Technical Note:

Multi-year Changes in the Brewer-Dobson Circulation from HALOE Methane

Ellis Remsberg

November, 2023

Abstract. This study makes use of Halogen Occultation Experiment (HALOE) methane (CH₄) in a search for multi-year changes in the Brewer-Dobson Circulation (BDC). Changes in CH₄ are determined for three, successive 5-yr time spans from 1992 to 2005, and there are significant differences in them. There is a clear separation for the changes in the northern hemisphere near 30 hPa or at the transition of the shallow and deep branches of the BDC. The CH₄ changes are positive and large in the shallow branch following the eruption of Pinatubo, but they then decrease and agree with tropospheric trends in the late 1990s and early 2000s. CH₄ decreases in the upper part of the deep branch from 1992 to 1997 or following the eruption of Pinatubo. CH₄ continues to decrease in the deep branch in the late 1990s but then increases in the early 2000s, although those changes are small compared with the seasonal and interannual variations of CH₄. Multi-year changes are due, in part, to wave forcings during El Nino Southern Oscillation (ENSO) of 1997-1998 and beyond and to episodic, sudden stratospheric warming (SSW) events during both time spans. It is concluded that time series of HALOE CH₄ provide effective tracer diagnostics for studies of the nature of the BDC from 1992 to 2005.

27

28 **1. Introduction**

29 Global-scale stratospheric transport is characterized in each hemisphere by a seasonal Brewer-
30 Dobson circulation (BDC), consisting of upward transport in the tropics, poleward transport to
31 higher latitudes, and descent in the polar vortex region (e.g., Butchart, 2014). Model studies
32 indicate that there are also multi-year changes in the BDC in response to increases in the
33 greenhouse gases (GHG) and to dynamical forcings during El Nino/Southern Oscillation
34 (ENSO) events, but where the effects of those forcings may differ within the shallow (lower) and
35 deep (upper) regions of the BDC. Remsberg (2015) reported that the distributions of methane
36 (CH_4) from the Halogen Occultation Experiment (HALOE) provide tracer diagnostics for
37 changes in the BDC. The present study is a refinement of his initial analysis and gives some
38 insight on mechanisms for changes in the BDC. Section 2 is a brief description of the methane
39 data and the analysis approach for them. Section 3 presents the results of the analyses in terms
40 of changes in the distribution of CH_4 for three successive 5-yr time spans. Qualitative
41 attributions are also considered for those changes. Section 4 summarizes the findings from this
42 exploratory study.

43

44 **2. Data and Analysis Method**

45 HALOE obtained sunrise (SR) and (SS) occultation measurements across latitude zones
46 throughout its mission of October 1991 to November 2005. The present study considers zonal
47 averages of CH_4 for nine latitude zones and at twelve pressure levels (0.4 to 50 hPa), for a total
48 of 108 separate time series. A minimum of 5 profiles gives representative zonal averages for
49 each latitude zone; averages are based on many more profiles in most instances. Figure 1 shows
50 example time series from zonal averages of the SR and SS measurements at specific pressure
51 levels and in three different latitude zones. Figure 1(a) is the time series for the 10 hPa level at
52 30°N latitude, and there is a clear QBO-signal in the data. Figure 1(b) is for 10 hPa at 30°S ,
53 where there is a combination of annual (AO), semi-annual (SAO), and QBO signals. One can
54 also see that seasonal and interannual variations are much larger than the longer-term changes.

55 Figure 1(c) is for 2 hPa at 45°N, where CH₄ decreases gradually in the early to middle 1990s and
56 where it has larger amplitudes in early 2002 and 2004.

57

58 The analysis of CH₄ for this study is in the manner of Remsberg (2015) with the following
59 modifications. The nine latitude zones are from 60°S to 60°N with a spacing of 15° and no
60 overlap. The latitude bins are a bit narrower than before (15° versus 20°) but still provide
61 representative sampling, even at ±45° from 2000 to 2005 when the samples from HALOE are
62 limited. To look for secular trends in the BDC, multiple linear regression (MLR) analysis was
63 applied to the CH₄ time series, as separated into three, 5-yr time spans that overlap by one year
64 (July 1992 to June 1997; July 1996 to June 2001; and July 2000 to June 2005). The beginning
65 and end months of July and June, respectively, were selected to avoid large excursions in CH₄ at
66 the end points of time series for the northern hemisphere during the dynamically active winter
67 season. Data prior to July 1992 were not used, to avoid issues related to variable solar lock-
68 down procedures for the HALOE sun sensor and because of significant extinction from
69 interfering aerosols following the Pinatubo eruption. The analyses also do not include the period
70 after June 2005, when HALOE operations were limited.

