15 **ABSTRACT**

16 Polycyclic aromatic compounds (PACs) continue to demand attention due to their widespread
17 presence and well-established health implications. Given that incomplete combustion is a
18 major contributor to PACs and inhalation constitutes a crucial human exposure pathway, a
19 comprehensive understanding of the concentrations, spatial distributions, and fates of a broad
20 range of PACs in the atmosphere is important. Passive air samplers (PASs) are a commonly
21 utilized technique for PAC sampling and monitoring. In this study, we present the results from
22 two one-year calibration experiments, one starting in summer and the other in winter, using a
23 passive air sampler equipped with XAD resin as the sorbent (XAD-PAS). Throughout both
24 experiments, PACs were consistently sorbed during the initial six-month period. However, the
25 sorbed amounts for many PACs exhibited a decrease after half a year of deployment. Three
26 hypotheses to explain this phenomenon were explored, including the uptake of atmospheric
27 particles, evaporation from the sorbent, and reactions with photooxidants. All had to be rejected
28 based on the obtained data, additional laboratory experiments and model results. Model
29 simulations were further used to (i) confirm that a loss process must be invoked to explain the
30 observed uptake behaviour and (ii) estimate the kinetics of that loss process for different PACs.
31 Sampling rates (*SRs*) for 28 PACs derived from the linearized uptake curves during the first
32 six months of deployment were comparable to those of other semi-volatile organic compounds
33 obtained during the same calibration experiment, and they also demonstrate a consistent
34 negative correlation with volatility.

35 1. INTRODUCTION

36 Approximately 4 million square kilometers of savanna, forest, grassland, and agricultural
37 ecosystems are burnt through both natural and controlled fires annually (Nolan et al., 2022).
38 These fire events have attracted global attention to the release of pollutants, including harmful
39 particles, organic vapors, and greenhouse gases, into the air as well as the related potential
40 health risks. In particular, the production and dispersion of polycyclic aromatic compounds
41 (PACs) in the environment have emerged as significant concerns. PACs comprise organic
42 molecules composed of fused aromatic rings, including unsubstituted polycyclic aromatic
43 hydrocarbons (PAHs), alkylated PAHs (alk-PAHs), and heterocyclic aromatic compounds
44 containing N, O, or S atoms in their structure (Moradi et al., 2022). PACs originate from a
45 multitude of sources, encompassing both natural and human-related activities, many related to
46 the incomplete combustion of organic matter. Natural sources include wild fires (Nolan et al.,
47 2022; Environment Canada and Health Canada, 1994; Nikolaou et al., 1984; Wnorowski et al.,
48 2021), volcanic eruptions (Nikolaou et al., 1984; United Nations Environment Programme,
49 2020), and biogenic processes (Wakeham et al., 1980). Anthropogenic activities contribute
50 substantially to the emissions of PACs into the environment (Environment Canada and Health
51 Canada, 1994), with vehicle emissions (Berthiaume et al., 2021; Muir and Galarneau, 2021),
52 cooking and heating (Shen et al., 2012; Environment Canada and Health Canada, 1994), wood
53 burning (Lima et al., 2005; Xu et al., 2006), industrial processes (Lima et al., 2005; Xu et al.,
54 2006), and tobacco smoke (Holme et al., 2022) releasing numerous PACs into the atmosphere.
55 PAHs have been widely studied due to their ubiquitous presence in the environment and their
56 potential for eliciting adverse health effects, such as allergic potential, carcinogenicity,
57 teratogenicity, and genotoxicity (Rice and Baker, 2007; Boffetta et al., 1997; White, 2002; Kim
58 et al., 2013; Organization, 1998; ATSDR (Agency for Toxic Substances Disease Registry),
59 1995), PAHs are regulated and routinely monitored by numerous agencies and governments
60 across the globe.

61 With past research efforts mainly focused on PAHs, alk-PAHs have only recently started to
62 garner attention from researchers. The addition of alkyl groups alters the physicochemical
63 properties of PAHs, affecting their solubility, volatility, and toxicological properties. Certain
64 alk-PAHs may be more toxic than their non-alkylated counterparts (Golzadeh et al., 2021;
65 Hawthorne et al., 2006; Andersson and Achten, 2015; Grung et al., 2011; Kaisarevic et al.,
66 2009; Pechillips et al., 1979; Sarma et al., 2017), raising concerns about their potential
67 ecological and human health impacts. Whereas alk-PAHs have been identified at elevated

68 concentrations, and in some cases, are even dominant among PACs in air (Wnorowski et al.,
69 2022; Moradi et al., 2022; Jariyasopit et al., 2019) and food (Golzadeh et al., 2021), they have
70 not been widely studied, monitored, and regulated (Moradi et al., 2022). Studies in Canada are
71 particularly limited in number, with some data available for the Greater Toronto Area
72 (Jariyasopit et al., 2019; Moradi et al., 2022) and Athabasca oil sands region (Harner et al.,
73 2013; Jariyasopit et al., 2018; Wnorowski et al., 2021; Mahoney et al., 2023; Cheng et al., 2018;
74 Rauert et al., 2020; Harner et al., 2018; Moradi et al., 2023.; Jariyasopit et al., 2021; Ahad et
75 al., 2021).

76 Because inhalation is a critical human exposure pathway (Carl-Elis et al., 2002; Liu et al.,
77 2007), achieving a comprehensive understanding of PAC concentrations, spatial distribution,
78 and fate in the atmosphere is important. As atmospheric PAC concentrations are related to
79 proximity to emission sources, urban areas, industrial zones, regions with high traffic density,
80 and places close to wildfire typically exhibit elevated PAC concentrations. Atmospheric
81 transport can disperse PACs widely, both while bound to particles and in the gas phase (Muir
82 and Galarneau, 2021; Zhou et al., 2019; Wnorowski et al., 2022; Masclet et al., 2000). Clearly,
83 there is a need for reliable air sampling techniques for a wide range of PACs.

