26 Abstract

27 Coastal regions face increasing threats from rising sea levels and extreme weather events,  
28 highlighting the urgent need for accurate assessments of coastal flood risk. This study  
29 presents a novel approach to estimating global Extreme Sea Level (ESL) exceedance  
30 probabilities, using a Regional Frequency Analysis (RFA) approach. The research combines  
31 observed and modelled hindcast data to produce a high-resolution (~1 km) dataset of ESL  
32 exceedance probabilities, including wave setup, along the entire global coastline, excluding  
33 Antarctica.

34  
35 The methodology presented in this paper is an extension of the regional framework from  
36 Sweet *et al.* (2022), with innovations made to incorporate wave setup and apply the method  
37 globally. Water level records from tide gauges and a global reanalysis of tide and surge  
38 levels are integrated with a global ocean wave reanalysis. Subsequently, these data are  
39 regionalised, normalised, and aggregated, and then fit with a Generalised Pareto  
40 distribution. The regional distributions are downscaled to the local scale using the tidal  
41 range at every location along the global coastline, obtained through a global tide model. The  
42 results show 8cm of positive bias at the 1-in-10-year return level, when compared against  
43 individual tide gauges.

44  
45 The RFA approach offers several advantages over traditional methods, particularly in regions  
46 with limited observational data. It overcomes the challenge of short and incomplete  
47 observational records by substituting long historical records with a collection of shorter but  
48 spatially distributed records. This spatially distributed data not only retains the volume of  
49 information but also addresses the issue of sparse tide gauge coverage in less populated  
50 areas and developing nations. The RFA process is illustrated using Cyclone Yasi (2011) as a  
51 case study, demonstrating how the approach can improve the characterisation of ESLs in  
52 regions prone to tropical cyclone activity.

53  
54 In conclusion, this study provides a valuable resource for quantifying global coastal flood  
55 risk, offering an innovative global methodology that can contribute to preparing for, and  
56 mitigating against, coastal flooding.

57

58 **Plain language summary**

59 Coastal areas are at risk of flooding from rising sea levels and extreme weather events. This study  
60 uses a new way to figure out how likely coastal flooding is around the world. The method uses data  
61 from observations and computer models to create a detailed map of where these floods might  
62 happen at the coast. The approach can predict flooding in areas where there is little or no data. The  
63 results can be used to help get ready for and prevent this type of flooding.

64

65

## 66 1. Introduction

67 Flooding provides one of the greatest threats to coastal communities globally, causing  
68 devastating impacts to affected regions. Notable events which have caused significant  
69 coastal flooding in recent years include: Cyclone Amphan (2020), which struck the Bay of  
70 Bengal producing a storm surge of up to 4.6m along the coast of Western Bengal, killing 84  
71 people, and causing total losses over 13 billion USD (India Meteorological Department,  
72 2020, Kumar *et al.*, 2021); Hurricane Harvey (2017), the second most costly hurricane to hit  
73 the US after Katrina (2005), which impacted 13 million people, hitting the state of Texas  
74 with a maximum storm surge of 3.8m (Amadeo, 2019); and Typhoon Jebi (2018), driving  
75 storm surges of over 3m in Osaka Bay, Japan, combined with wave action which led to  
76 flooding exceeding 5m above mean sea level (Mori *et al.*, 2019). Approximately 10% of the  
77 world's population (768 million people) live below 10m above mean sea level (Nicholls *et*  
78 *al.*, 2021). Coastal flooding is expected to increase dramatically into the future,  
79 predominantly caused by sea-level rise (Taherkhani *et al.*, 2020), and compounded by  
80 continued growth and development in coastal populations (Neumann *et al.*, 2015).  
81 Therefore, continuing to improve the understanding of coastal flooding is vital.

