifically for this analysis; however, many of the assumptions around

321 the model complexity and mathematical formulations are borrowed from literature cited

322 (Ladwig et al. 2022, Hipsey et al. 2022, Hanson et al. 2014, McCullough et al. 2018). We

323 chose to develop our own process-based model rather than use an existing model, such as

324 GLM (Hipsey et al. 2022) or Simstrat (Goudsmit et al. 2002), so that we could simulate and  
325 measure the specific metabolism fluxes related to our study questions.

326

### 327 **2.3.1 Stratification Dynamics**

328 Lake physical dynamics are taken from the output of a previous hydrodynamic modeling  
329 study on these same lakes over a similar time period (Read et al. 2021), which used the  
330 General Lake Model (Hipsey et al. 2019). Before running the metabolism model, a  
331 thermocline depth for each time step is estimated using derived temperature profiles for each  
332 lake (Read et al. 2021) by determining the center of buoyancy depth (Read et al. 2011). After  
333 calculating the thermocline depth, the volumes and average temperatures for each layer, and  
334 the specific area at thermocline depth are determined using lake-specific hypsography. The  
335 criteria for stratification include a vertical density gradient between the surface and bottom  
336 layer of at least  $0.05 \text{ kg m}^{-3}$ , an average water column temperature above  $4 \text{ }^{\circ}\text{C}$ , and the  
337 presence of a derived thermocline (Ladwig et al. 2022). For any day that does not meet all of  
338 these criteria, the water column is considered to be fully mixed. The thermocline depth  
339 values are smoothed using a moving average with a window size of 14 days to prevent large  
340 entrainment fluxes that can destabilize the model at very short time scales when thermal  
341 strata are shallow. During mixed periods, the entire lake is treated as the epilimnion, and a  
342 separate hypolimnion is not incorporated into the model dynamics. Ice cover in the model is  
343 determined using the “ice flag” provided in the derived temperature profile data from Read et  
344 al. (2021). Our metabolism model does simulate under-ice conditions, however we do not  
345 include the presence of inverse stratification during winter periods.

346

### 347 **2.3.2 External Lake and Environment Physical Fluxes**

348 Atmospheric exchange of DO, external loading of OC, and outflow of OC are the three  
349 environmental boundary fluxes accounted for in the water quality model (Table 3 Eq. 9-11).

350 The gas exchange velocity for atmospheric exchange is determined using the Cole and  
351 Caraco model (1998) and is calculated using the LakeMetabolizer R package (Winslow et al.  
352 2016). Oxygen saturation values are also calculated using this package. During ice covered  
353 conditions, we assume that the atmospheric exchange value is ten percent of the value during  
354 non-ice covered conditions based on sea ice gas exchange estimates (Loose and Schlosser,  
355 2011).

356

357 ~~For the northern lakes (TR, AL, BM, SP), we use the allochthonous OC load and recalcitrant~~  
358 ~~OC export values from Hanson et al. (2014) to calibrate total annual allochthonous OC load~~  
359 ~~and recalcitrant OC export in our model. We specifically use the allochthonous OC load~~  
360 ~~values in this study to assist in the manual calibration of inflow recalcitrant POC and DOC~~  
361 ~~concentrations for each lake. For the southern lakes (ME, MO), we also use derived~~  
362 ~~hydrology information (Hanson et al. 2020), but only for discharge that is the inflow for ME.~~  
363 ~~We assume for ME and MO that evaporation from the lake surface is approximately equal to~~  
364 ~~precipitation on the lake surface and that groundwater inputs and outputs to the lake are a~~  
365 ~~small part of the hydrologic budgets (Lathrop & Carpenter 2014). Therefore, ME outflow is~~  
366 ~~assumed to be equal to ME inflow. ME is the predominant hydrologic source for MO~~  
367 ~~(Lathrop & Carpenter 2014), thus, MO inflow is assumed to be equal to ME outflow, and~~

368 ~~MO outflow is assumed to be equal to MO inflow. ME allochthonous load is calibrated based~~  
369 ~~on model fitting and observational data (Hart et al. 2019). MO inflow concentrations are~~  
370 ~~equivalent to the in-lake epilimnetic concentrations of OC from ME at each model time step.~~  
371 ~~The OC loads for MO are calibrated based on the total allochthonous load found in~~  
372 ~~McCullough et al. 2018.~~

373

374 For the northern lakes (TR, AL, BM, SP), we assume that allochthonous OC loads consist of  
375 entirely recalcitrant substrates. We verify total OC load, total inflow concentration, and  
376 recalcitrant OC export values with estimates from Hanson et al. (2014). For ME, we verify  
377 the total annual allochthonous OC load and OC inflow concentrations against observed  
378 inflow data from Hart et al. (2017) by back calculating inflow concentrations based on the  
379 modeled OC equilibrium of the lake. MO inflow concentrations are equivalent to the in-lake  
380 epilimnetic concentrations of OC from ME at each model time step. The total OC loads for  
381 MO are verified based on the total allochthonous load found in McCullough et al. 2018.

382

383 **Table 2.** Equations for the model, organized by state variables, [*DO* (dissolved oxygen),  
384 *DOCL* (labile dissolved organic carbon), *DOCR* (recalcitrant dissolved organic carbon),  
385 *POCL* (labile particulate organic carbon), *POCR* (recalcitrant particulate organic carbon),  
386 *Secchi*] and relevant fluxes. *Note:* The entrainment flux (*Entr*) is only included during  
387 thermally stratified periods. The inflow (*IN*) and outflow (*OUT*) fluxes are not included in  
388 the calculations for the hypolimnetic layer. **The inflow of labile DOC (*IN<sub>DOCL</sub>*) parameter in**  
389 **Eq. 2 is only used for calculating allochthonous OC loads for MO.** Atmospheric gas  
390 exchange of dissolved oxygen (*AtmExch*) is not included for the hypolimnetic DO  
391 calculation. Normalized total phosphorus is represented by (*TP<sub>norm</sub>*). The volume (*V*) term  
392 represents the respective lake layer volume, or the discharge volume for the inflow and  
393 outflow equations. The term (*r<sub>rate</sub>*) is included in Eq. 13 to represent the respiration rates of  
394 the different OC pools. It is included to simplify the table of equations. Terms not defined  
395 here are included in Table 3.

396

<i>State Variables</i>
------------------------

<b>DO [gDO]</b> $\frac{dDO}{dt} = (NPP * O2_{convert}) + AtmExch + Entr_{DO} - (R_{sed} * O2_{convert}) - (R_{wc} * O2_{convert})$	(1)
<b>DOCL [gC]</b> $\frac{dDOCL}{dt} = (NPP * (1 - C_{NPP})) + IN_{DOCL} + Entr_{DOCL} - R_{DOCL} - OUT_{DOCL}$	(2)
<b>DOCR [gC]</b> $\frac{dDOCR}{dt} = IN_{DOCR} + Entr_{DOCR} - OUT_{DOCR} - R_{DOCR Epi}$	(3)
<b>POCL [gC]</b> <b>Mixed and Epi:</b> $\frac{dPOCL}{dt} = (NPP_{Epi} * C_{NPP}) + IN_{POCL} + Entr_{POCL} - R_{POCL Epi} - Settle_{POCL Epi} - OUT_{POCL}$	(4)
<b>Hypo:</b> $\frac{dPOCL}{dt} = (NPP_{Hypo} * C_{NPP}) + Settle_{POCL Epi} - Settle_{POCL Hypo} - R_{POCL Hypo} - Ent_{POCL}$	(5)
<b>POCR [gC]</b> <b>Mixed and Epi:</b> $\frac{dPOCR}{dt} = IN_{POCR} + Entr_{POCR} - OUT_{POCR} - R_{POCR Epi} - Settle_{POCR Epi}$	(6)
<b>Hypo:</b> $\frac{dPOCR}{dt} = Settle_{POCR Epi} - Settle_{POCR Hypo} - R_{POCR Hypo} - Entr_{POCR}$	(7)
<b>Secchi [m]</b> $Secchi = \frac{1.7}{K_{LEC}}$	(8)
<b>Fluxes</b>	
<b>Atm exchange [gDO d<sup>-1</sup>]</b> $AtmExch = K_{DO} * (DO_{sat} - DO_{prediction}) * Area_{sfc}$	(9)
<b>Inflow [gC d<sup>-1</sup>]</b> $IN = Carbon\ Concentration_{inflow} * V_{inflow}$	(10)
<b>Outflow [gC d<sup>-1</sup>]</b> $OUT = Carbon\ Concentration_{outflow} * V_{outflow}$	(11)
<b>Net Primary Productivity [gC d<sup>-1</sup>]</b> $NPP = Pmax * (1 - e^{(-IP * \frac{Light}{Pmax})}) * TP_{norm} * \theta_{NPP}^{(T-20)} * V$	(12)
<b>Respiration [gC d<sup>-1</sup>]</b> $R_{wc} = Carbon\ Pool * r_{rate} * \theta_{Resp}^{(T-20)} * \frac{DO\ Concentration}{DO_{1/2} + DO\ Concentration}$	(13)
<b>Sediment Respiration [gC d<sup>-1</sup>]</b> $R_{sed} = r_{sed} * \theta_{Resp}^{(T-20)} * \frac{DO\ Concentration}{DO_{1/2} + DO\ Concentration} * Area_{sed}$	(14)
<b>POC settle [gC d<sup>-1</sup>]</b> $Settle = (POC\ Pool * K_{POC}) * \frac{Area}{V}$	(15)
<b>Entrainment [gC d<sup>-1</sup>]</b> $V_{Entr} = V_{epi}(t) - V_{epi}(t - 1)$	(16)
$V_{Entr} > 0$ (Epilimnion growing) $Entr = \frac{V_{Entr}}{V_{Hypo}} * Carbon\ Pool_{Hypo}$	(17)
$V_{Entr} < 0$ (Epilimnion shrinking) $Entr = \frac{V_{Entr}}{V_{Epi}} * Carbon\ Pool_{Epi}$	(18)
<b>Light [W m<sup>-2</sup>]</b> $Light = \int_{z_1}^{z_2} (I_{z_1} * e^{-(K_{LEC} * z)}) dz * (1 - \alpha)$	(19)
<b>Light Extinction Coefficient [Unitless]</b> $K_{LEC} = LEC_{water} + (LEC_{POC} * ((\frac{POCL}{V}) + (\frac{POCR}{V}))) + (LEC_{DOC} * ((\frac{DOCL}{V}) + (\frac{DOCR}{V})))$	(20)