71

72 An initial MLR analysis was applied to the 13-yr time span of the HALOE measurements for a
73 range of pressures and latitudes but using only AO and SAO terms. Time series residuals from
74 those runs were analyzed for interannual cycles, yielding significant terms with periods of 882
75 days (~29-month or QBO-like) and of 690 days (22.6-month or sub-biennial (SB)). Those two
76 terms were highly significant for many of the latitude/pressure time series, so they were included
77 along with the seasonal terms for the MLR model. The 5-yr (or 60 month) time span is
78 equivalent to two complete QBO cycles and avoids biases in the MLR trends due to that periodic
79 term. A biennial (718-dy) term was also indicated for the subtropics, but it was not uniformly
80 present elsewhere and was not retained for the model. A linear term completes the final MLR
81 model; the analyses also correct for lag-1 autoregressive (AR1) effects. The MLR model fit to
82 the data points is shown by the oscillating solid curve for July 1996 to June 2001 in each panel of
83 Fig. 1, and the combination of the constant and linear terms is the dashed line. One can see that
84 the seasonal and interannual variations have large amplitudes compared with the overall 5-yr

85 trend line, such that even minor changes from year to year can affect the linear changes.
86 Although the MLR fits and trends are based on analyzed AR1 values for each case, the MLR
87 curves in Fig. 1 are based on $AR1 = 0$ and give maximum amplitudes for the periodic terms.

88

89 The sensitivity of the trend coefficient to the approximate QBO term of the MLR fit was
90 determined for Fig. 1(a) ($30^{\circ}N$, 10 hPa), where a QBO cycle shows clearly. Specifically, the
91 length of the QBO cycle was altered (28 months versus 29.5 months) as well as the length of the
92 time span for the MLR analysis (58 months rather than 60 months). The resulting trend
93 coefficients in each case differ by less than 6% from the one of Fig. 1(a). Figure 1(c) focuses on
94 the upper stratosphere, where CH_4 decreases from 1992 to 1997 or from one year after the
95 Pinatubo eruption. The 5-yr trend is less negative from 1996 to 2001 and then is positive from
96 2000 to 2005, punctuated by two winter maximums in early 2002 and 2004.

97

98 The distribution of the average CH_4 (its constant term) is shown in Figure 2 for the time span of
99 July 1996 to June 2001. Tropical entry-level values extend upward and are transported poleward
100 in each hemisphere. CH_4 decreases with altitude and latitude, due to the relatively slow chemical
101 conversion of CH_4 to water vapor (H_2O) and molecular hydrogen (H_2) in the upper stratosphere
102 (Brasseur and Solomon, 2005). That decay of CH_4 is nearly symmetric between the two
103 hemispheres. The primary purpose of Fig. 2 is to show the vertical and meridional gradients of
104 CH_4 that are acted upon by the BDC. Although the CH_4 distributions for the other two 5-yr time
105 spans are like that of Fig. 2, there are small but distinct differences in the 5-yr changes in CH_4 for
106 the three successive time spans.

107

108 Distributions of the linear terms (% change / 5-yr) from the zonally averaged CH_4 data are shown
109 and discussed in Section 3 for each of the three periods of July 1992 to June 1997, July 1996 to
110 June 2001, and July 2000 to June 2005. Notably, there is good continuity for the trends with
111 pressure and latitude, indicating that each distribution is meaningful and related physically to
112 multi-year changes for the large-scale BDC.