82 Coastal floods are driven by extreme sea levels, which arise as combinations of: (1)  
83 astronomical tides; (2) storm surges (driven by tropical and extra-tropical cyclones) and  
84 associated seiches; (3) waves, especially setup and runup; and (4) relative mean sea level  
85 changes (including sea-level rise and vertical land movement). Risk assessments of coastal  
86 flooding require high-quality and high-resolution flood hazard data, typically in the form of  
87 flood inundation maps. Inundation maps are usually derived from hydraulic models, which  
88 use high resolution extreme sea level (ESL) exceedance probabilities as a key input (e.g.,  
89 Bates *et al.*, 2021; Mitchell *et al.*, 2022). The development of coastal inundation maps is  
90 reliant on coastal boundary conditions points that vary in resolution depending on  
91 application. Previous studies (e.g., Barnard *et al.*, 2019) have used 100m resolution at local  
92 scales, while regional studies (e.g., Bates *et al.*, 2021, Environment Agency, 2018) have  
93 employed resolutions between 500m and 2km.

94 Traditional methods for computing ESL exceedance probabilities involve extreme value  
95 analysis of measurements from individual tide gauges or wave buoys. However, long,  
96 complete records spanning numerous decades are necessary to obtain robust estimates of

97 ESL return levels (Coles, 2001). The Global Extreme Sea Level Analysis (GESLA-3) database  
98 provides sea level records for over 5,000 tide gauge stations (Haigh *et al.*, 2021), but these  
99 tide gauges still cover only a small fraction of the world's coastlines. Wave buoys are even  
100 more sparse, largely restricted to the Northern Hemisphere and long historical records are  
101 marred by discontinuities (Timmermans *et al.*, 2020). Even in areas with relatively high tide  
102 gauge or wave buoy density, there are still large expanses of coastline which remain  
103 ungauged. While rare extreme weather events (such as intense tropical cyclones (TCs)) are  
104 often many hundreds of kilometres in size, the precise impact of the corresponding ESL can  
105 often be highly localised (Irish *et al.*, 2008), meaning the peak surge occurs in an ungauged  
106 location. The particular locale of peak surge for an event is determined by storm  
107 characteristics, local bathymetry and coastal geography, amongst other factors (Shaji *et al.*,  
108 2014). Therefore, relying on past observation-based analyses of ESL exceedance  
109 probabilities to characterise return levels across a region will likely lead to the under  
110 representation of rare extreme events. Finally, another limitation is that many previous  
111 analyses of ESL exceedance probabilities consider the still water level component (i.e., tide  
112 plus storm surge) separately from the wave set up and run up (Haigh *et al.*, 2016, Muis *et*  
113 *al.*, 2016, Ramakrishnan *et al.*, 2022).

114 One solution to overcome sparse datasets is to use ESL hindcasts created by state-of-the-art  
115 models. These include regional (e.g., (Andrée *et al.*, 2021, Siah Sarani *et al.*, 2021, Tanim &  
116 Akter, 2019) or global tide-surge (such as Deltares' Global Tide Surge Model v3.0 (hereafter  
117 referred to as GTSM; Muis *et al.*, 2020) or wave models (e.g., Liang *et al.*, 2019). These are  
118 used to fill the spatial and temporal gaps in the observation records via historical reanalysis  
119 simulation. However, their ability to accurately capture extreme events is hampered by the  
120 atmospheric forcing data that is used to drive the models, as reanalysis products like ERA5  
121 (Hersbach *et al.*, 2020) commonly contain biases in representing meteorological extremes  
122 such as TCs (Slocum *et al.*, 2022), leading to an underestimation of event intensity.

123 Furthermore, the time period captured in reanalysis products is not adequate to represent  
124 the characteristics (e.g., frequencies) of particularly rare events such as intense TCs. To  
125 overcome this limitation, some studies have used synthetic event datasets representing TC  
126 activity over many thousands of years (e.g., Haigh *et al.*, 2014; Dullaart *et al.*, 2021),  
127 however this approach is computationally expensive.