84 Atmospheric PACs can be sampled using active air samplers (AASs) and passive air samplers
85 (PASs). In AASs, pumps are used to pull air through a sampling medium (e.g., a sorbent or/and
86 a filter) to capture atmospheric PACs in the gas or/and particle phase. While accurate sampling
87 volumes are usually easily obtained, the need for a stable electrical power supply and high
88 maintenance requirements and operational expenses limit the geographical scope of AASs,
89 especially in remote areas. Without using pumps, PASs sample and retain chemicals by relying
90 on chemical vapors' diffusing and sorbing to a sorbent. Low cost and maintenance
91 requirements expand their potential spatial applications, e.g., in areas close to wildfire regions.
92 However, obtaining accurate sampling volumes can be challenging. Confidently using a PAS
93 requires quantitative knowledge of the uptake kinetics and of the limits of linear uptake for the
94 targeted compounds, which is typically obtained by calibration studies using co-located AAS
95 and PASs.

96 Sorbents used for sampling PACs in PASs include polyurethane foam (PUF) (Cheng et al.,
97 2013; Domínguez-Morueco et al., 2017; Pozo et al., 2015), polyethylene (PE) (Bartkow et al.,
98 2004; Meierdierks et al., 2021), polydimethyl siloxane (PDMS) (Barthel et al., 2012; Bohlin-
99 Nizzetto et al., 2020), and styrene–divinylbenzene co-polymeric resin (commercial name XAD)
100 (Barthel et al., 2012; Lévy et al., 2018). Calibration studies have been conducted for PACs in

101 PAS based on PE (Meierdierks et al., 2021), PUF (Harner et al., 2013; Bohlin-Nizzetto et al.,
102 2020; Tromp et al., 2019; Holt et al., 2017; Bohlin et al., 2014a; Melymuk et al., 2011), PDMS
103 (Tromp et al., 2019), and XAD (Ellickson et al., 2017; Armitage et al., 2013). However, due to
104 a relative low uptake capacity, some sorbents, such as PE and PDMS, are less widely used in
105 PAS. Even though PUF-PASs are widely used, they have some limitations: (1) the uptake
106 capacity of PUF is too small to sample more volatile PACs within the linear uptake regime
107 during longer deployment periods, which may lead to relatively high uncertainties and
108 difficulties in data interpretation (Li and Wania, 2021; Li et al., 2022). (2) Gas-phase
109 concentrations of PACs, especially of less volatile PACs, may be hard to obtain as the PUF-
110 PAS samples both gaseous and particle-bound PACs (Melymuk et al., 2011), with sampling
111 rates for the latter suffering from high variability and uncertainty (Holt et al., 2017).

112 The significantly greater uptake capacity (Wania and Shunthirasingham, 2020; Hayward et al.,
113 2011) of the XAD-PAS (Wania et al., 2003) results in a demonstrably longer linear uptake
114 period (Wania and Shunthirasingham, 2020; Li et al., 2023a, b) for many semi-volatile organic
115 compounds (SVOCs) compared to other PASs. Moreover, the XAD-PAS's shelter was
116 intentionally designed to mitigate the impact of wind and particle uptake. Although the XAD-
117 PAS has been calibrated for PAC twice (Ellickson et al., 2017; Armitage et al., 2013), these
118 studies only targeted a limited number of PAHs and no alk-PAHs or heterocyclic aromatic
119 compounds. While Armitage et al. (2013) deployed AASs and PASs side-by-side, Ellickson et
120 al. (2017) positioned certain PASs at a considerable distance from the AASs, which could
121 potentially introduce heightened levels of uncertainty into the findings. The current study
122 sought to conduct a “gold standard” calibration for XAD-PAS with the following objectives:
123 (1) evaluate the uptake behaviors of a large number of PACs in XAD-PAS, including PAHs,
124 alk-PAHs, and the heterocyclic aromatic compound dibenzothiophene; (2) determine the linear
125 uptake regimes and obtain experimental sampling rates for these PACs; (3) assess the impact
126 of meteorological conditions and chemical properties on the sampling of these PACs.

127 **2. METHODS AND MATERIALS**

128 **Field Sampling.** The main calibration experiment was conducted in 2020/2021 on the campus
129 of the University of Toronto Scarborough in the eastern suburbs of Toronto (43.7837, -
130 79.1903), with results for other SVOCs reported previously (Li et al., 2023b, a). For
131 comparison, we also present the results of calibration experiments conducted in 2001/2002 in
132 a forest (44.3184, -79.9341) and a nearby clearing (44.3270, -79.9169) site in Borden, Ontario,
133 with air concentrations having been previously reported (Su et al., 2007a, b). The Borden sites

134 are approximately 85 km to the Northwest of the Toronto site. In each study, XAD-PASs were
135 deployed simultaneously ca. 1.5 m above the ground, and AASs, collecting particle and gas
136 phase separately, were placed side by side with the PASs. Both calibration experiments lasted
137 ~1 year, with the Borden experiments starting in November 2001 and the Toronto experiment
138 in June 2020. During the experiments, XAD-PASs were retrieved every four weeks in Toronto
139 and after 36, 60, 120, 181, 246, 323, and 365 days in Borden. Periodical 24-hour-long active
140 air samples in Borden and consecutive week-long active air samples in Toronto were obtained
141 using high-volume active air samplers (HV-AASs) and mid-volume active air samplers (MV-
142 AAS), respectively. Detailed sampling information has been described in previous publications
143 (Su et al., 2007a, b; Li et al., 2023b, a).

144 **Sample Treatment.** Glass fiber filters (GFFs) and PUFs from the Borden experiment were
145 Soxhlet extracted with dichloromethane and petroleum ether, respectively. Extracts were
146 cleaned, fractionated, and concentrated as described previously (Su et al., 2006, 2007a). The
147 XAD from the PASs deployed at Borden was loaded to and extracted in an elution column with
148 250 mL of methanol, followed by 350 mL of dichloromethane. After removing methanol with
149 250 mL of 3% sodium chloride, extracts were concentrated and fractionated using the method
150 described in Wania et al. (2003) The fractionated extracts were solvent exchanged into iso-
151 octane, and finally concentrated to 0.5 mL using nitrogen. More detail on sample treatment is
152 available in earlier publications (Su et al., 2006, 2007a; Wania et al., 2003).