113

114 **3. Multi-year changes in CH₄**

115 *(a) July 1992 to June 1997*

116 Figure 3 shows that CH₄ decreased in the upper stratosphere and lower mesosphere from July
117 1992 to June 1997 or after one year from the Pinatubo eruption of June 1991. The shading
118 indicates where the trends are robust, the dark shading having a confidence interval (CI) of
119 greater than 90% and the light shading having CI between 70 and 90%. Positive changes in CH₄
120 at low and middle latitudes indicate an acceleration of the BDC, and negative changes imply
121 deceleration of the BDC. The negative changes in CH₄ in the upper regions of Fig. 3 imply that
122 there was an overall slowdown of the deep branch of the BDC during this time. Changes are
123 larger at middle latitudes of the northern than of the southern hemisphere, indicating that ascent
124 occurred within the deep branch of the BDC in the northern subtropics immediately after the
125 eruption and then there was a decrease from those values. Separate, zonal mean cross sections of
126 HALOE CH₄ (not shown) reveal that the 0.8 ppmv contour of CH₄ occurred at ~4 hPa in
127 November 1991 but rose to ~2 hPa by February 1992 in response to the BDC of that winter (e.g.,
128 Russell et al. 1999). Thereafter, CH₄ values that had been lofted to higher altitudes underwent a
129 gradual decline over time. Sudden stratospheric warming (SSW) events tend to accelerate the
130 deep branch of the BDC and mix middle latitude and polar air; that mixing flattens the contours
131 of zonal average CH₄ mixing ratio. However, there were no SSW events in the northern
132 hemisphere during 1992 to 1997 (Choi et al., 2019).

133

134 A more traditional indicator of changes in the BDC is stratospheric age-of-air (AoA), where
135 negative AoA indicates acceleration and positive AoA implies a deceleration of the BDC.
136 Pitari et al. (2016) estimated that AoA decreased in the middle to upper stratosphere by ~0.5 to
137 0.7 yr during 1991-1992, due mainly to ascent following the eruption of Pinatubo. Fig. 3
138 indicates a decline of CH₄ (and presumably an increase in AoA) from July 1992 onward.
139 Methane is not a perfect tracer, however, as it has a chemical lifetime as short as only a few
140 months at 45 km (~1.5 hPa) and then lengthening to 6 months and longer at 55 km and above
141 and at 40 km and below (Brasseur and Solomon, 2005). The relatively short lifetime of CH₄ at
142 1.5 hPa means that even the seasonal variations of CH₄ are dampened at that level. The near-

143 zero changes for CH₄ near 15°S and 2 hPa in Fig. 3 may imply that there was still some transport
144 of CH₄ to that region from the tropics after July 1992.

145

146 The 5-yr changes in Fig. 3 also indicate that there was an accumulation of CH₄ at ~20 to 30 hPa
147 at middle latitudes of both hemispheres during this period, in reasonable accord with a net
148 poleward transport of tropical CH₄ at the top of the shallow branch of the BDC. The tropical
149 trend of 3 to 4 % at 20 to 30 hPa is half that at middle latitudes, although it is still larger than the
150 tropospheric trends for CH₄ of ~0.3 to 0.4 % / yr (or 1.5 to 2.0 % for the 5-yr period)
151 (Dlugokencky et al., 2009).

152

153 Figure 4 gives more detail about the effects of the Pinatubo eruption on CH₄ in the lower
154 stratosphere. Fig. 4(a) is for 15°N, 50 hPa and shows an initial increase in CH₄ in 1991 to the
155 middle of 1992, followed by decreasing values through 1993. HALOE CH₄ values are of the
156 order of 1.55 ppmv in 1992, declining to 1.45 ppmv in 1993, and then increasing again.
157 Independent CH₄ measurements at ground level are between 1.70 and 1.75 ppmv (Dlugokencky
158 et al., 2009). As an aside, HALOE CH₄ values for SR in 4(a) are consistently larger than for SS.
159 Those differences are likely due to uncorrected detector hysteresis effects for tropical SR
160 measurements just above cloud tops; they decrease at 30 hPa and are negligible at 20 hPa. Diallo
161 et al. (2017) reported that AoA decreased during the first six months following the eruption of
162 Pinatubo due to tropical upwelling. Then, AoA increased from early 1992 to spring 1993
163 between 20°S and 30°N and from 20 to 27 km (~50 hPa to 15 hPa), implying a deceleration of
164 the shallow branch of the BDC during that time. The HALOE SR and SS CH₄ variations are in
165 accord with the changes in AoA from 1991 to 1993 in the shallow branch of the BDC.

166

167 Figure 4(b) is the HALOE CH₄ time series for 45°N, 30 hPa, and it shows a gradual increase of
168 CH₄ for 1993 to 1997. Yet, Diallo et al. (2017) reported increases in AoA for 1993 at tropical
169 and middle latitudes due to meridional mixing, followed by decreases in mixing and AoA
170 through 1997. Fig. 3 suggests that there was an accumulation of CH₄ at middle latitudes between
171 ~20 and 30 hPa, due in part to that mixing trend. It may also be that there was an overall

172 slowdown in the BDC during this 5-yr period, which was absent of SSW events and any
173 enhanced descent of CH₄-poor, polar air plus its subsequent mixing to middle latitudes.