397

### 398 2.3.3 Internal Lake Physical Fluxes

399 The two in-lake physical fluxes included in the model are POC settling and entrainment of all  
400 state variables. POC settling is the product of a sinking rate ( $\text{m d}^{-1}$ ) and the respective POC  
401 pool (g), divided by the layer depth (m) (Table 3 Eq. 15). Sinking rates are either borrowed  
402 from literature values (Table 3) or fit during model calibration (see below). Entrainment is  
403 calculated as a proportion of epilimnetic volume change (Table 2 Eq. 17-18). A decrease in  
404 epilimnetic volume shifts mass of state variables from the epilimnion into the hypolimnion,  
405 and an increase in volume shifts mass from the hypolimnion to the epilimnion.

406

407 ~~Table 3. Model Parameters, grouped by static and free parameters~~

408

409

410 **Table 3.** Model Parameters, grouped into three categories: constants, which are values that  
411 were not tuned; manually calibrated, which are parameters manually tuned, typically guided  
412 by ranges from the literature; and parameters calibrated through constrained parameter  
413 search, which are calibrated through an automated search of parameter space.

414

Parameter	Abbreviation	Value	Units	Source
<b>Constants</b>				
Conversion of Carbon to Oxygen	$O2_{convert}$	2.67	Unitless	Mass Ratio of C:O
Respiration rate of DOCR	$r_{DOCR}$	0.001	$day^{-1}$	(Hanson et al., 2011)
Respiration rate of POOCR	$r_{POOCR}$	0.005	$day^{-1}$	Taken from ranges provided in (Hanson et al. 2004)
Respiration rate of POOCR	$r_{POOCR}$	0.005	$day^{-1}$	Taken from ranges provided in (Hanson et al. 2004)
Respiration rate of POCL	$r_{POCL}$	0.2	$day^{-1}$	Taken from ranges provided in (Hipsey et al. 2022)

Parameter	Abbreviation	Value	Units	Source
Michaelis-Menten DO half saturation coefficient	$DO_{1/2}$	0.5	$g\ m^{-3}$	Taken from ranges provided in (Hipsey et al. 2022)
Light extinction coefficient of water	$LEC_{water}$	0.125	$m^{-1}$	Taken from ranges in Hart et al. (2017)
Ratio of DOC to POC production from NPP	$C_{NPP}$	0.8	Unitless	Biddanda & Benner (1997)
Albedo	$\alpha$	0.3	Unitless	Global average (Marshall & Plumb, 2008)
Atmospheric gas exchange adjustment during ice covered conditions	$C_{winter}$	0.1	Unitless	Taken from ranges in (Loose & Schlosser, 2011)
Coefficient of light transmitted through ice	$C_{ice}$	0.05	Unitless	Taken from ranges provided in (Lei et al. 2011)
Settling velocity rate of POC_R	$K_{POCR}$	1.2	$m\ day^{-1}$	Taken from ranges found in (Reynolds et al.1987)
Settling velocity rate of POC_L	$K_{POCL}$	1	$m\ day^{-1}$	Taken from ranges ranges found in (Reynolds et al.1987)
Temperature scaling coefficient for NPP	$\theta_{NPP}$	1.12	Unitless	Taken from values provided in (Hipsey et al. 2022) and (Ladwig et al. 2022)
Temperature scaling coefficient for Respiration	$\theta_{Resp}$	1.04	Unitless	Taken from values provided in (Hipsey et al. 2022) and (Ladwig et al. 2022)
<b>Manually calibrated</b>				
Light extinction of DOC	$LEC_{DOC}$	0.02 - 0.06	$m^2\ g^{-1}$	Manually calibrated based on observed Secchi Depth ranges for the study lakes

Parameter	Abbreviation	Value	Units	Source
Light extinction of POC	$LEC_{POC}$	0.7	$m^2 g^{-1}$	Manually calibrated based on observed Secchi Depth ranges for the study lakes
Maximum Daily Productivity	$P_{max}$	0.5-5	$g m^{-3} day^{-1}$	Manually calibrated from mean productivity values from Wetzel (2001)
Recalcitrant DOC inflow concentration	$DOCR_{inflow}$	5-10	$g m^{-3}$	Based on ranges found in (Hanson et al. 2014, McCullough et al. 2018, Hart et al. 2017)
Recalcitrant POC inflow concentration	$POCR_{inflow}$	2-5	$g m^{-3}$	Based on ranges found in (Hanson et al. 2014, McCullough et al. 2018, Hart et al. 2017)
<b>Calibrated through constrained parameter search</b>				
Slope of the irradiance/productivity curve	$IP$	0.045, 0.015	$gCd^{-1}(Wm^{-2})^{-1}$	Based on ranges found in (Platt et al. 1980) and tuned separately for each lake region (South, North)
Sediment respiration flux	$r_{SED}$	0.05 – 0.4	$g m^{-2} day^{-1}$	Based on ranges found in (Ladwig et al. 2021) and (Mi et al. 2020) and fit independently for each lake
Respiration rate of DOCL	$r_{DOCL}$	0.015 - 0.025	$day^{-1}$	Based on ranges found in (McCullough et al. 2018) and fit for each lake independently

415

416

#### 417 2.3.4 Internal Lake Metabolism Fluxes

418 The metabolism fluxes in the model are net primary production (NPP) and respiration (R).

419 Respiration includes water column respiration for each OC state variable in the epilimnion

420 and hypolimnion and is calculated at each time step as the product of the OC state variable

421 and its associated first order decay rate (Table 2, Eq. 13). Sediment respiration for the  
422 hypolimnion during stratified periods and the epilimnion (entire lake) during mixed periods  
423 is a constant daily rate that is individually fit for each lake. [Note that we did not include](#)  
424 [anaerobic carbon metabolism in our modeling approach and discuss potential shortcomings](#)  
425 [in the discussion section](#). We assume inorganic carbon is not a limiting carbon source. In the  
426 model, we consider any DO concentration less than 1 g DO m<sup>-3</sup> to be anoxic (Nürnberg  
427 1995).