153 For the samples from the Toronto experiment, one XAD-PAS cylinder from each retrieval date,
154 all blank samples, the PUF-XAD-PUF sandwiches, and GFFs were subjected to extraction
155 using an accelerated solvent extractor (Dionex 350). Prior to extraction, labeled standards
156 (Table S2) were spiked onto the samples as surrogates. The extracts were then concentrated
157 using rotary evaporation, water residues were removed using sodium sulfate columns, solvent-
158 exchanged into iso-octane, and further concentrated to 0.1 mL for PAS and 0.5 mL for AAS
159 using nitrogen-blowdown. Prior to instrumental analysis, 2.96 ng and 14.8 ng injection
160 standards (Table S2) were added to PAS and AAS extracts, respectively. Detailed procedures
161 were reported previously (Li et al., 2023b, a).

162 **Instrumental Analysis.** Extracts from the Borden experiment were analysed for 16 PAHs with
163 an Agilent 6890 gas chromatograph (GC) equipped with an Agilent 5973 mass spectrometric
164 (MS) detector using electron ionization in selected ion monitoring mode. In extracts from the
165 Toronto experiment, a total of 22 PAHs, 22 alk-PAHs and dibenzothiophene were analyzed.
166 This analysis were carried out using an Agilent 7890A GC coupled with a 7000A triple

167 quadrupole MS for PAS and PUF/XAD sandwich extracts and an Agilent 8890 GC coupled
168 to with a 7010B MS/MS for the GFF extracts, using electron ionization in multiple reaction
169 monitoring mode. Details on instruments, columns, temperatures, and other parameters are
170 given in the Supporting Information (SI).

171 **Ozone Exposure Experiment.** A laboratory experiment was conducted to examine the
172 potential of PAHs to undergo reactions with ozone while being sorbed to XAD. Approximately
173 150 g of pre-cleaned XAD-2 resin was added to ~300 mL of an acetone solution containing
174 ~3500-5000 ng each of acenaphthene, anthracene, phenanthrene, pyrene, and fluoranthene. To
175 make sure the XAD-resin was well mixed, it was stirred continuously using a clean spatula
176 until all acetone had evaporated (confirmed by repeatedly weighing of the PAC-loaded XAD-
177 resin). ~5.0 g of the spiked XAD resin was added to 10 mesh cylinders (2.0 cm diameter), as
178 used in the XAD-PAS, reducing the amount of resin required by placing a smaller empty mesh
179 cylinder (1.0 cm diameter) in their centre (Zhang et al., 2011). The exact weight of the XAD
180 in each mesh cylinder was recorded and used for data normalization.

181 Five randomly selected spiked mesh cylinders were extracted and analyzed using the same
182 method as for the samples from the Toronto experiment mentioned above in order to investigate
183 the variability of the PAHs in these cylinders. Three mesh cylinders were exposed to 1000 ppb
184 ozone at 0% relative humidity (RH) in a flowtube (Zhou and Abbatt, 2021) (Figure S1), two
185 for 24 hours and one for 72 hours. As a control, two mesh cylinders were exposed to air for 24
186 hours at 0% RH in the same flow tube. The volume of the flow tube was ~1.8 L and the flow
187 rate inside the tube was 1800 cm³ min⁻¹. Upon retrieval, the five mesh cylinders from the flow
188 tube experiments were extracted and analyzed as before.

189 **Calculation of Sampling Rates (SR).** During the linear uptake phase, the *SR* of a compound
190 in the XAD-PAS is linearly related to the effective sampling volume V_{eff} (m³):

$$191 \quad V_{eff} = \frac{M_{PAS}}{C_{air}} = SR \cdot t \quad (1)$$

192 where M_{PAS} (ng) is the field blank corrected amount of a PAC sorbed to the XAD-2 resin, and
193 C_{air} is the atmospheric gas phase concentration of the PAC (ng m⁻³) averaged over the
194 deployment period t of a sampler (day). C_{air} is derived by averaging the concentrations recorded
195 by the AAS during a PAS's deployment. The *SR* for each compound during the period of linear
196 uptake is then obtained as the slope of the linear regression between V_{eff} and t .

197 **Chemical Properties Compilation.** The logarithm of the equilibrium concentration ratios

198 between XAD-resin and air ($K_{\text{XAD/air}}$, L air g^{-1} XAD) at 20 °C (Table S4) and the internal
199 energies of phase transfer between XAD and the gas phase $\Delta U_{\text{XAD/air}}$ (J mol^{-1} , Table S4) were
200 calculated using solute descriptors for PACs from the UFZ-LSER database (UFZ-LSER
201 database v 3.2.1 [Internet], 2022) and the poly parameter free energy relationships (ppLFERs)
202 by Hayward et al. (2011) The log $K_{\text{XAD/air}}$ values at the mean temperatures over the entire
203 deployment period of the Borden and Toronto calibration experiments (7.9 and 12.2°C,
204 respectively) (Table 2) were obtained from log $K_{\text{XAD/air}}$ at 20 °C and $\Delta U_{\text{XAD/air}}$ using the van't
205 Hoff equation (Atkinson and Curthoys, 1978; Goss, 1996).

206 **Model Simulations.** A mechanistic model developed by Zhang and Wania (2012) was used to
207 simulate the uptake of PACs with different $K_{\text{XAD/air}}$ during the two calibration experiments
208 beginning in different seasons (June and November). This model describes the diffusion of
209 chemicals from the atmospheric gas phase to the sorbent of a PAS and the kinetics of reversible
210 sorption to that sorbent. It has been modified to consider degradation loss of chemical sorbed
211 to the XAD-resin and to incorporate time-variant temperature and atmospheric ozone
212 concentrations. The Levenberg-Marquardt algorithm was used to find the combinations of
213 sorption rate k_{sorb} and degradative loss rate k_{d} that provide the best fit between predicted and
214 measured uptake curves. The actual temperature measured during the two calibration
215 experiments (Figures S2 and S3) were used in the simulations. Measured ozone concentrations
216 reported for the vicinity of the sampling sites (Figures S4 and S5) were used as input for
217 photooxidant degradation simulations only. The thickness of the stagnant air boundary layer
218 was assumed to be 0.01 cm (Zhang and Wania, 2012, Li et al., 2023b) and the simulated
219 deployment length was 336 days.

