## S1 Measurements

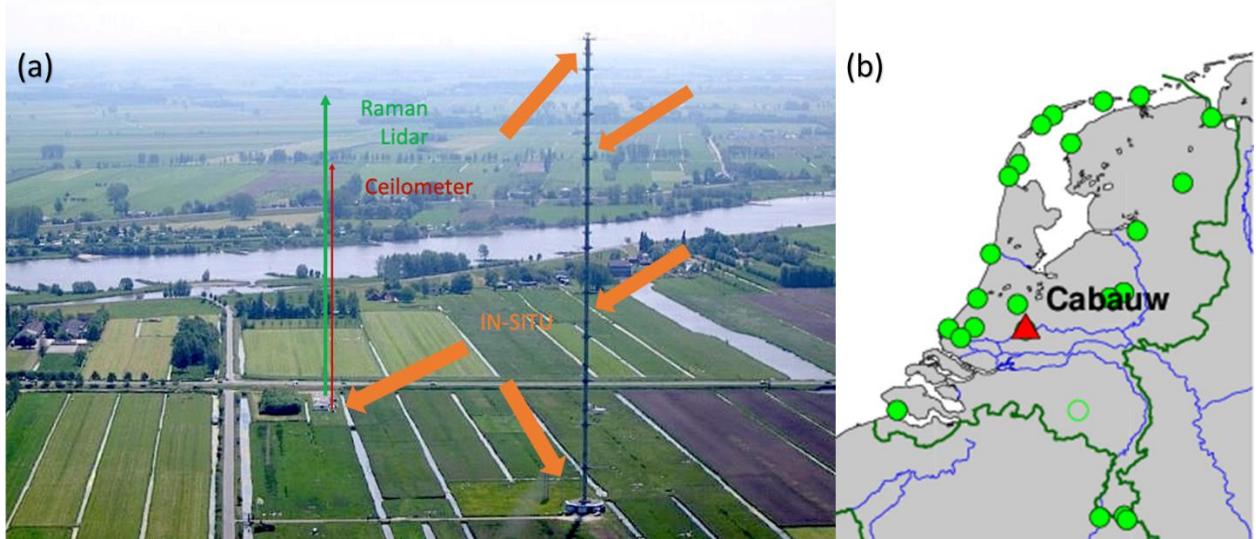

Figure S1: (a) An aerial view of the infrastructure setup during the RITA-2021 campaign (photo by Wouter Knap, KNMI). (b) The CESAR site (marked in red) location in the Netherlands<sup>1</sup>.

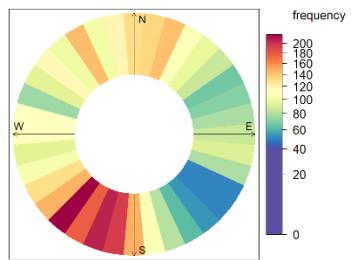

Figure S2: The frequency of the hourly average wind direction at CESAR in RITA campaign from May 7<sup>th</sup> 2021 to October 20<sup>th</sup> 2021.