128 An alternative and less computationally demanding solution that helps address some of the  
129 problems inherent in estimating ESLs around the world's coastlines from the observational  
130 record, is regional frequency analysis (RFA). The RFA methodology was originally developed  
131 to estimate streamflow within a hydrological context (e.g., Hosking and Wallis, 1997), but  
132 has since been used in many applications requiring extreme value analysis of meteorological  
133 parameters including coastal storm surge (e.g., Bardet *et al.*, 2011; Weiss and Bernardara,  
134 2013; Arns *et al.*, 2015; Calafat *et al.* 2022) and extreme ocean waves (e.g., Campos *et al.*,  
135 2019, Lucas *et al.*, 2017, Vanem, 2017). The principle of an RFA is founded on the basis that  
136 a homogenous region can be identified, throughout which similar meteorological forcings  
137 and resultant storm surge or wave events could occur, even if the extreme events have not  
138 been seen in part of that region in the historical record (Hosking and Wallis, 1997). RFA has  
139 been used on a regional scale to produce coastal ESL exceedance probabilities including:  
140 France (Andreevsky *et al.*, 2020, Hamdi *et al.*, 2016); the US coastline (Sweet *et al.*, 2022);  
141 Northern Europe (Frau *et al.*, 2018); US coastal military sites (Hall *et al.*, 2016); and the  
142 Pacific Basin (Sweet *et al.*, 2020). However, an RFA approach has not (to our knowledge)  
143 been applied globally.

144 The overall aim of this paper is to, for the first time, apply an RFA approach to estimate ESL  
145 exceedance probabilities, including wave setup, along the entire global coastline. These  
146 exceedance probabilities aim to better characterise ESLs driven by rare, extreme events,  
147 such as those from TCs, which are poorly represented in the historical record. Uniquely, this  
148 study uses both measured and hindcast datasets; includes tides, storm surges, and wave  
149 setup; and calculates exceedance probabilities at high resolution (1 km) globally. The  
150 specific objectives of this paper are to:

- 151 (1) develop and apply the RFA globally (excluding Antarctica), utilising both  
152 observational tide gauge, and modelled hindcast sea level and wave records;
- 153 (2) illustrate how the RFA methodology improves the representation of rare extreme  
154 events in the ESL exceedance probabilities using cyclone Yasi, which impacted the  
155 Australian coastline in 2011, as a case study;
- 156 (3) validate the RFA against exceedance probabilities estimated from the GESLA-3 global  
157 tide gauge database; and

158 (4) Finally, quantify how much the RFA increases the estimation of ESL exceedance  
159 probabilities in areas prone to TC activity when compared to single site analysis,  
160 using hindcast datasets (Muis *et al.*, 2020 and Dullaart *et al.*, 2021).

161 This paper is laid out as follows: The datasets used are described in Section 2. The  
162 methodology is detailed in Section 3, addressing objective 1. Results and validation are  
163 described in Section 4, addressing objectives 2, 3, and 4. A discussion of the key findings and  
164 conclusions are then given in Sections 5 and 6, respectively.

165

## 166 2. Data

167 We use seven primary sources of data in this study, namely: (1) still sea-level observations  
168 contained in the GESLA-3 tide gauge dataset; (2) global still sea-level simulations from the  
169 GTSM hindcast based on the ERA5 climate reanalysis; (3) tidal predictions from the FES2014  
170 finite element hydrodynamic model; (4) significant wave heights derived from the ERA5  
171 climate reanalysis; (5) mean dynamic topography from HYBRID-CNES-CLS18-CMEMS2020;  
172 (6) Copernicus DEM to create a global coastline dataset; and (7) the COAST-RP dataset from  
173 Dullaart *et al.*, (2021) to validate the RFA methodology. These seven datasets are described  
174 in turn below.