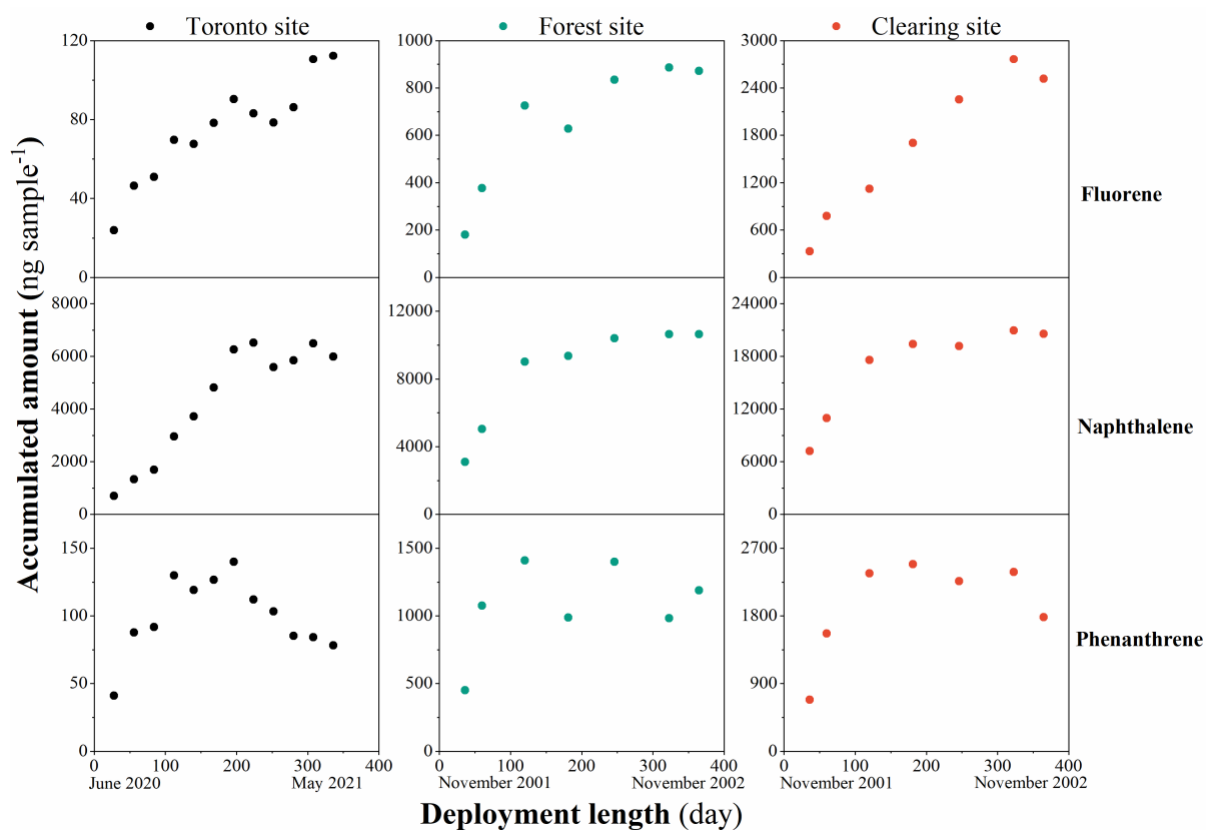

220 3. RESULTS AND DISCUSSION

221 **Amounts Accumulated in PASs.** Fifteen PAHs, twelve alk-PAHs and dibenzothiophene were
222 reliably detected in the PAS extracts from the Toronto experiment (Table S6). Seven of these
223 PAHs were also detected in the extracts from the Borden experiment (Table S7). The amounts
224 of fluorene, naphthalene, and phenanthrene accumulated in the PASs are plotted versus
225 deployment length in Figure 1. Plots for the remaining 25 PACs are provided in Figures S6 and
226 S7 in the Supporting Information. These plots reveal that for only five of the 28 PACs in the
227 Toronto experiment, namely, acenaphthylene, fluorene, 1-methylfluorene, chrysene, and
228 benzo[b]fluoranthene, does the amount sorbed to the XAD increase relatively continuously
229 with increasing deployment for the entire length of the experiment. The amounts of the
230 remaining PACs either were largely constant (e.g., naphthalene in Figure 1) or decreased (e.g.,

231 phenanthrene in Figure 1) after approximately six-months of deployment. The observed uptake
232 behaviour was consistent between the three study sites, i.e., was observed in Toronto and the
233 forest and clearing sites in Borden (Figure 1). This behaviour is in contrast to continuous uptake
234 observed for a large number of SVOCs targeted in the same calibration study in Toronto (Li et
235 al., 2023a, b).

236 Theoretically, the amount of a chemical taken up in a PAS should always increase with
237 deployment length (Wania and Shunthirasingham, 2020). A decrease with increasing
238 deployment length might occur if the chemical is degraded while being sorbed or if the rate of
239 evaporation from the sorbent exceeds the rate of uptake. The latter occurs only if a chemical's
240 air concentration decreases or temperature increases after the chemical has reached a state of
241 equilibrium between atmospheric gas phase and sorbent. Equilibrium is more easily established
242 for volatile chemicals, sorbents with low uptake capacity and long deployments. We explored
243 three hypotheses to explain these unexpected decreasing trends in the amounts accumulated in
244 PASs.

245 **Can Uptake of Particle-bound Compounds Explain Decreasing Trends in the Amounts**
246 **Accumulated in PASs?** The first hypothesis posits that the observed uptake behaviour was
247 caused by the uptake and accumulation of atmospheric particles in the XAD-PAS. This
248 hypothesis is based on previous studies showing that some PASs do not efficiently block wind
249 from carrying particle-bound substances to the sorbent, as is, e.g., observed in the case of the
250 PUF-PAS with double bowl shelters (Wania and Shunthirasingham, 2020; Chaemfa et al., 2009;
251 Bohlin et al., 2014b; Harner et al., 2013). Even though there is currently no evidence of the
252 uptake of particle-bound SVOCs in the XAD-PAS, if such uptake were to occur, the
253 accumulated amount of a chemical in the XAD-PAS would be the sum of the amount taken up
254 from the gas phase and the amount derived from sampled particle phase. While this admittedly
255 cannot explain why the amount of a chemical quantified in the sorbent would decrease with
256 deployment time, it could result in inconsistent and unpredictable uptake of PACs, because
257 such uptake would be influenced by the size, type, and concentrations of particles in air and
258 the wind exposure of a PAS during deployment. Some such inconsistent uptake could
259 conceivably be suggestive of compound loss from the sampler sorbent.