428

~~429 NPP is tracked in both the epilimnion and hypolimnion. NPP is a function of light, total  
430 phosphorus concentration, temperature, a maximum productivity coefficient, and a slope  
431 parameter defining the irradiance and productivity curve (Table 2 Eq. 12). We compared our  
432 coefficients for primary production with those found in (Wetzel, 2001), which are in the  
433 following units [mgC/m<sup>2</sup>/day]. Note that such coefficients are not per unit phosphorus, but  
434 rather, subsume lake-specific nutrient concentrations. In order to do our comparison, we  
435 subsumed nutrient concentrations into our calculations of primary production. Our approach  
436 was to remove the mean of observed P and normalize by the P variance. Those two statistical  
437 features of P become subsumed in the estimates of IP and P<sub>max</sub>, but the time dynamics of  
438 normalized P are retained to represent seasonal P dynamics in the lake. Average light in a  
439 layer is calculated for each day and is dependent on the depth of a layer and the light  
440 extinction coefficient (Table 2 Eq. 19). During ice covered conditions, average light is  
441 assumed to be five percent of the average non-ice covered value (Lei et al. 2011). Total  
442 phosphorus concentration in a layer is from observational data for each lake interpolated to~~

443 ~~the daily time scale. The interpolated values are then normalized for each individual lake to~~  
444 ~~drive NPP. These values are normalized so that differences among lakes are only present in~~  
445 ~~the  $IP$  and  $P_{max}$  parameters. The Arrhenius equation provides temperature control for NPP,~~  
446 ~~and we determined through model fitting a  $\theta$  of 1.12. OC derived from NPP is split between~~  
447 ~~particulate and dissolved labile OC production, with eighty percent produced as POC and~~  
448 ~~twenty percent produced as DOC. This ratio was determined through model fitting and is~~  
449 ~~similar to previously reported values (Hipsey et al. 2019).~~

450 NPP is tracked in both the epilimnion and hypolimnion. NPP is a function of light, total  
451 phosphorus concentration, temperature, a maximum productivity coefficient ( $P_{max}$ ), and a  
452 slope parameter defining the irradiance and productivity curve ( $IP$ ) (Table 2 Eq. 12). Total  
453 phosphorus concentration in a layer taken is from observational data for each lake  
454 interpolated to the daily time scale. Maximum daily primary production rates were taken  
455 from Wetzel (2001). As these maximum production rates are not phosphorus-specific but  
456 subsume lake-specific nutrient concentrations, we multiplied them with time-transient,  
457 normalized TP concentrations. Normalizing was done by removing the mean of observed TP  
458 and dividing by TP variance. This allows us to retain the time dynamics of the normalized  
459 TP, which we use to represent seasonal TP dynamics for each lake. The Arrhenius equation  
460 provides temperature control for NPP, and we determined through model fitting a  $\theta$  of 1.12.  
461 All OC derived from NPP is assumed to be labile and is split between particulate and  
462 dissolved OC production, with eighty percent produced as POC and twenty percent produced  
463 as DOC. This ratio was determined through model fitting and is similar to previously  
464 reported values (Hipsey et al. 2022). Average light in a layer is calculated for each day and is

465 dependent on the depth of a layer and the light extinction coefficient (Table 2 Eq. 19). During  
466 ice covered conditions, average light is assumed to be five percent of the average non-ice  
467 covered value (Lei et al. 2011).

468

469 Epilimnetic and hypolimnetic water column respiration is tracked independently for each OC  
470 pool in the model. During mixed periods, there are four OC pools – DOCR, DOCL, POCR,  
471 POCL. During stratified periods, those pools are split into a total of eight pools that are  
472 tracked independently for the epilimnion and hypolimnion. Respiration is calculated as a  
473 product of the mass of a respective variable, a first order decay rate coefficient, temperature,  
474 and oxygen availability (Table 2 Eq. 13). The respiration decay rate coefficients are based on  
475 literature values (Table 3) or were fit during model calibration. An Arrhenius equation is  
476 used for temperature control of respiration, with  $\theta_{Resp}$  equal to 1.04, which was determined  
477 through manual model fitting. The respiration rates fluxes are also scaled by oxygen  
478 availability using the Michaelis-Menten equation with a half saturation coefficient of 0.5 g  
479 DO m<sup>-3</sup>, such that at very low DO concentrations, the respiration flux approaches zero.

480

481 Sediment respiration is calculated from a constant daily respiration flux, adjusted for  
482 temperature and oxygen availability, using the Arrhenius and Michaelis-Menten equations,  
483 respectively (Table 2 Eq. 14). The mass of sediment OC is not tracked in the model. During  
484 stratified periods, we assume that the majority of epilimnetic sediment area is in the photic  
485 zone, and therefore has associated productivity from macrophytes and other biomass. It is  
486 assumed that this background productivity and sediment respiration are of similar magnitude

487 and inseparable from water column metabolism, given the observational data. Therefore,  
488 epilimnetic sediment respiration is not accounted for in the model during stratified  
489 conditions. During mixed conditions, we assume that sediment respiration is active on all  
490 lake sediment surfaces, which are assumed to be equivalent in area to the total surface lake  
491 area. During stratified periods, we use the area at the thermocline as the sediment area for  
492 calculating hypolimnetic sediment respiration.

493

### 494 **2.3.5 Other in-lake calculations and assumptions**

495 We calculate a total light extinction coefficient (LEC) for the epilimnion and hypolimnion.  
496 The total LEC for each layer is calculated by multiplying the dissolved and particulate  
497 specific LEC values with their respective OC state variable concentrations, combined with a  
498 general LEC value for water (Table 2 Eq. 20). This total LEC value is used to calculate a  
499 daily estimate of Secchi depth (Table 2 Eq. 8). The coefficients for the light extinction of  
500 water, DOC, and POC are manually calibrated based on observed Secchi depth ranges for the  
501 study lakes (Table 3, SI Table 5).

502

### 503 ~~2.4 Model calibration and validation~~

504 ~~The model was run for twenty years from 1 January 1995 to 31 December 2014. This period~~  
505 ~~was chosen due to an absence of hydrologic data for the northern lakes after 2014 and~~  
506 ~~because consistent observational data weren't available for the southern lakes until 1995. The~~  
507 ~~first 15 years of the model output was used for calibration and the last 5 years were used for~~  
508 ~~model validation. We chose the first 15 years for calibration because the observational data~~

509 were relatively stable and were not indicative of any large trends in ecosystem processes, as  
510 opposed to the last five years which showed slightly more model deviation from DOC  
511 observational data in the southern lakes (SI Fig. 2).

512

513 Initial conditions for each lake state variable are based on literature values or lake  
514 observational data (SI Table 5). The model is initialized on January 1st of the first year, so  
515 we set the initial labile POC mass to zero under the assumption that the concentration is low  
516 in the middle of winter. The initial DO value is set to the saturation value based on the  
517 conditions of the initial model run day and is calculated using the LakeMetabolizer R  
518 package (Winslow et al. 2016).

519

## 520 **2.5 Model Fitting and Parameter Uncertainty Estimation**

521 The free parameters in the model are the slope of the irradiance/productivity curve (IP), the  
522 respiration rate of labile DOC (Resp\_DOCL), and the respiration rate of the hypolimnetic  
523 sediments (Resp\_sed) (Table 3). These were in part chosen due to the high uncertainty  
524 around the parameter values, and our assumptions that they have a higher impact on  
525 ecosystem dynamics in the model. Optimized values and uncertainties for each free  
526 parameter and lake are included in SI Table 4.

527

528 IP controls the amount of productivity in low light scenarios, and fitting the parameter helps  
529 to calibrate productivity during ice-covered winter conditions as well as during times of high  
530 OC concentrations in the epilimnion. Resp\_DOCL controls the seasonal dynamics of DOC in

531 a lake and treating it as a free parameter helps capture the across-lake variability in DOC  
532 processes related to variations in landscape, hydrology, and productivity. Resp\_sed is  
533 important for controlling hypolimnetic oxygen depletion in lakes and is related to lake  
534 productivity and associated legacy OC in each lake. The Resp\_sed parameter also helps  
535 adjust burial rates for the study lakes. We fit unique IP and Resp\_DOCL values for the  
536 southern lake region (ME, MO), and unique values for the northern region (TR, AL, BM,  
537 SP). Resp\_sed is individually fit for each lake.

538

539 We manually optimized free parameters by manually adjusting them over their respective  
540 ranges to find the parameter values that returned the smallest model residuals (SI Table 4).  
541 Automated optimization proved too computationally demanding. To gain a better sense of  
542 the contributions of parameter uncertainty in the model, we created parameter uncertainty  
543 distributions using standard deviations of 20% of the estimated parameter value. To evaluate  
544 the influence of parameter uncertainties on model predictions, the parameter distributions are  
545 randomly sampled over 100 model iterations to create the uncertainty bounds for all  
546 predictions of model state variables and fluxes.