<sup>1</sup> <http://gnss1.tudelft.nl/dpga/station/Cabauw.html>

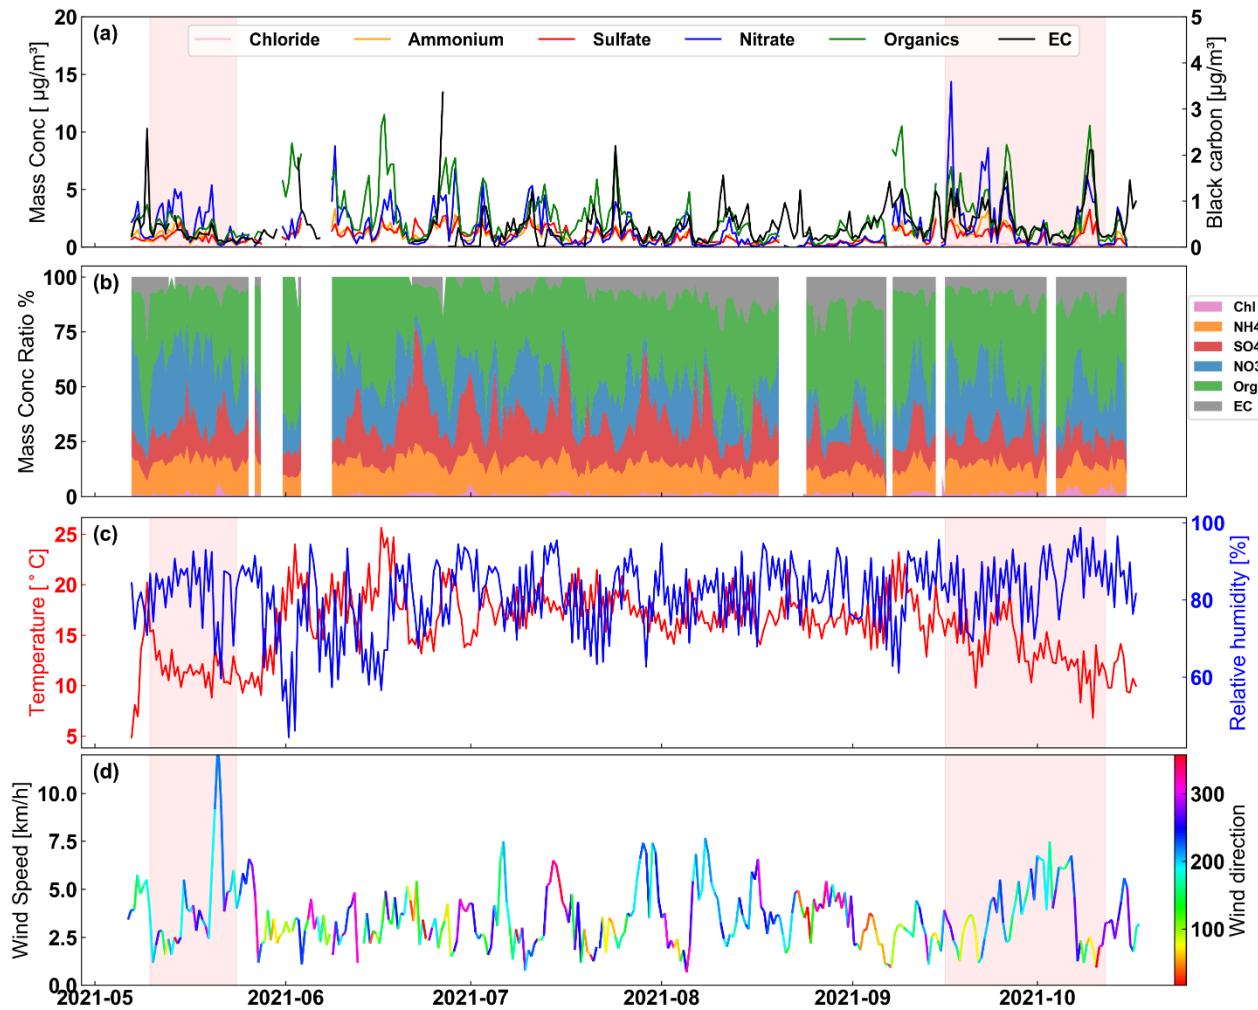

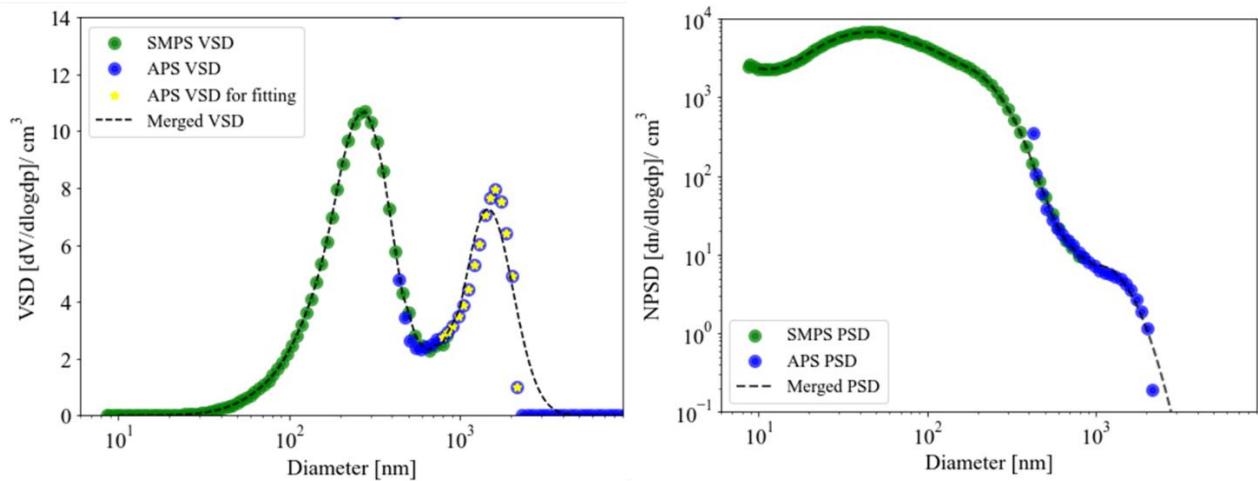

Figure S3: Time series of (a) aerosol chemical composition mass concentration and (b) the corresponding mass fraction (c) temperature and relative humidity (d) wind speed and wind direction from May to November in 2021. The two intensive RITA-2021 campaigns are marked with a pink background.