260

261 **Figure 1:** The amounts of three representative chemicals accumulating in the XAD-PASs throughout
 262 the one-year deployment period. The black, green, and red markers indicate the blank-
 263 corrected measured values at the site in Toronto, and the forest and clearing sites in Borden,
 264 respectively. The deployment month and the month in which the last PAS was retrieved are
 265 also indicated at the bottom part of this figure.

266 Seventeen PAHs and four alk-PAHs were reliably detected in the particles collected on the
 267 GFFs from the AASs in the Toronto experiment. Almost all two- and three-rings PACs were
 268 only detected in the gas phase, some four-rings and five-rings PACs could be detected in both
 269 gas and particle phase, and nine less volatile PACs were only found in the particle phase (Figure
 270 2). This is consistent with previous studies (Lewis and Coutant, 2020; Ravindra et al., 2008;
 271 Terzi and Samara, 2004) indicating less volatile PACs with four or more rings mainly being
 272 associated with atmospheric particles, whereas volatile PACs are mostly in the gas phase.

273 Only PACs with at least four or more fused rings in their structure could be detected with a
 274 high percentage in the particle phase, whereas the chemicals taken up by the XAD-PASs were
 275 primarily more volatile PACs with three or fewer rings. The absence of these relatively volatile
 276 PACs in the particle phase (i.e., levels below the LOD) demonstrates that the variation of their
 277 accumulated amount in XAD-PASs in the second half of the year-long deployment cannot be
 278 associated with the uptake of atmospheric particles. Because concentrations of particle-bound

279 PACs in Ontario are much higher in winter than in summer (Su et al., 2007a), their hypothetical
 280 uptake would be expected to occur during the latter half of the Toronto experiment and the first
 281 half of the Borden study. However, the same deviations from continuous uptake are apparent
 282 in the second half of both experiments (Figure 1).

283
 284 **Figure 2:** The average percentages of PACs detected in the particle (green) and gas phase (orange) of
 285 the 48 week-long active air samples taken during the Toronto experiment. PACs were
 286 grouped based on the number of rings in their structure.

287 In the case of the least volatile PACs with five and six rings that were only detected in the
 288 particle phase, their absence in PAS extracts provides further evidence that the XAD-PAS does
 289 not take up atmospheric particles. Daly et al. (2007) previously reported that involatile
 290 chemicals tend to have levels below the limit of detection in XAD-PAS extracts, which is also
 291 consistent with our previous studies indicating that no SVOCs with $\log K_{XAD/air}$ higher than 7.0
 292 at 12.2 °C were detected in XAD-PASs (Li et al., 2023a, b). All evidence therefore refutes the
 293 first hypothesis that particle uptake may be the cause of the variation in the uptake amounts.

294 **Can a Limited Sorbent Uptake Capacity Explain Decreasing Trends in the Amounts**
 295 **Accumulated in PASs?** The second hypothesis is that the uptake capacity for XAD-PAS is
 296 too small to prevent some PACs from reaching equilibrium between sorbent and atmospheric
 297 gas phase after six months of deployment. A subsequent decrease in sorbed amount could then
 298 be attributed to a decrease in air concentration or an increase in temperature, both of which
 299 would allow evaporative loss to exceed uptake. A variant of this hypothesis is that something
 300 is causing a decrease in the sorption capacity of the XAD-resin over time, i.e. the aging of the

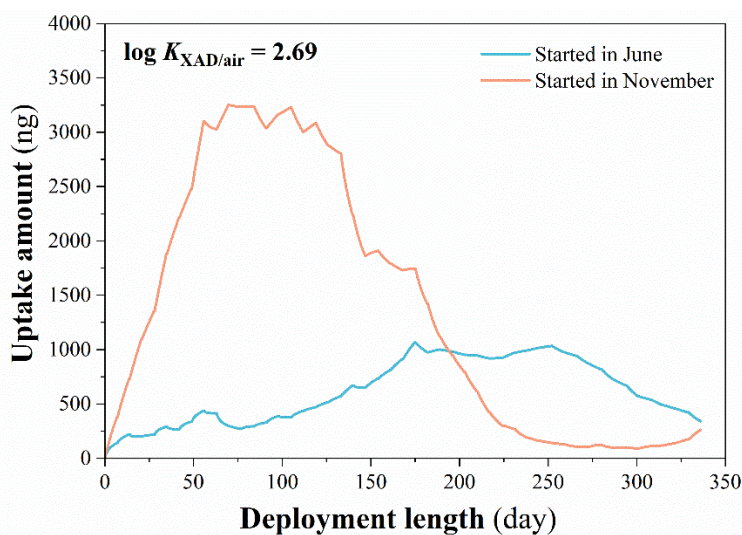

301 resin or competition by other sorbates. Several pieces of evidence do not support this
302 interpretation:

303 During the same calibration experiment in Toronto, we observed highly linear uptake over the
304 entire 48 weeks for SVOCs as volatile as hexachlorobutadiene and monochlorinated biphenyl,
305 with estimated $\log (K_{\text{XAD/air}} / (\text{L air g}^{-1} \text{XAD}))$ values of 2.95 and 3.56 at 20 °C, respectively.
306 Naphthalene, the most volatile of the PACs targeted, has an estimated $\log (K_{\text{XAD/air}} / (\text{L air g}^{-1}$
307 $\text{XAD}))$ of 2.69. It is implausible that some chemicals remain in the linear uptake phase, while
308 chemicals with a very similar or higher affinity for sorbing to XAD from the gas phase would
309 reach equilibrium in the same experiment. Furthermore, there is no indication that the extent
310 of loss of PAC from the PAS during the second half of deployment is related to compound
311 volatility. For example, whereas phenanthrene is less volatile than either naphthalene or
312 fluorene, i.e., has a higher $K_{\text{XAD/air}}$ (Table 2), it was lost from the XAD-PAS to a greater extent
313 than either of these PACs (Figure 1).