547

548 During the model fitting, errors in modeled DO, DOC, and Secchi depth are weighted  
549 equally in the southern lakes. In the northern lakes, fitting Secchi depth was challenging.  
550 Initial model fits revealed that patterns in observed Secchi did not show regular seasonality  
551 and were highly stochastic. Therefore, we use a moving average on observational data and  
552 predictions of Secchi depth and calculate the residuals as the difference between the two

553 ~~averaged time series. This is done to remove stochasticity from the observational data and fit~~  
554 ~~the model predictions to the average observed Secchi value. We use a moving average~~  
555 ~~window of 15 observations because we want to capture the average annual Secchi depth~~  
556 ~~trend, and there are roughly 15 observations per year.~~

## 557 **2.4 Model Sensitivity and Parameter Calibration**

558 To better understand the sensitivities of the model output to parameter values, we performed  
559 a sensitivity analysis of the model parameters using the global sensitivity method from  
560 Morris (1991). The sensitivity analysis showed that there were nine parameters to which the  
561 model was consistently sensitive across the six study lakes. This group included the ratio of  
562 DOC to POC produced from NPP ( $C_{NPP}$ ), the maximum daily productivity parameter  
563 ( $P_{max}$ ), the inflow concentration of recalcitrant POC ( $POCR_{inflow}$ ), the settling velocity of  
564 recalcitrant POC ( $K_{POCR}$ ), the temperature fitting coefficients for productivity and respiration  
565 ( $\theta_{NPP}$ ,  $\theta_{Resp}$ ) the slope of the irradiance/productivity curve ( $IP$ ), the sediment respiration flux  
566 ( $r_{SED}$ ), and the respiration rate of DOCL ( $r_{DOCL}$ ). We chose a subset of the nine parameters to  
567 include in the uncertainty analysis based on the following justifications. The model results  
568 showed that recalcitrant substrates are of lesser importance for lake metabolism dynamics, so  
569 we chose not to further investigate the uncertainty of the  $POCR_{inflow}$  and  $K_{POCR}$  parameters.  
570 The  $P_{max}$  and  $IP$  parameters are directly correlated, so we chose to remove  $P_{max}$  from  
571 further uncertainty considerations. The  $\theta_{NPP}$  and  $\theta_{RESP}$  parameters act as substitutes for water  
572 temperature, a well-known “master variable” in water quality modeling, and directly reflect  
573 seasonality in the model. Therefore, we chose to omit these parameters for further  
574 uncertainty calculations. The final subset of parameters for uncertainty analysis consisted of

575  $C_{NPP}$ ,  $r_{DOCL}$ ,  $r_{SED}$ , and  $IP$ . Of the four parameters, we felt  $C_{NPP}$  was best constrained by the  
576 literature. To reduce the number of parameters estimated in the calibration process we  
577 restricted the automated constrained parameter search to the remaining three.

578  
579 Model parameters are grouped into three categories: constants, manually calibrated, and  
580 parameters calibrated through an automated constrained parameter search. The constant  
581 parameters are consistent across the study lakes and are not tuned. The manually calibrated  
582 parameters were allowed to vary by lake and are typically guided by ranges from the  
583 literature. The constrained parameter search uses an automated search of parameter space,  
584 constrained by literature values, to fit the  $IP$ ,  $r_{SED}$ , and  $r_{DOCL}$  parameters for the study lakes.  
585 Specifically, we performed a constrained fitting of the model to observational data using the  
586 Levenberg-Marquardt algorithm within the “modFit” function of the “FME” R package  
587 (Soetaert & Petzoldt, 2010).

588  
589 The first 15 years of the model output was used for calibration and the last 5 years were used  
590 for model validation. We chose the first 15 years for calibration because the observational  
591 data were relatively stable and were not indicative of any large trends in ecosystem  
592 processes, as opposed to the last five years which showed slightly more model deviation  
593 from DOC observational data in the southern lakes (SI Fig. 2).

594

## 595 **2.5 Model Uncertainty**

596 Sensitivity guided the uncertainty analysis. To quantify uncertainty around model  
597 predictions, we sampled  $IP$ ,  $r_{SED}$ , and  $r_{DOCL}$  simultaneously from uniform distributions

598 defined by  $\pm 30\%$  of the literature ranges used for our calibrated parameter values (Table 3).  
599 We ran one hundred model iterations randomly sampling the three model state variables  
600 across these distributions. We plotted the minimum and maximum values for these uniform  
601 distributions and included them in the time series plots (Fig. 2, 3, 4, SI Fig. 1,2,3).

602

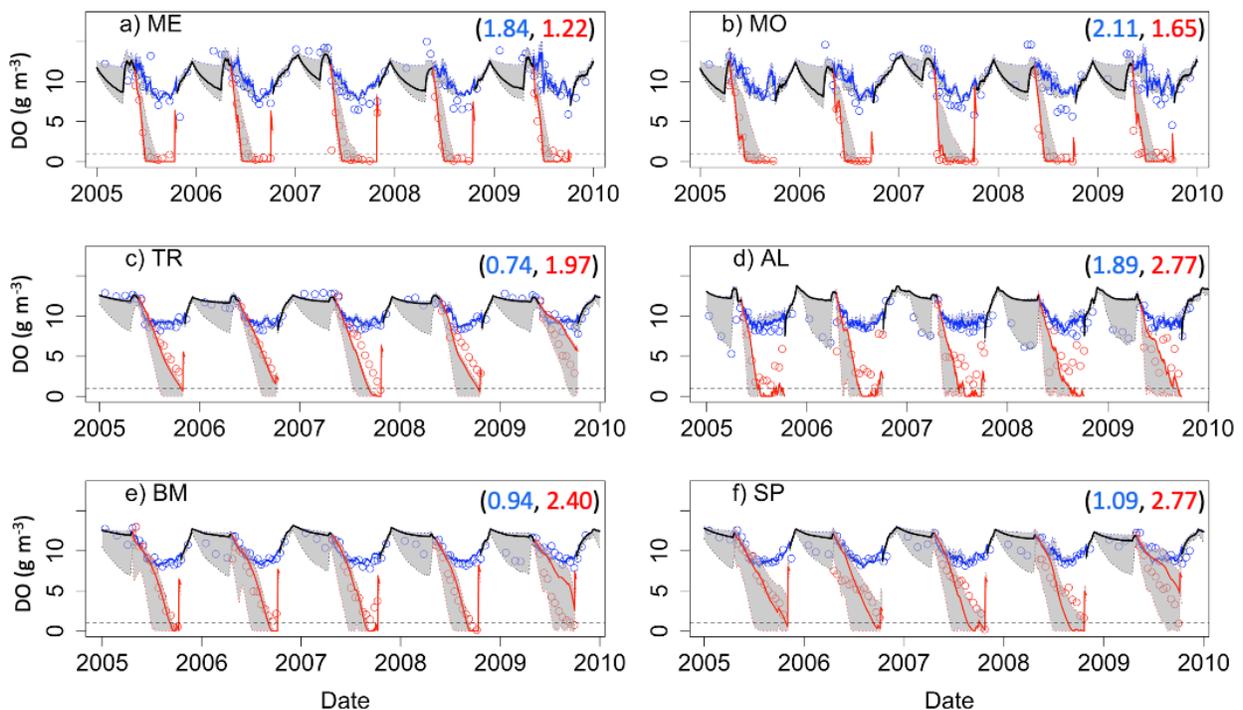

### 603 **3 Results**

604

#### 605 **3.1 Model Fit to Ecosystem States**

606 Model predictions of DO reproduce observed seasonal variability well. Note that RMSE  
607 values presented here represent model error combined over both the validation and  
608 calibration periods (see Supplementary Material: Table S1 for calibration and validation  
609 specific RMSE values), and that state variables are presented with truncated time ranges for  
610 visual clarity (see Supplementary Material: Fig. S1-S3 for full time series). Epilimnetic DO  
611 generally has lower RMSE than DO in the hypolimnion (Fig. 2). ~~In the epilimnion, RMSE~~  
612 ~~ranges from 0.73 g DO m<sup>-3</sup> (TR) to 2.11 g DO m<sup>-3</sup> (ME), and in the hypolimnion, RMSE~~  
613 ~~ranges from 1.20 g DO m<sup>-3</sup> (TR) to 2.69 g DO m<sup>-3</sup> (AL).~~ In the epilimnion, RMSE ranges  
614 from 0.74 g DO m<sup>-3</sup> (TR) to 2.11 g DO m<sup>-3</sup> (MO), and in the hypolimnion, RMSE ranges from  
615 1.22 g DO m<sup>-3</sup> (ME) to 2.77 g DO m<sup>-3</sup> (AL, SP). Validation NSE values for DO ranged from -  
616 1.45 (AL) to 0.02 (ME) in the epilimnion and -0.30 (SP) to 0.86 (ME) in the hypolimnion.  
617 Validation KGE values for DO ranged from 0.40 (AL) to 0.90 (TR) in the epilimnion and  
618 0.35 (SP) to 0.80 (ME) in the hypolimnion. KGE and NSE values for all lakes can be found  
619 in SI Table 7. In the southern lakes, modeled values reach anoxic levels and generally follow  
620 the DO patterns recorded in the observed data (Fig. 2a-b). Observational data for the northern