## S2 Merged particle size distribution

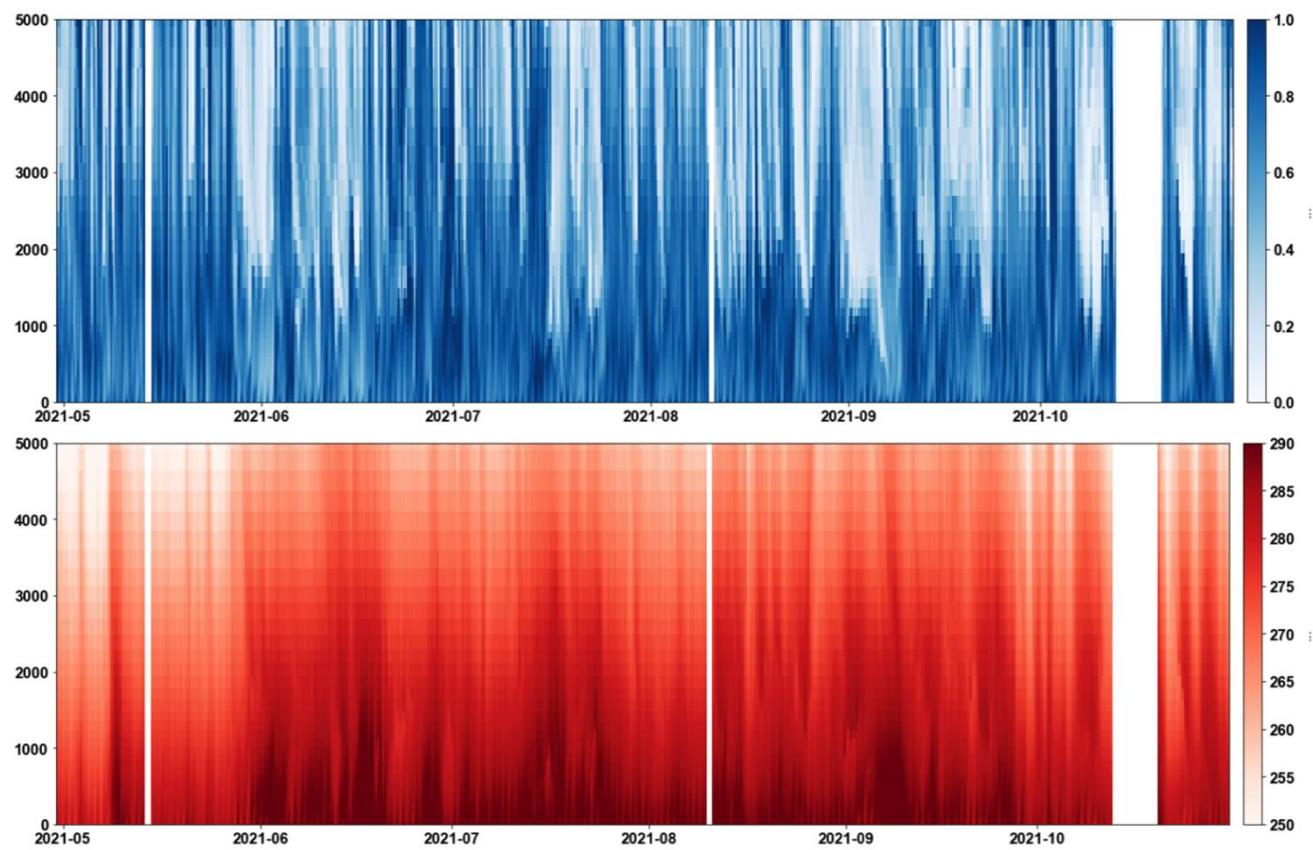

**Figure S4: Example of the joined particle size distribution.** (a) The volume size distribution (VSD) ( $dV/d\log(dp)$   $cm^{-3}$ ) of raw SMPS data (green dots). The VSD of APS data (blue dots). The selected APS data for fitting (yellow stars). The final joined VSD with dash line. (b) The PSD (particle number size distribution) ( $dn/d\log(dp)$   $cm^{-3}$ ) of SMPS (green dots), and the PSD of APS (blue dots), as well as the joined PSD (dash line).