314 The potential for evaporative net loss of a PAC from the XAD-PAS is largest in summer, when
315 PAC air concentrations tend to be lower and temperatures are highest. This implies that this
316 potential for evaporative loss during the second half of a one-year experiment would be higher
317 in the case of the Borden calibrations (starting in November) than in the Toronto experiment
318 (starting in June). Figure 3 displays simulated uptake curves for a compound that is volatile
319 enough to reach equilibrium between XAD and gas phase. Applying the seasonal variability of
320 naphthalene air concentrations and the temperatures measured in Borden and Toronto (Figure
321 S7), the model predicts widely divergent uptake curves for deployments starting in November
322 and June. The loss of sorbed naphthalene occurs earlier during an experiment starting in winter
323 (after ca. 120 days of deployment), and the extent of loss is more pronounced. In contrast, the
324 naphthalene uptake curves observed in the field calibration experiments are remarkably similar
325 (Figure 1). In summary, all evidence indicates that PACs did not reach equilibrium and a
326 limited XAD uptake capacity cannot explain the absence of continuous uptake.

327 **Can Reactions with Photooxidants Explain Decreasing Trends in the Amounts**
328 **Accumulated in PASs?** The third hypothesis posits that reactions of sorbed PACs with
329 photooxidants present in the atmosphere could account for the lack of continuous uptake
330 (Jariyasopit et al., 2015; Melymuk et al., 2017). It is well established that ozone can react with
331 PAHs sorbed to solid phases (Borrowman et al., 2016; Zhou et al., 2019) and atmospheric
332 particles (Van Vaeck and Van Cauwenberghe, 1984; Kasumba and Holmén, 2018). While
333 nitrogen dioxide may also react with some PAHs, either no reactions were found (Grosjean et

334 al., 1983; Pitts et al., 1980), or only negligible percentages of PAHs were observed to react
335 with nitrogen dioxide (Tokiwa et al., 1981). Even though gaseous and sorbed PAHs can react
336 with OH radicals (Brubaker and Hites, 1998; Atkinson and Arey, 2007; Esteve et al., 2004,
337 2006; Bedjanian et al., 2010), such reactions are less likely to occur within the dark
338 environment of a XAD-PAS housing, because of the short atmospheric lifetime of OH radicals.
339 Consequently, we focused solely on the reaction between ozone and PACs.

340
341 **Figure 3:** Predicted uptake curves for a volatile chemical reaching equilibrium between XAD and gas
342 phase, i.e., with a $\log (K_{\text{XAD/air}} / (\text{L air g}^{-1} \text{XAD}))$ value of 2.69 at 20 °C, during calibration
343 experiments starting in June and November, while assuming air concentration and
344 temperature variability typical for Southern Ontario. The thickness of the stagnant air
345 boundary layer was set to 0.01cm, the sorption rate was set as $3 \times 10^5 \text{ day}^{-1}$ and no degradation
346 was assumed.

347 Specifically, we exposed PAC sorbed to XAD to high concentrations of ozone in a flow tube
348 to probe the possibility of degradative loss. If the reaction rate of the PACs with ozone is
349 assumed to be proportional to the ozone concentration, an exposure to ~1000 ppb of ozone for
350 24 and 72 hour is equivalent to two to four months of continuous exposure to atmospherically
351 relevant ozone levels of ~25 ppb. During the sampling period in Toronto, the ozone
352 concentration measured at an air monitoring station (43.7479, -79.2741) located ca. 8 km from
353 our sampling site ranged from 10 to 50 ppb with an annual average of 26 ppb (Figure S4). The
354 ozone concentration in the vicinity of the Borden site had a similar range (10 to 60 ppb) and
355 mean (27 ppb) (Figure S5).

356 We succeeded in obtaining a consistent loading of PAHs in the XAD-filled mesh cylinders:
357 The amounts of five PAHs on the XAD, when normalized to the net weight of resin in a mesh

358 cylinder, had a relative standard deviation (RSD) between 4.6 and 6.6% (Table 1). Neither
 359 extended exposure to ozone in the flow tube nor exposure to air in the control experiment
 360 resulted in a significant change ($p > 0.05$) in these amounts of PAHs in the XAD-filled mesh
 361 cylinders (Table 1). In other words, the experiments suggest that ozone did not react with the
 362 PACs sorbed to XAD resin. Interestingly, even though the wall loss of ozone in the flowtube
 363 is negligible (Zhou and Abbatt, 2021), we did observe the continuous loss of ozone during the
 364 flow tube experiments (Figure S8). This loss was much larger than when no XAD was present
 365 in the flow tube, i.e., can be attributed to the resin. One potential explanation is that ozone
 366 reacts with the benzene rings in the XAD resin and because of the orders of magnitude higher
 367 abundance of these aromatic structures compared with the sorbed PAHs, this reaction may
 368 protect the sorbed PAHs from being attacked.

369 **Table 1** The amounts of spiked PAHs on XAD resin before and after ozone exposure

	The amounts of PAHs on XAD resin (ng)				
	Acenaphthene	Anthracene	Phenanthrene	Pyrene	Fluoranthene
Loading Test	60.2 ± 3.1	84.1 ± 5.6	66.9 ± 3.1	120.3 ± 6.6	63.2 ± 3.4
Control Group					
0 ppb O ₃ (1 day)	64.5 ± 1.3	87.1 ± 8.1	68.1 ± 4.8	126.4 ± 2.6	65.5 ± 3.0
Experimental Group					
1000 ppb O ₃ (1 day)	61.7 ± 1.2	84.8 ± 2.5	66.4 ± 2.4	123.8 ± 3.5	64.8 ± 1.9
1000 ppb O ₃ (3 days)	62.5	91.3	68.7	126.9	67.0

370 Further evidence that reactions with photooxidants are not responsible for the loss of PACs
 371 from the XAD-resin is provided again by the expected seasonal variability in the importance
 372 of that process. In both Toronto and Borden, the ozone concentrations are seasonally variable
 373 with higher levels in late summer and early fall and lower levels in winter (Figures S4 and S5).
 374 It thus should affect the second half of a one-year deployment much more strongly in the
 375 Borden experiment than the Toronto experiment. No such difference is apparent. To simulate
 376 the influence of ozone on the uptake amount of a PAC, a model simulation was conducted for
 377 three representative PACs in the Toronto experiment using the model by Zhang and Wania
 378 (2012) modified to allow the sorbed PAC to react with atmospheric ozone. The results from
 379 simulations show that the R^2 values of the best fitting uptake curves for these three PACs
 380 decrease when the actual time-variant ozone concentration is used as an input parameter
 381 (Figure S9). Finally, we note that PAHs that are known to have a higher reactivity with ozone
 382 than others, such as fluorene (Kasumba and Holmén, 2018), anthracene (Kasumba and Holmén,
 383 2018), and benz(a)anthracene (Van Vaeck and Van Cauwenberghe, 1984), do not appear to
 384 show a higher rate of loss from the XAD-PAS when compared to the other PACs. Consequently,

385 based on these discussions and analyses, we conclude that ozone was not the cause of the
386 decreasing trend of these PACs in the XAD-PASs.