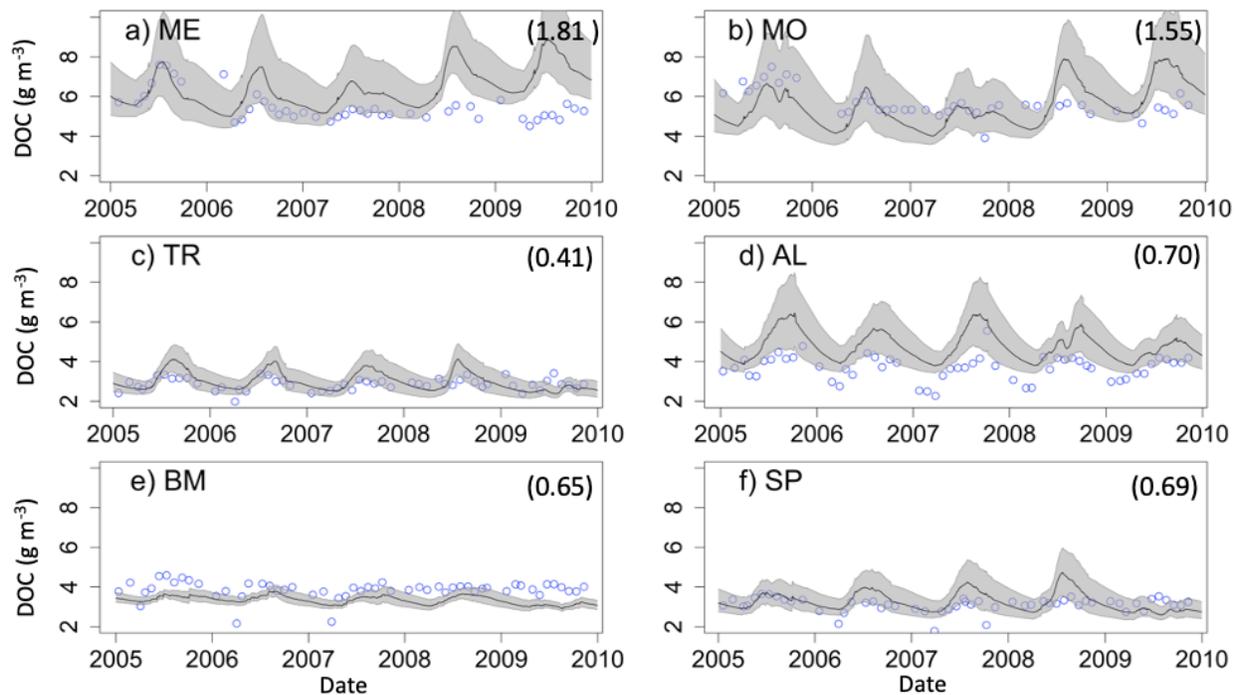

621 lakes show an occasional late summer onset of anoxia, and these events are generally  
 622 captured in the model output. A late summer spike in hypolimnetic DO predictions  
 623 commonly occurs as well, which is likely a model artifact caused by the reduction of  
 624 hypolimnetic volumes to very small values over short time periods prior to fall mixing.  
 625 Reduction to small volumes, coincident with modest fluxes due to high concentration  
 626 gradients, result in transient high concentrations. Overall, the goodness-of-fit of hypolimnetic  
 627 DO in our study lakes does not seem to follow any regional or lake characteristic patterns.

628  
 629 **Figure 2.** Dissolved oxygen (DO) time series for the years, 2005-2010, for the six study  
 630 lakes (a-f). Model predictions are represented by lines, and circles represent the observational  
 631 data. Epilimnetic DO values are blue and Hypolimnetic DO values are red. Fully mixed  
 632 periods for the lake are indicated by a single black line. RMSE values (epilimnion,  
 633 hypolimnion;  $\text{g m}^{-3}$ ) for the validation period are included in the upper right of each panel.  
 634 Uncertainty is represented by gray shading.  
 635

636

637 ~~The two southern lakes (ME, MO) have DOC RMSE values equal to or greater than 1.00 g C~~  
638 ~~m<sup>-3</sup>, while the RMSE for northern lakes ranges from 0.28 g C m<sup>-3</sup> (TR) to 0.60 g C m<sup>-3</sup> (AL)~~  
639 ~~(Fig. 3).~~ The two southern lakes (ME, MO) have epilimnetic DOC RMSE values greater than  
640 1.00 g C m<sup>-3</sup>, while the RMSE for northern lakes ranges from 0.41 g C m<sup>-3</sup> (TR) to 0.70 g C m<sup>-3</sup>  
641 (AL) (Fig. 3). In the southern lakes, NSE epilimnetic DOC values were below -3.00 and  
642 KGE values ranged from -0.29 to -0.32. In the northern lakes, NSE values for DOC ranged  
643 between -2.75 (SP) and -0.31 (AL). KGE values ranged from -0.07 (BM) to 0.35 (TR). All  
644 NSE and KGE metrics for DOC can be found in SI Table 7. Observational data in both  
645 southern lakes indicate a decrease in DOC concentration beginning around 2010, which is  
646 largely missed in the model predictions (Fig.3a-b, Supplementary Material: Fig. S2a-b) and  
647 cause an overestimation of DOC by about 1-2 g C m<sup>-3</sup>. However, model predictions converge  
648 with observed DOC toward the end of the study period (Supplementary Material: Fig. S2a-  
649 b). In AL, the seasonal patterns of modeled DOC are smaller in amplitude than the  
650 observational data (Supplementary Material: Fig. S2d).

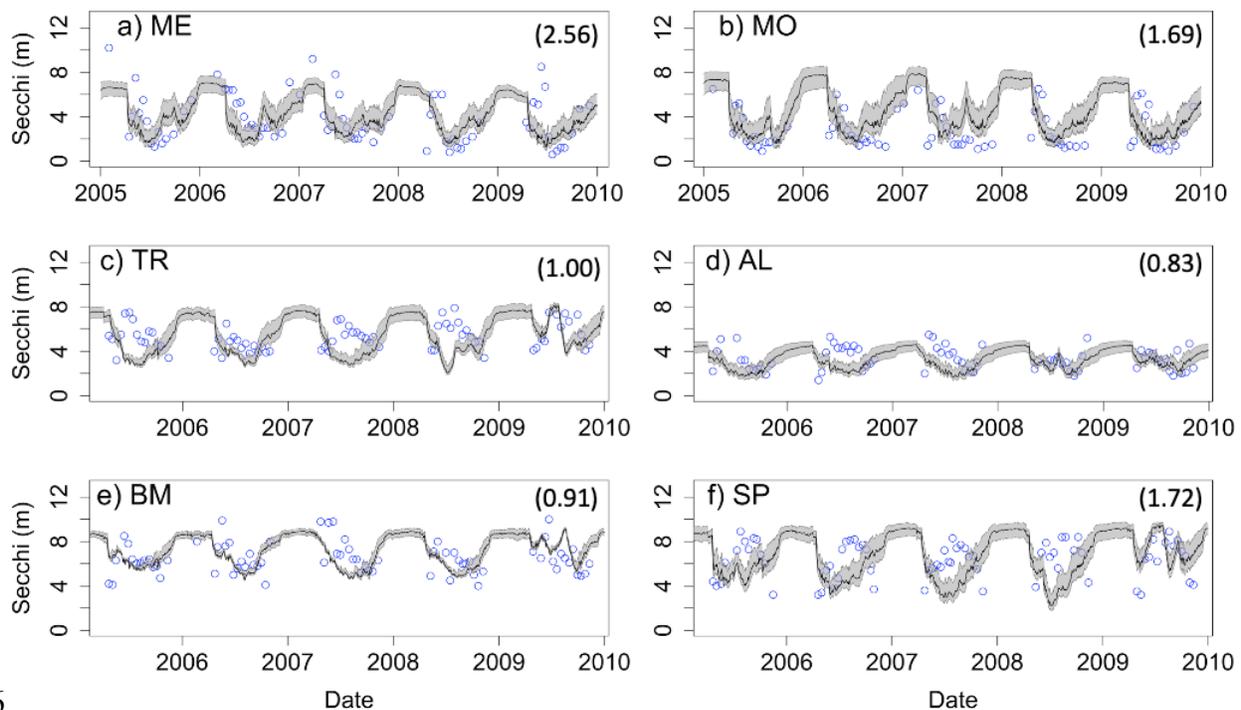

651  
 652 **Figure 3.** Epilimnetic dissolved organic carbon (DOC) time series for the years, 2005-2010,  
 653 for the six study lakes (a-f). Model predictions are represented by lines, and circles represent  
 654 the observational data. RMSE values for the validation period are included for each lake (g C  
 655 m<sup>-3</sup>). Uncertainty is represented by gray shading.  
 656

657 Secchi depth predictions reproduce the mean and seasonal patterns in all lakes (Fig. 4).

658 Although the model produced annual cycles of Secchi depth that generally covered the range  
 659 of observed values, short term deviations from annual patterns in the observed data are not  
 660 reproduced. The timing of minima and maxima Secchi depth sometimes differed between  
 661 predicted and observed values for the northern lakes. In addition, winter extremes in  
 662 observed Secchi depth are not always reproduced by the model, which is especially evident  
 663 for ME (Fig. 4a). However, winter observational data for Secchi are more sparse than other  
 664 seasons.