Figure S4 shows an example of the merged particle size distribution by the SMPS and APS. The APS aerodynamic diameters were converted to volume equivalent diameters by dividing by the square root of particle effective density. The effective density was derived by an iterative approach. The volume size distribution for coarse particles (greater than 2.5 micrometres aerodynamic diameter) is converted to a mass size distribution assuming various effective densities spanning from 1.0 to 2.0 ( $g\cdot cm^{-3}$ ), with steps of 0.1. Each obtained mass distribution is then integrated to compute the total mass concentration of coarse particles. The calculated coarse mass concentrations for each assumed density are then compared to the measured coarse mode mass concentrations, determined as the difference between  $PM_{10}$  and  $PM_{2.5}$  mass concentrations from gravimetric analysis. The effective density for each case is the density for which the calculated and measured coarse mode mass concentrations agree best. The average effective density is  $1.6\ g\cdot cm^{-3}$ . For missing or unrealistic APS data, showing a sudden drop to 0 (see figure S4 a) or negative values or unrealistically high values, it was assumed that the coarse mode volume size distribution follows a lognormal distribution. The mean and standard deviation of the coarse mode was then fixed based on the coarse mode distributions that were measured during earlier Trolix campaigns in 2019. Then the lognormal distribution fitting and interpolation were performed on the obtained particle size distribution data (as shown in Figure S4). An average  $\mu = 7.70$  and  $\sigma = 0.46$  (shown in section S7 in TableS2) were used in the correction for the wrong APS data with fitting equation as below:

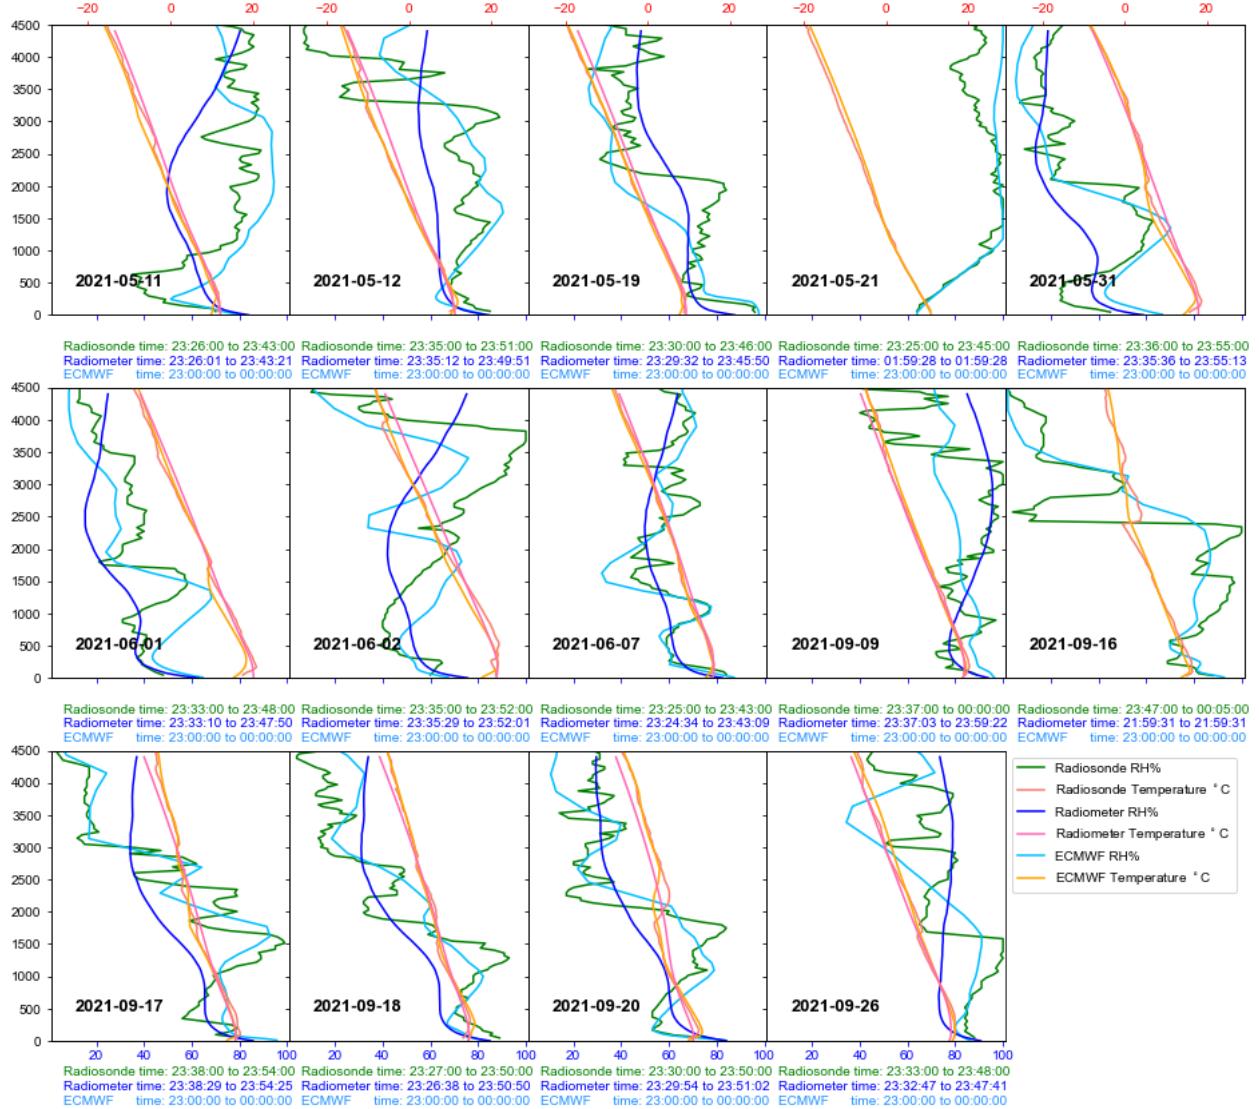

$$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} \exp\left(-\frac{(lnx - \mu)^2}{2\sigma^2}\right),$$

where the  $x$  is the diameter (nm), the yellow point in FigureS3 in this case. The  $\mu$  is the mean of samples in distribution, and  $\sigma$  is the standard deviation.

### S3 Meteorological profiles

**Figure S5:** Time series of the meteorological profiles from the ECMWF model, including the relative humidity (top graph) and Temperature (K, bottom graph) at CESAR from May to November in 2021.

**Figure S6:** The relative humidity profiles of the radiosonde (in green), and the radiometer (in blue), and ECMWF (in sky blue) the tempreture profiles of radiosonde (in red), radiometer (in pink), and ECMWF (in orange) measured at times corresponding to Radiosonde balloon measurements during the RITA-2021 campaign.