174

175 *(b) July 1996 to June 2001*

176 Figure 5 shows the 5-yr CH₄ changes for 1996 to 2001, when there were several SSW events—
177 on 15 December 1998, 25 February 1999, and 20 March 2000 (Choi et al., 2019). The negative
178 trends in the upper stratosphere are smaller in the northern hemisphere and larger in the southern
179 hemisphere than in Fig. 3, suggesting that there was tropical ascent but also increased mixing of
180 CH₄ to higher latitudes, related in part to SSW activity. Those changes are also where the
181 chemical loss of CH₄ to H₂O and H₂ may be a factor. It is apparent that there was greater
182 meridional transport of CH₄ from the tropics to middle latitudes and an accumulation of CH₄ at
183 ~10 hPa in both hemispheres during 1996 to 2001. Those positive trends are at a level of the
184 stratosphere where the conversion of CH₄ to H₂O and H₂ is not as effective.

185

186 There was a major warm ENSO event in 1997-1998 that altered wave forcing effects on CH₄ and
187 for the BDC. Randel et al. (2009) and Calvo et al. (2010) reported enhanced upwelling in the
188 tropics and an acceleration of the BDC at that time. Diallo et al. (2019) reported that ENSO
189 leads to the overall strengthening of the shallow branch of the BDC in the extratropics. It may
190 be that enhanced poleward transport in the shallow branch is why the CH₄ changes are more
191 nearly zero in the tropics and agree more closely with tropospheric trends. There is a clear
192 separation at ~30 hPa in the sign of the changes in the shallow versus the deep branch of the
193 BDC in the northern hemisphere.

194

195 The 1997-1998 warm ENSO event occurred near solar minimum, for which Calvo and Marsh
196 (2011) also found enhanced wave forcing in the middle and upper stratosphere. That activity
197 leads to acceleration of the BDC and poleward transport of CH₄ to the extratropics. Barriopedro
198 and Calvo (2014) also found connections between ENSO and SSW events, although the exact
199 effects depend on the relative sequence of those events. Since major SSWs within 1996-2001

200 occur in December 1998, February 1999 and in March 2000, it is likely that they merely led to
201 further accelerations of the BDC. As an example, Tao et al. (2015) gave details about how the
202 SSW of 2009 led to an acceleration of the BDC. Their analyses may support the present finding
203 of increases in CH₄ in the extratropics near 10 hPa in Fig. 5. However, more focused studies of
204 the relative roles of SSWs and ENSO on the results of Fig. 5 are beyond the scope of the present
205 exploratory study.

206

207 *(c) July 2000 to June 2005*

208 There was even more SSW activity in the northern hemisphere during the 5-yr span from 2000 to
209 2005 (on 11 February 2001, 2 January 2002, 18 January 2003, and 7 January 2004, according to
210 Choi et al., 2019). The distribution of changes in CH₄ in Figure 6 includes the net effect of those
211 episodic SSW events. There was an increase in CH₄ at upper altitudes, where the effect of SSWs
212 may have also led to greater poleward transport of CH₄ to higher latitudes. As before, an SSW
213 event accelerates the deep branch of the BDC, bringing more CH₄ to high altitudes and greater
214 meridional transport to higher latitudes. At the stratopause (~1 hPa) and in the lower mesosphere
215 even small changes in CH₄ mixing ratio translate to relatively large percentage changes. Those
216 changes are from negative to positive from Fig. 5 to Fig. 6 and are rather uniform across latitude.
217 On the other hand, the changes near 10 hPa and at middle latitudes of the northern hemisphere
218 are weaker now than in Fig. 5. Fig. 1(a) indicates that this change may be a consequence, in part,
219 of large seasonal amplitudes for CH₄ in early 2001 and in 2005 or near the end points of the 5-yr
220 period from July 2000 to June 2005.