665

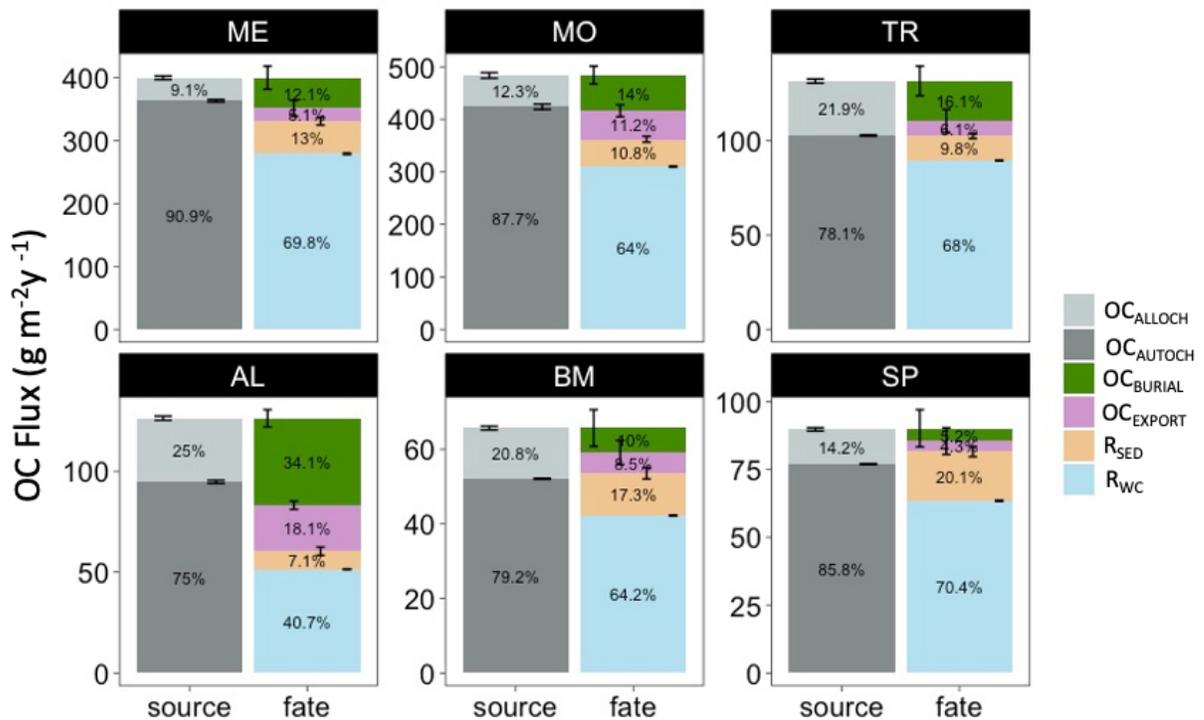

666  
 667 **Figure 4.** Secchi depth time series for the years, 2005-2010, for the six study lakes (a-f).  
 668 Model predictions are represented by lines, and circles represent the observational data.  
 669 RMSE values for the validation period are included for each lake (m). Uncertainty is  
 670 represented by gray shading.  
 671

672

### 673 3.2 Ecosystem Processes

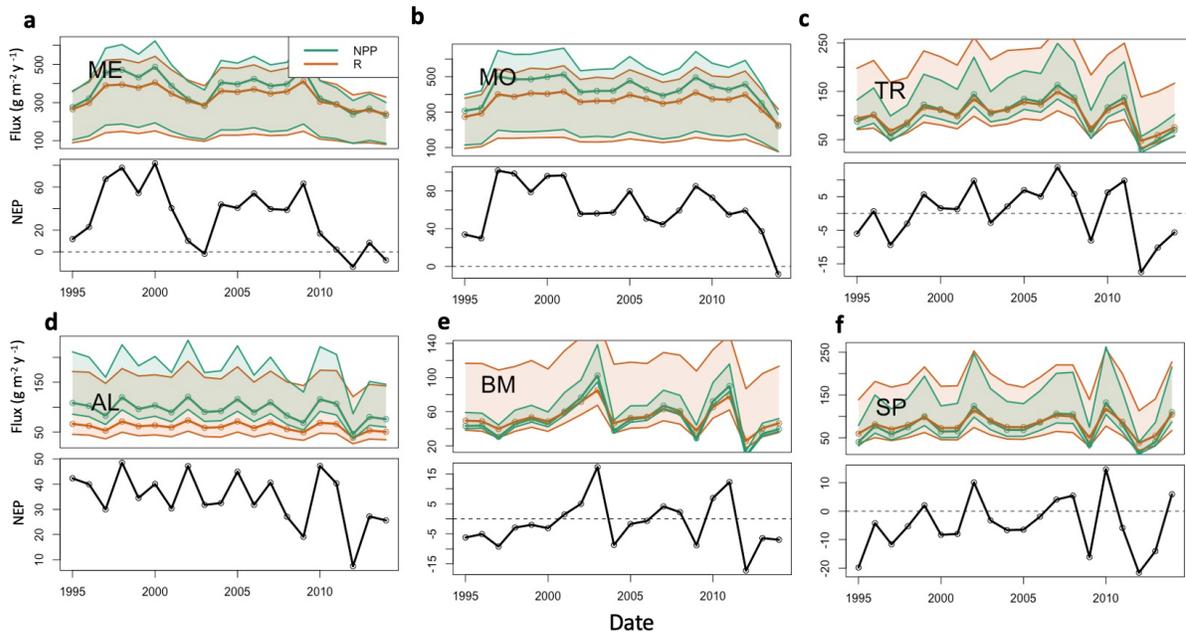

674 The mean annual OC budgets of all six lakes show large differences in the sources and fates  
 675 of OC among lakes (Fig. 5; Supplementary Material: Table S3). Autochthony is the dominant  
 676 source of OC for all study lakes. Water column respiration is the largest portion of whole-  
 677 lake respiration in ME, MO, TR, SP, and BM. Sediment respiration contributions are a lower  
 678 proportion of total respiration in ME, MO, and TR (mean of ~~15.0%~~ 14.1%), and are slightly  
 679 higher in BM and SP (mean of ~~23.7%~~ 18.7%). AL has a more even distribution of OC fates.  
 680 OC burial amounts also vary across the study lakes, with the highest percentage in AL  
 681 (~~26.4%~~ 34.1%), and lowest in SP (~~2.5%~~ 5.25%).

683  
 684 **Figure 5.** Total annual budget, sources (left stacked bars) and fates (right stacked bars), of  
 685 organic carbon (OC) in each lake over the study period. The OC sources include  
 686 allochthonous OC (OC<sub>ALLOCH</sub>) and autochthonous OC (OC<sub>AUTOCH</sub>). The OC fates include  
 687 burial of OC (OC<sub>BURIAL</sub>), export of OC (OC<sub>EXPORT</sub>), sediment respiration of OC (R<sub>SED</sub>), and  
 688 water column respiration of OC (R<sub>WC</sub>). Standard error bars for the annual means are  
 689 indicated for each source and fate as well. Note that the magnitudes of the y-axis differ  
 690 among the lakes. [A significance test comparing these fluxes across the study lakes can be](#)  
 691 [found in SI Table 6.](#)  
 692

693 The lakes show inter-annual variation in trophic state, as quantified by NEP (Fig. 6). Total  
 694 respiration (water column and sediment) exceeds autochthony in SP, BM, and TR, indicating  
 695 predominantly net heterotrophy for these systems. The remaining lakes (ME, MO, AL) are  
 696 generally net autotrophic. The southern lakes (ME, MO) are net autotrophic (positive NEP)  
 697 for the majority of the study years but became less autotrophic over the last five years of the  
 698 study period (2010-2014). BM and SP are mostly net heterotrophic (negative NEP) over the