#### S4 Optical properties compared by calculation and Nephelometer

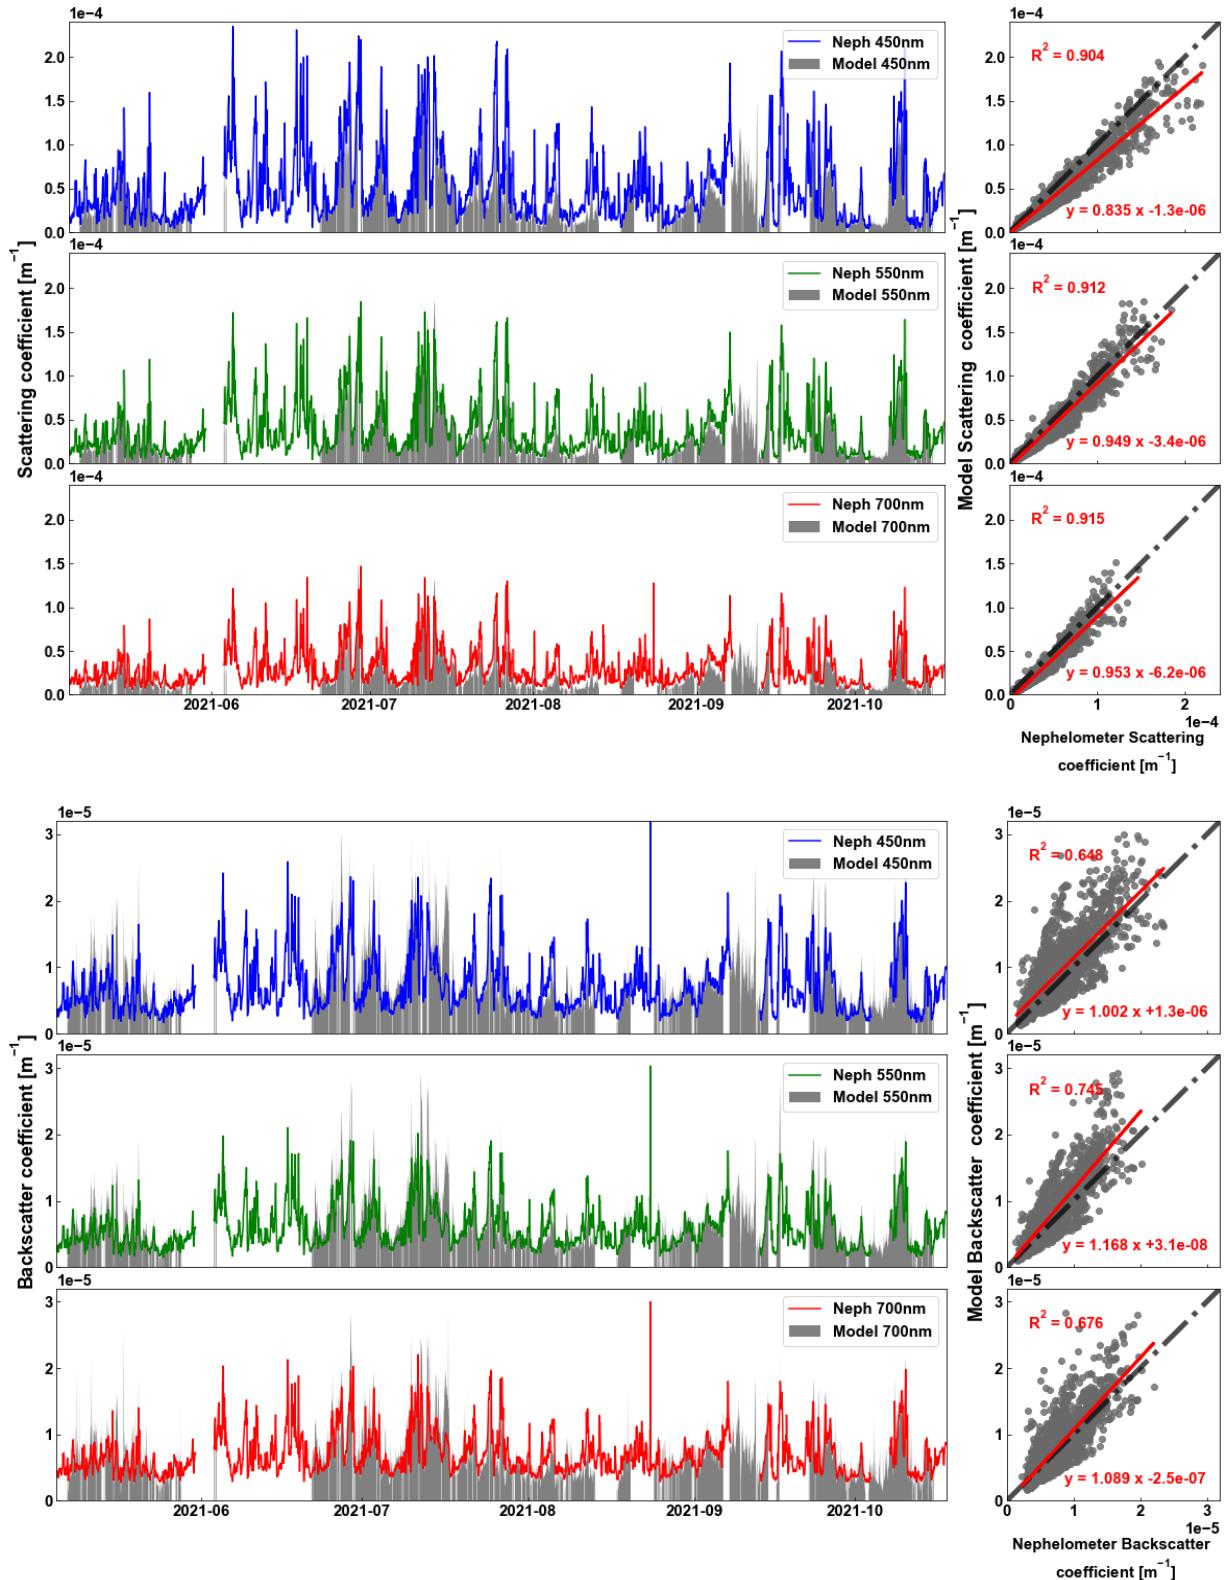

Figure S7: Corresponding to Figure 3 and Figure 4 for the scattering coefficient and backscatter coefficient from the nephelometer measurements and from the calculations by assuming all sea salt in coarse mode.