387 **What Can Explain Decreasing Trends in the Amounts Accumulated in PASs?** After
388 rejecting all three of our hypotheses, we can formulate a number of constraints on any further
389 potential explanations. We find that the phenomenon is affecting different PACs to a different
390 extent, but this extent is neither related to the PACs' volatility, e.g., as expressed through the
391 $K_{\text{XAD/air}}$, nor to their relative reactivity with photo-oxidants. We further find that the
392 phenomenon appears to be very similar in calibration studies started in early winter and early
393 summer in a region with a strongly seasonal climate. This suggests that the strength of the
394 process causing this phenomenon cannot be strongly affected by season. All three of our
395 hypotheses relied on a seasonally variable process: PAC particle concentrations peak in winter,
396 temperature and therefore evaporative loss potential is highest in summer, and photo-oxidant
397 concentrations and degradative loss potential are also highest in summer.

398 We used additional model simulations (Zhang and Wania, 2012) to further shed light on this
399 issue. For 18 PACs we determined the combination of k_{sorb} and k_{d} values that resulted in the
400 best fit between model-predicted uptake curves and the uptake curves measured during the
401 Toronto experiment ($R^2 > 0.4$). The fits are shown in Figure S10 and the fitted parameters are
402 summarized in Table S10. The k_{sorb} values range between 2,500 and 300,000 day^{-1} , with higher
403 values for more volatile PACs, as had been observed previously.⁶² This range encompasses the
404 range of k_{sorb} values previously estimated for polychlorinated biphenyls (10,000 to 80,000 day^{-1}).⁶² The k_{d} values range from extremely low values for benzo[b]fluoranthene to 0.073 day^{-1}
405 for triphenylene, the latter corresponding to a half-life on the order of 9 days. For many of the
406 PACs the fitted k_{d} values indicate a loss process with a half-life ranging from 10 days (2-
407 methylfluoranthene) to 100 days (phenanthrene). We further explored whether it is possible to
408 obtain model results that describe the observation, if it is assumed that the sorbed PACs do not
409 undergo loss. Uptake curves predicted using the k_{sorb} values in Table S10 and a k_{d} of zero, i.e.,
410 without degradative loss, deviate strongly from the measured ones (Figure 11). In other words,
411 the model cannot find a best fit to the observations without a loss process.
412

413 In summary, the evidence suggests the presence of a process that results in the loss of PACs
414 from the XAD-resin with half-lives on the order of weeks to months. The kinetics of that loss
415 process is different for different PACs, with the k_{d} values in Table 10 approximating the relative
416 susceptibility of different PACs. We have to concede that we presently do not know the nature
417 of that loss process. Microbial degradation could be a possibility, although reported relative

418 rates of degradation for PAHs (Ghosal et al., 2016) are not consistent with our k_d values, i.e.,
419 PAHs with shorter biodegradation half-lives do not appear to show a higher rate of loss from
420 the XAD-PAS. Microbial degradation is likely to be very complex and potentially related to
421 microbial species and communities, as well as environment conditions. More efforts are needed
422 in future studies to further identify the process leading to the loss of PACs from the resin.

423 **Is It Possible to Still Derive Useful Kinetic Information from the Calibration Experiments?**

424 V_{eff} values calculated using Eq. (1) are provided in Tables S7 and S9. Remarkably, when V_{eff}
425 for 15 PAHs, 12 alk-PAHs and dibenzothiophene from the Toronto calibration experiment are
426 plotted against deployment length, i.e., if we linearize the uptake curves from Figures 1 and S2,
427 almost all of the data show good linearity for the first six months of deployment (most linear
428 regressions have $R^2 > 0.90$ and p values < 0.05 , Table 2). Examples of such plots for 2-
429 methylanthracene, 1-methylfluorene, and retene are shown in Figure 4, with the remainder
430 being compiled in Figure S12. This is also true for fluoranthene and pyrene measured at the
431 clearing site in Borden, but not at the forest site (Figure S13). As only PUF plugs were used in
432 the AASs to sample PAHs from the gas phase in Borden, five light PAHs (i.e., naphthalene,
433 acenaphthylene, acenaphthene, fluorene, and phenanthrene) suffered from breakthrough,
434 yielded unreliable C_{air} and therefore were excluded from the data analysis.

435
436 **Figure 4:** The effective sampling volume of three representative PACs throughout the 48-week
437 deployment period for XAD-PASs in Toronto. The markers indicate field blank-corrected
438 measured values, whereby data points marked with open symbols were excluded from the
439 regression analysis. The red lines indicate linear regressions forced through the origin. The
440 shaded areas represent the uncertainties of the calculated sampling rates obtained from the
441 uncertainties of the slopes of these regressions. Sampling rates in $\text{m}^3 \text{ day}^{-1}$ are obtained from
442 the slope of these regressions.

443 As might be expected from the uptake curves, the V_{eff} for most PACs is leveling-off or
444 decreasing after six months (Figures 3, S11, and S12). Nevertheless, the linear uptake within
445 the first half year of deployment suggests that the XAD-PAS can be used to sample PACs from
446 the gas phase, even the most volatile one (naphthalene), as long as the deployment period does
447 not exceed six months. Experimental sampling rates ($SR_{\text{experimental}}$) for 28 PACs, including 15
448 PAHs, 12 alk-PAHs, and dibenzothiophene, were estimated from the slopes of linear
449 regressions for the data points from the first six months of deployment and ranged from 0.05
450 to $0.53 \text{ m}^3 \text{ day}^{-1}$. Uncertainties of the $SR_{\text{experimental}}$ values in the range of 2 to 15% were estimated
451 from the standard error of the slopes of these linear regressions. For fourteen compounds (2
452 PAHs, 11 alk-PAHs, and dibenzothiophene), these are the first SR s ever reported for the XAD-
453 PAS. The $SR_{\text{experimental}}$ values for fluoranthene and pyrene from the Toronto and Borden
454 experiments are very close, lending support to the reliability of the two experiments. The actual
455 sampling rates (SR_{actual}) for 18 PACs were obtained using the simulated no-degradation uptake
456 amounts in the first six months of deployment (Figure S11) and AAS data in our Toronto
457 experiment based on Eq. (1) (Table S11).