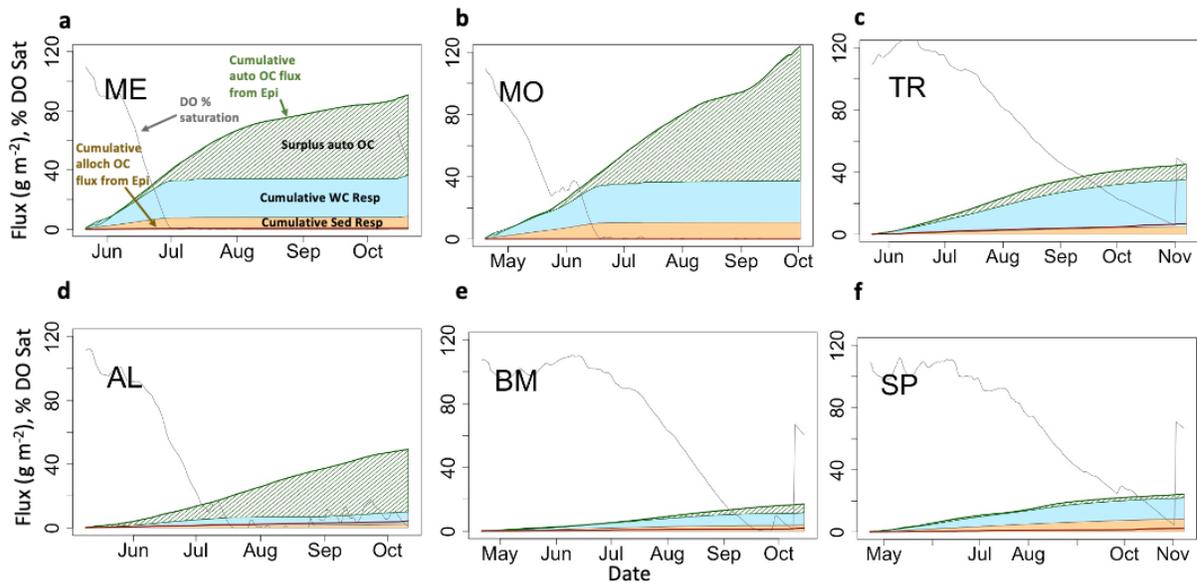

699 study period with a few brief instances of net autotrophy. The strongest autotrophic signal for  
 700 these lakes occurred around 2010. TR experienced prolonged periods of both autotrophy and  
 701 heterotrophy. AL is net autotrophic over the study period but had lower average NEP than  
 702 the southern lakes. ME, MO, and AL all have negative trends in NPP, but only ME and AL  
 703 were significant ( $p\_value < 0.1$ , Mann-Kendall test) (SI Table 2). Of these three lakes,  
 704 ME and AL also have decreasing significant trends in annual total phosphorus concentration  
 705 (SI Table 2). No significant trends were found for NPP or total phosphorus in the other lakes  
 706 (MO, TR, BM, SP).

707  
 708 **Figure 6.** Time series of calibrated lake Net Primary Production (green), Total Respiration  
 709 (red) (top panels), and Net Ecosystem Production (NEP, bottom panels) for the six lakes: (a)  
 710 Lake Mendota; (b) Lake Monona; (c) Trout Lake; (d) Allequash Lake; (e) Big Muskellunge  
 711 Lake, and; (f) Sparkling Lake. Fluxes are in units of  $gC\ m^{-2}y^{-1}$ . Solid line represents  
 712 prediction based on best parameter estimates. Shaded regions represent prediction  
 713 uncertainty based on parameter ranges in Table 3. Shaded region for NEP not shown to  
 714 reduce axis limits and emphasize NEP pattern.

715  
 716

717 Hypolimnetic DO consumption during stratified periods was modeled as a function of the  
718 two components of hypolimnetic respiration, hypolimnetic water column respiration and  
719 hypolimnetic sediment respiration. Water column respiration contributes more than sediment  
720 respiration to total hypolimnetic respiration in the southern lakes compared to the northern  
721 lakes, with the exception of TR, where cumulative water column respiration is much larger  
722 than cumulative sediment respiration. In ME and MO, the mass of summer autochthonous  
723 POC entering the hypolimnion is similar to the total hypolimnetic OC mass respired for the  
724 beginning of the stratified period (Fig. 7a-b; green line). Later in the stratified period, an  
725 increase in epilimnetic POC and associated settling exceeds total hypolimnetic respiration  
726 (Fig. 7a-b; green hashed area). This is due, in part, to lower respiration rates that occur once  
727 DO (gray line) has been fully depleted, which occurs in early July for ME and late June for  
728 MO. In BM and SP the total hypolimnetic respiration slightly exceeds autochthonous POC  
729 inputs during parts of the stratified period, indicating the importance of allochthony in these  
730 systems (Fig. 7c,f). BM shows that autochthonous POC entering the hypolimnion and total  
731 hypolimnetic respiration are similar for much of the stratified period (Fig. 7d). AL is the only  
732 lake to have autochthonous POC inputs consistently larger than total hypolimnetic respiration  
733 during the stratified season. All lakes show that summer allochthonous POC entering the  
734 hypolimnion is a small contribution to the overall hypolimnetic POC load.  
735

753

Respiration of autochthonous POC and sediment respiration account for most of the total hypolimnetic respiration in all lakes (Fig. 8). Respiration of DOC accounts for a relatively small proportion of total respiration. Total hypolimnetic respiration is higher in the southern lakes than the northern lakes. TR has the highest amount of hypolimnetic respiration for the northern lakes, and AL and BM have the least amounts of hypolimnetic respiration. ~~Water column respiration contributed the most towards total hypolimnetic respiration in ME, MO, and TR. Sediment respiration and water column respiration contributed similar proportions towards total hypolimnetic respiration in BM, SP, and AL. As total respiration across lakes increases, a larger proportion of that respiration is attributable to respiration of POC in the water column. DOC water column respiration was the smallest proportion of total hypolimnetic respiration in all six study lakes.~~ Water column respiration contributed the most

754 towards total hypolimnetic respiration in all lakes. Sediment respiration contributed the  
 755 largest proportion towards total hypolimnetic respiration in BM and SP. DOC water column  
 756 respiration was the smallest proportion of total hypolimnetic respiration in all six study lakes.

757 **Figure 8.** Total average annual hypolimnetic respiration, separated by percentages attributed  
 758 to water column DOC ( $R_{DOC\ WC}$ ), water column POC ( $R_{POC\ WC}$ ), and sediment ( $R_{SED}$ ) organic  
 759 carbon sources. Standard error bars for the annual respiration values are indicated as well.

762

763

## 764 4 Discussion

765

### 766 4.1 Autochthonous and Allochthonous Loads

767 Autochthony was the dominant source of OC subsidizing hypolimnetic respiration in the  
768 study lakes. The importance of autochthonous OC pools in ecosystem respiration was  
769 surprising, given ample research highlighting the dominance of allochthonous OC in north  
770 temperate lakes (Wilkinson et al. 2013; Hanson et al. 2011; Hanson et al. 2014). This  
771 outcome emphasizes the utility of process-based models in studying mechanisms that discern  
772 the relative contributions of different pools of organic matter to lake metabolism.  
773 Autochthonous OC pools have higher turnover rates than allochthonous OC pools (Dordoni  
774 et al., 2022) and often are lower in concentration than the more recalcitrant allochthonous  
775 pools (Wilkinson et al. 2013). Thus, studies based on correlative relationships between lake  
776 concentrations of organic matter and water quality metrics, likely overlook the importance of  
777 more labile organic matter in driving observable ecosystem phenomena, such as gas flux and  
778 formation of hypolimnetic anoxia (Evans et al., 2005; Feng et al., 2022). By quantifying  
779 metabolism fluxes relevant to both OC pools, we can recreate shorter-term OC processes that  
780 quantify high turnover of labile organic matter, which would typically be missed by  
781 empirical studies based on monthly or annual observations.

782

783 Allochthony and autochthony are important to lake carbon cycling, but in ways that play out  
784 at different time scales. Allochthonous OC has been well-established as an important factor  
785 in driving negative NEP through a number of mechanisms (Wilkinson et al., 2013; Hanson et  
786 al., 2014; Hanson et al., 2011). Allochthony contributes to water quality variables, such as  
787 Secchi depth (Solomon et al. 2015), by providing the bulk of DOC in most lakes (Wilkinson  
788 et al., 2013) and can drive persistent hypolimnetic anoxia in dystrophic lakes (Knoll et al.,

789 2018). In contrast, autochthony contributes to seasonal dynamics of water quality through  
790 rapid changes in OC that can appear and disappear within a season. Within that seasonal time  
791 frame, autochthonous POC settling from the epilimnion can drive hypolimnetic respiration,  
792 thus controlling another key water quality metric, oxygen depletion. It is worth noting that  
793 our model does not discern allochthonous and autochthonous sediment OC, however we  
794 show that autochthonous OC makes up the largest proportion of OC loads in our study lakes  
795 and therefore autochthony likely contributes substantially to the sediment OC pool. For  
796 highly eutrophic lakes, the model results show excess autochthony stored in the sediments  
797 which may carry into subsequent years, potentially providing additional substrate for  
798 sediment respiration. Thus, understanding and predicting controls over hypolimnetic oxygen  
799 depletion benefits from quantifying both allochthonous and autochthonous OC cycles.

800

801 Differences in trophic status, hydrologic residence time, and inflow sources help explain the  
802 relative proportion of allochthonous versus autochthonous OC among lakes in our study.

803 Water residence times (Hotchkiss et al. 2018; McCullough et al. 2018) and surrounding land  
804 cover (Hanson et al. 2014) have been shown to have a substantial impact on OC dynamics by  
805 controlling allochthonous OC loading and NEP trends on lakes included in our study  
806 (Hanson et al. 2014, McCullough et al. 2018). We built upon these ideas by recreating daily  
807 watershed loading dynamics of POC and DOC from derived discharge data and incorporating  
808 nutrient control over lake primary production by using high quality and long-term  
809 observational data. The northern lakes are embedded in a forest and wetland landscape,  
810 which are characteristic of having higher DOC than the urban and agricultural landscape of

811 the southern lakes (Creed et al., 2003). This creates variation in allochthonous loading across  
812 the study lakes. Lake trophic state and productivity are a major control for autochthonous  
813 production, which influences autochthonous loads across the study lakes as well. For lake  
814 metrics that are comparable between studies, such as allochthonous loading and export,  
815 allochthonous water column respiration, and total OC burial, our results were within 20% of  
816 values in related studies (Hanson et al. 2014, McCullough et al. 2018).