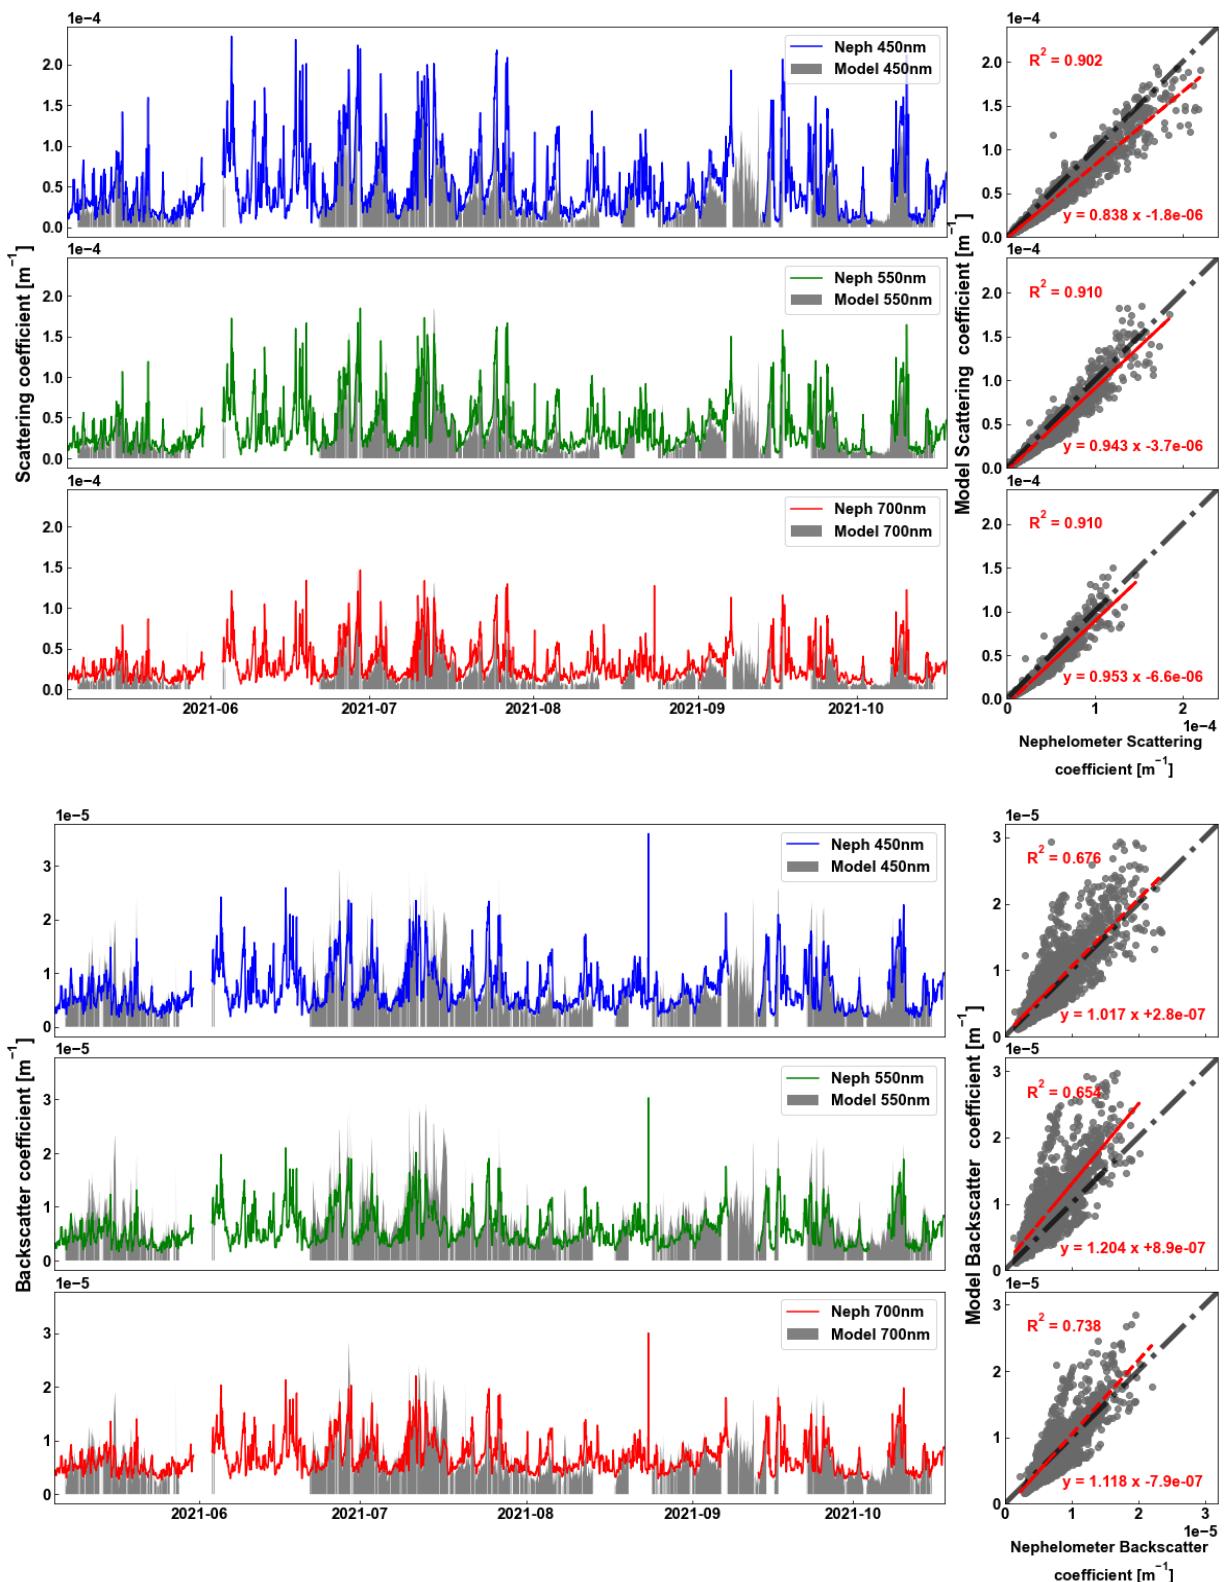

Figure S8: Corresponding to Figure 3 and Figure 4 for the scattering coefficient and backscattering coefficient from the nephelometer measurements and from the calculations by assuming all mineral dust in coarse mode.

**S8 the estimation of the Mineral Dust and Sea Salt**

As the coarse mode chemical composition was not measured during the RITA campaign, we made use of the measurements obtained from the previous Trolix campaign in 2019.

Sea salt (SS) aerosols are prominently found in the atmosphere over the Netherlands. They originate from seawater, which is entrained into the atmosphere by breaking waves and spumes. Hence, the composition of pure sea salt aerosol reflects that of sea water, encompassing natural organic compounds and pollutants. In this research, sodium serves as the ideal tracer because it offers the advantage of minimal losses due to depletion, ensuring reliable measurements. The recovery rate for sodium prior to analysis using ICP-MS stands at 100%, guaranteeing dependable detections. Conversely, when considering chloride, atmospheric reactions may lead to interactions with sulfuric and nitric acids, potentially resulting in the depletion of Cl- ions within the aerosol. As such, the presence of SS was estimated based on:

$$SS = 3.26 * [Na^+].$$

Where the factor 3.26 stems from the relative mass contribution of Na in North Sea water. This approach is adopted from Schaap et al(2010).