458 The $SR_{\text{experimental}}$ values in this study are lower than those reported for PAHs previously
459 (Armitage et al., 2013; Ellickson et al., 2017). The $SR_{\text{experimental}}$ values for various SVOCs
460 obtained from the same Toronto calibration experiment were also lower than those reported in
461 other literature (Li et al., 2023b, a). The difference between the $SR_{\text{experimental}}$ values calculated
462 in our study and those previously reported may be caused by the difference in ambient wind
463 speed (1.7 , ~ 4.0 , and $\sim 8.0 \text{ m}\cdot\text{s}^{-1}$ during our study, the study of Armitage et al. (2013), and the
464 study of Ellickson et al. (2017), respectively) and possibly also in the rates of degradative loss.
465 Other reasons for the relatively higher SR s in the study of Ellickson et al. (2017) may be due
466 to (1) break-through losses for more volatile PAHs during the high-volume AAS; (2) failure to
467 sample episodes of elevated air concentration when only sampling episodically with the AASs;
468 and (3) lower air concentrations at active air sampling sites than those at passive air sampling
469 sites.

470 The reliability of $SR_{\text{experimental}}$ and SR_{actual} values for PACs presented here is supported by them
471 falling within a similar range as those for other SVOCs from the same calibration experiment
472 (Li et al., 2023b, a). Also, the SR s for PACs exhibit a consistent negative correlation with \log
473 $K_{\text{XAD/air}}$, mirroring the pattern observed for other SVOCs (Figure 5). However, the $SR_{\text{experimental}}$
474 for PACs are relatively lower than those of the PCBs and other SVOCs with similar $K_{\text{XAD/air}}$
475 values, presumably due to the degradative loss, whereas the SR_{actual} for PACs have a

476 relationship with $K_{\text{XAD/air}}$ that is very similar to that of the PCBs (Figure 5). A linear regression
 477 with the $\log(K_{\text{XAD/air}} / (\text{L air g}^{-1} \text{XAD}))$ at 12.2 °C yields the following relationship:

478 $SR_{\text{experimental}} (m^3 \text{ day}^{-1}) = -0.06(\pm 0.02) \log(K_{\text{XAD/air}} / \text{L g}^{-1}) + 0.55(\pm 0.08)$ (2)

479 $n = 30, p < 0.0005, R^2 = 0.35$

480 $SR_{\text{actual}} (m^3 \text{ day}^{-1}) = -0.11(\pm 0.03) \log(K_{\text{XAD/air}} / \text{L g}^{-1}) + 0.90(\pm 0.17)$ (3)

481 $n = 18, p < 0.0005, R^2 = 0.40$

482 Going forward, we recommend deployment periods for the XAD-PAS to be kept shorter than
 483 6 months, if PACs are among the targeted SVOCs. We suggest that for such shorter
 484 deployments, the $SR_{\text{experimental}}$ reported in Table 2 can be used. For PACs not included in Table
 485 2, their $SR_{\text{experimental}}$ and SR_{actual} can be estimated using a predicted $K_{\text{XAD/Air}}$ value and Eqs. (2)
 486 and (3). A quantitative interpretation of PAC levels in XAD-PAS deployed for periods longer
 487 than half a year may be compromised by the variable degradation loss of PACs from the XAD-
 488 resin. This applies retroactively also to studies that have reported PAH levels in XAD-PAS
 489 deployed for one year; they should be considered to be semi-quantitative only (Daly et al., 2007;
 490 Lévy et al., 2018; Choi et al., 2009; Westgate et al., 2010; Abdul Hussain et al., 2019;
 491 Schummer et al., 2014; Schrlau et al., 2011).

492
 493 **Figure 5:** The increase of the sampling rates of 120 chemicals with an increase in volatility. Different
 494 markers are used to indicate sampling rates of different chemical groups, and the lines in

495 different colors indicate linear regressions between the sampling rate and $\log K_{\text{XAD/air}}$ at
496 12.2 °C for different chemical groups. The dark green dots and line indicate the simulated
497 sampling rates for PACs without degradation and linear regression for these PACs.

498 **Table 2** Passive Sampling Rates ($\text{m}^3 \text{d}^{-1}$) of PACs Determined in Our Study and Reported in Literature

499 * Data for the clearing site from the Borden experiment. The originally calculated sampling rates are for the long version XAD-PAS, i.e., the length of XAD-2 mesh cylinders is 20 cm; thus, in
500 this table, they were converted to the sampling rates of short version XAD-PAS (10 cm length) by dividing by two (Zhang et al., 2012), ^a (Armitage et al., 2013), ^b (Ellickson et al., 2017)

501 **Acknowledgement**

502 We are grateful to Rudy Boonstra for logistical help during field work in Toronto, and Bondi
503 Gevao for help sampling in Borden. Financial support from a Grant and Contribution
504 Agreement (GCXE20S008) with Environment and Climate Change Canada and a Connaught
505 scholarship to YL is gratefully acknowledged. The work at Borden was supported by a grant
506 from the Canadian Foundation for Climate and Atmospheric Sciences (CFCAS).

507 **Code/Data availability**

508 All data generated for this project are contained in the supplement.

509 **Author contribution**

510 YL and FZ performed measurements and analyzed samples from the Toronto experiment, YS
511 performed measurements and analyzed samples from the Borden experiment, both under the
512 supervision of YDL. CS analysed the atmospheric particle samples. YL performed the ozone
513 flow tube experiment with guidance by ZZ and JPDA. YL and FZ performed the model
514 simulations and YL interpreted the data and wrote the manuscript under guidance by FW. HH
515 coordinated the project. All authors reviewed the manuscript.