817

## 818 **4.2 Hypolimnetic Respiration**

819 Given the importance of autochthonous POC to hypolimnetic respiration, we assume it  
820 contributes substantially to both sediment respiration and respiration in the water column.

821 While previous work found that sediment respiration was the dominant respiration source for  
822 lakes with depth ranges encompassed within our study (Steinsberger 2020), we found that  
823 water column respiration was at least as important, if not more so. Differences in these  
824 findings could be linked to uncertainty in the settling velocity of POC, due to lack of  
825 empirical POC settling velocity measurements. Perhaps, POC mineralized in the hypolimnia  
826 of our modeled lakes passes more quickly to the sediments in real ecosystems, shifting the  
827 balance of respiration more toward the sediments. ~~It has been shown that POC respiration~~  
828 ~~contributes substantially to hypolimnetic DO depletion (Jenny et al. 2016)~~ OC respiration can  
829 contribute substantially to hypolimnetic DO depletion in both lakes and reservoirs (Beutel,  
830 2003), and POC settling velocities can be highly variable, suggesting that assumptions  
831 around vertical distribution of lake POC deserve further investigation. Another possible  
832 explanation for these differences could be that our model missed allochthonous POC loads

833 from extreme events (Carpenter et al., 2012), which can increase the amount of legacy OC  
834 stored in the sediments and increase sediment respiration. Our model also does not account  
835 for reduced respiration rates due to OC aging, which may explain our higher values of water  
836 column respiration. Finally, our model includes entrainment as a possible oxygen source to  
837 the hypolimnion, which must be offset by respiration to fit observed hypolimnetic DO  
838 changes. Any study that underestimates DO sources to the hypolimnion likely underestimates  
839 total respiration.

840

841 Anaerobic mineralization of organic carbon is an important biogeochemical process and can  
842 be a substantial carbon sink through methanogenesis (Maerki et al. 2009). Although  
843 methanogenesis is not incorporated into our model, methane dissolved in the water column of  
844 Lake Mendota is mostly oxidized (Hart 2017), thus contributing to the overall oxygen  
845 demand, which is accounted for in our model. What remains unaccounted is ebullition of  
846 methane, which is a carbon flux that is difficult to quantify (McClure et al. 2020). Future  
847 metabolism studies that include these processes might find a decrease in annual OC burial  
848 rates relative to rates in our study. Although we believe that ebullition is not a substantial  
849 portion of the lake's carbon mass budget, that remains to be studied more carefully. As the  
850 model accounts for DO consumption through calibration, the overall flux would not change  
851 even if we link DO consumption to methane oxidation, only the process description would be  
852 more realistic.

853

854 ~~Finally, our model includes entrainment as a possible oxygen source to the hypolimnion,~~  
855 ~~which must be offset by respiration to fit observed hypolimnetic DO changes. Any study that~~  
856 ~~underestimates DO sources to the hypolimnion likely underestimates total respiration.~~ Our  
857 findings highlight the importance of autochthonous POC in hypolimnetic oxygen depletion  
858 and suggest that related processes, such as the timing of nutrient loading, changes in  
859 thermocline depth, or zooplankton grazing, could impact overall lake respiration dynamics  
860 and anoxia formation (Schindler et al., 2016; Ladwig et al., 2021; Müller et al., 2012).

861

### 862 **4.3 Long-term Dynamics**

863 Although autochthonous OC dominated the loads across the study lakes, analysis of the long-  
864 term OC dynamics supports the importance of allochthony in lakes. Net Ecosystem  
865 Production (NEP) has been used to quantify heterotrophy and autotrophy in lakes (Odum  
866 1956, Hanson et al. 2003, Cole et al. 2000, Lovett et al. 2006), and using this metric over  
867 multiple decades allowed us to analyze long-term impacts of allochthony. TR, BM, and SP  
868 fluctuated between heterotrophy and autotrophy, usually in tandem with trends in hydrology,  
869 which acts as a main control of allochthonous OC. This suggests that allochthonous OC  
870 inputs may be less important for seasonal anoxia but can still drive a lake toward negative  
871 NEP and contribute to sediment carbon storage over long time periods. ME, MO, and AL  
872 tended to become less autotrophic over time (Fig. 6), a pattern that coincided with significant  
873 decreasing trends in mean epilimnetic total phosphorus concentrations for ME and AL (SI  
874 Fig. 5). In our model, NPP and phosphorus are directly related, so decreases in phosphorus  
875 are likely to cause decreases in NEP. Short-term respiration of autochthonous POC can

876 account for rapid decreases in hypolimnetic DO, but allochthonous POC, which tends to be  
877 more recalcitrant, provides long-term subsidy of ecosystem respiration that can result in  
878 long-term net heterotrophy. Thus, it's critical to understand and quantify both the rapid  
879 internal cycling based on autochthony and the long and slow turnover of allochthony.

880

881 Through explicitly simulating the cycling of both allochthony and autochthony, we can  
882 expand our conceptual model of metabolism to better understand time dynamics of lake  
883 water quality at the ecosystem scale. Autochthony has pronounced seasonal dynamics,  
884 typically associated with the temporal variability of phytoplankton communities and the  
885 growth and senescence of macrophytes (Rautio et al., 2011). While allochthony can also have  
886 strong seasonal patterns associated with leaf litter input, pollen blooms, and spring runoff  
887 events, its more recalcitrant nature leads to a less pronounced seasonal signal at the  
888 ecosystem scale (Wilkinson et al., 2013, Tranvik 1998). When considered together, it seems  
889 that allochthony underlies long and slow changes in metabolism patterns, while autochthony  
890 overlays strong seasonality. Both OC pools are important for ecosystem scale metabolism  
891 processes, and their consequences are evident at different time scales. Therefore, the  
892 interactions of both OC sources and their influences on water quality patterns deserve further  
893 investigation.

894

895 Autochthonous OC control over hypolimnetic respiration should be a primary consideration  
896 for understanding the influence of OC on ecosystem dynamics. Hypolimnetic oxygen  
897 depletion and anoxia in productive lakes can be mitigated by reducing autochthonous

898 production of OC, which we show is mainly driven by nutrient availability. This study also  
899 identifies the need for a better understanding of internal and external OC loads in lakes.  
900 Previous studies have found heterotrophic behavior in less productive lakes, but our findings  
901 highlight the importance of autochthony in these lakes, especially for shorter-time scale  
902 processes that can be missed by looking at broad annual patterns. By using a one-  
903 dimensional, two-layer model, we are able to also understand how surface metabolism  
904 processes can impact bottom layer dynamics, which would not be possible with a zero-  
905 dimensional model. Looking forward, we believe that our understanding of these processes  
906 could be improved by building a coupled watershed - metabolism model to more closely  
907 explore causal relations between watershed hydrology, nutrient dynamics, and lake  
908 morphometry.

910

911

912 *Code Availability*

913 Model code and figure creation code are archived in the Environmental Data Initiative  
914 repository (<https://doi.org/10.6073/PASTA/1B5B947999AA2F9E0E95C91782B36EE9>,  
915 Delany, 2022).

916

917 *Data Availability*

918 Driving data, model configuration files, and model result data are archived in the  
919 Environmental Data Initiative repository  
920 (<https://doi.org/10.6073/PASTA/1B5B947999AA2F9E0E95C91782B36EE9>, Delany, 2022).

921

922 *Author Contributions*

923 AD, PH, RL, and CB assisted with model development and analysis of results. AD and PH  
924 prepared the manuscript with contributions from RL, CB, and EA.

925

926 *Competing Interests*

927 The authors declare that they have no conflict of interest.

928

929 *Acknowledgements:*

930 Funding was provided through the National Science Foundation (NSF), with grants DEB-  
931 1753639, DEB-1753657, and DEB-2025982. Funding for Ellen Albright was provided by the  
932 NSF Graduate Research Fellowship Program (GRFP), and the Iowa Department of Natural  
933 Resources (contract #22CRDLWBMBALM-0002). Funding for Robert Ladwig was  
934 provided by the NSF ABI development grant (#DBI 1759865), UW-Madison Data Science  
935 Initiative grant, and the NSF HDR grant (#1934633). Data were provided by the North  
936 Temperate Lakes Long Term Ecological Research Program and was accessed through the  
937 Environmental Data Initiative (DOI: 10.6073/pasta/0dbbfdbcdee623477c000106c444f3fd).