Mineral Dust (MD) is also part of the atmospheric aerosol mixture in the Netherlands(Denier van der Gon et al., 2010). Silicon (Si) and Aluminum (Al) have been identified as promising tracers for MD analysis, but both element analyses suffer from recovery issues. In our analyses, the Silicon was biased low (40% recovery) in the analysis because in the open destruction step with HF, SiF<sub>4</sub> is evaporated. In contrast, Al exhibited a considerably higher recovery rate, approximately 70%. Given the superior recovery rate of Al, we have opted to utilize Al elemental analyses as the basis for estimating atmospheric MD concentrations (Hendriks et al., 2008; Denier van der Gon et al., 2010). We correct the Al concentration for unrecovered material by division with 0.70. As SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> are the most abundant minerals for Si and Al, respectively, we represent the entire mixture as follows:

$$[Al\text{-based mass}] = [Al] * (1 + 1.5 * (M-O/M-Al)), \text{ where } M-O = 16.0 \text{ and } M-Al = 27.0$$

$$[Si\text{-based mass}] = [Si] * (1 + 2 * (M-O/M-Si)), \text{ where } M-Si = 28.1$$

It's important to note that the MD mass estimated using Al and Si as tracers typically serves as a conservative estimate, representing a lower limit of the total MD mass. Then the volume concentration of the SS and MD can be obtained by dividing their mass concentrations by the corresponding densities, and those parameters are listed in Table S3.