221

222 In the southern hemisphere there was an anomalous SSW event on 22 September 2002, leading
223 to a splitting of the polar vortex (Newman and Nash, 2005). The CH₄ changes from Fig. 5 to
224 Fig. 6 at 10 hPa and 30°S were likely altered by that event (c.f., the time series segments in Fig.
225 1(b) for those two 5-yr periods). Note that there is no clear separation of the shallow and deep
226 branches of the BDC for the southern hemisphere in Fig. 6.

227

228 Figure 7 provides a clearer picture of what occurred from 2000 to 2005. Fig. 7(a) is a time series
229 of CH₄ at 45°S and 20 hPa, and it shows pronounced annual cycles in CH₄. A peak seasonal
230 value occurs in 2001, and it may be influencing the overall analyzed trend for that time span. On
231 the other hand, there is little indication of a change in CH₄ at the time of the anomalous SSW
232 event of September 2002. Fig. 7(b) shows the corresponding CH₄ time series at the Equator and
233 20 hPa, where CH₄ variations are forced primarily by the QBO. There is a clear decrease in CH₄
234 in 2001 compared to the maximum at 45°S in Fig. 7(a). Fig. 7(b) also shows that tropical QBO
235 signals are nearly absent in CH₄ from 1996 to 2000. Bönisch et al. (2011) reported that tropical
236 upwelling increased after 2000 and accelerated the shallow branch of the BDC. Similar studies
237 based on variations in CH₄ may be helpful in determining the nature of the shallow layer of the
238 BDC both prior to and after 2000.

239

240 **4. Summary findings**

241 The present study is an analysis of the distributions of HALOE CH₄ for indications of secular
242 changes in the BDC. Linear trends in CH₄ were determined for three, successive 5-yr time
243 spans, and there are significant differences between them. There is a clear separation of the deep
244 and shallow branches of the BDC at about 30 hPa in the northern hemisphere in each time span.
245 Although the changes for CH₄ in the shallow branch are rather large following the eruption of
246 Pinatubo, they agree well with tropospheric trends for CH₄ during the late 1990s and early
247 2000s. There are decreasing changes in the upper part of the deep branch of the BDC in the
248 early to middle 1990s, indicating a decline of CH₄ from one year after the eruption. CH₄
249 changes in the middle and upper stratosphere differ markedly for the early 2000s compared to
250 those of the late 1990s, although those differences are small compared to the seasonal and
251 interannual variations of CH₄. In addition, the seasonal changes within the deep branches differ
252 in each hemisphere, perhaps due to episodic SSW events and to wave forcings during ENSO.

253

254 In terms of multi-year changes for the BDC, it appears that during the period of 1992 to 1997
255 there was acceleration of the shallow branch and deceleration of the deep branch. However,
256 those implied changes in the BDC may be anomalous because of the large perturbation to the

257 CH₄ distribution in 1991 from the Pinatubo eruption. During 1996 to 2001 the changes in the
258 shallow branch were nearer to zero, while decreasing trends persisted in the deep branch. Yet, it
259 also appears that there was acceleration of the poleward transport and mixing at middle latitudes
260 within the layer from ~30 hPa to ~7 hPa during that 5-yr period. Then, there was a deceleration
261 in the shallow branch and acceleration in the deep branch of the BDC during 2000 to 2005. The
262 implied BDC also differed markedly in the two hemispheres over that final 5-yr span. It is
263 concluded that time series of HALOE CH₄ provide effective tracer diagnostics for studies of the
264 secular nature of the BDC from 1992 to 2005.

265

266 *Data availability.* The HALOE V19 profiles are at the NASA EARTHDATA site of EOSDIS,
267 and its website is https://disc.gsfc.nasa.gov/datacollection/UARHA2FN_019.html (Russell et al.,
268 1999).

363

364 Figure 1—Time series of HALOE CH₄ (a) 30°N and 10 hPa, (b) 30°S and 10 hPa, and (c) 45°N
365 and 2 hPa. MLR fit for July 1996 through June 2001 is the solid curve, and its linear trend is the
366 dashed line. Day numbers on the abscissa are from 1 January 1991. Model terms are listed at
367 bottom left.

388

389

390 Figure 3—Changes in CH₄ for July 1992 through June 1997 (in % / 5-yr); positive changes are
 391 solid, negative changes are dotted, and zero is dashed. Contour interval is 2 % within ±12 % but
 392 4 % outside that range. Dark shading shows where the confidence interval (CI) for the trends is
 393 greater than 90 %, and light shading shows where CI is between 70 and 90 %.