175 Still sea level records are assembled from the GESLA-3 (Global Extreme Sea Level Analysis)  
176 tide gauge dataset version 3 (Caldwell *et al.*, 2015, Haigh *et al.*, 2021). The GESLA-3 dataset  
177 includes high-frequency water level time series from over 5,000 tide gauges around the  
178 globe, collated from 36 international and national providers. Data providers have differing  
179 methods of quality control, however each record was visually assessed by the authors of the  
180 GESLA-3 dataset and graded as either: (i) no obvious issues; (ii) possible datum issues; (iii)  
181 possible quality control issues; or (iv) possible datum and quality control issues. Only  
182 records with no obvious issues were used in this study.

183 As discussed in Section 3, the hindcast, GTSM-ERA5 is used in all areas which are not  
184 covered by tide gauge observations. GTSM is a depth-averaged hydrodynamic model built  
185 using the DELFT-3D hydrodynamic model, which makes use of an unstructured, global,  
186 flexible mesh with no open boundaries (Muis *et al.*, 2020). The model has a coastal

187 resolution of 2.5km (1.25km in Europe), and a deep ocean resolution of 25km. The GTSM-  
188 ERA5 dataset spans the period 1979-2018, and is developed by forcing GTSM with hourly  
189 fields of ERA5 10-metre wind speed and atmospheric pressure (Hersbach *et al.*, 2020).  
190 GTSM-ERA5 has a 10-minute temporal resolution and provides a timeseries at locations  
191 approximately every 50km along the coastline (10km in Europe). Validation carried out by  
192 Muis *et al.* (2020) shows that the dataset performs well against observations of annual  
193 maximum water level, exhibiting a mean bias of -0.04 m and a mean absolute percentage  
194 error of 14%.

195 We use the FES2014 tidal database to generate tidal timeseries at GTSM-ERA5 locations and  
196 RFA output locations. The RFA output resolution is much higher than the output resolution  
197 of GTSM-ERA5, which is why FES2014 is used instead. FES2014 is a finite element  
198 hydrodynamic model which combines data assimilation from satellite altimetry and tide  
199 gauges (Lyard *et al.*, 2021). The model solves the barotropic tidal equations, as well as the  
200 effects from self-attraction and loading. The gridded resolution of the output is  $1/16^\circ$ . The  
201 model was extensively validated against tide gauges, satellite altimeter observations, and  
202 alternative global tide models by Lyard *et al.* (2021) and was found to have an improved  
203 variance reduction in nearly all areas, especially in shallow water regions. The Python  
204 package distributed with the FES2014 data (<https://github.com/CNES/aviso-fes>) was used to  
205 simulate tidal timeseries.

206 To calculate wave set up we use significant wave heights ( $H_s$ ) from the ERA5 reanalysis  
207 (Hersbach *et al.*, 2020), covering the period 1979 to 2020. The spatial resolution of the ERA5  
208 wave model output is  $0.5^\circ \times 0.5^\circ$ , and the temporal resolution is hourly. Independent  
209 validation of hourly  $H_s$  performed by Wang & Wang (2022) finds little bias in the dataset (-  
210 0.058 m), however the authors go on to conclude that  $H_s$  of extreme waves tends to be  
211 underestimated (by 7.7% in the 95% percentile), a conclusion supported by Fanti *et al.*  
212 (2023).

213 We use mean dynamic topography (MDT) to convert water levels from mean sea level as  
214 measured by tide gauges to mean sea level as referenced by a geoid, for use in subsequent  
215 future studies involving inundation assessments using hydraulic modelling. MDT describes  
216 the change in sea surface height due to the effects of the winds and currents in the ocean.  
217 Digital elevation models (DEMs), a key input to hydraulic models, typically use a geoid as a

218 vertical datum. A geoid is an equipotential surface of mean sea level under the sole effect of  
219 gravity, in the absence of land masses, currents and tides (Bingham & Haines, 2006). To  
220 convert water levels from tide gauge mean sea level to the geoid mean sea level, the  
221 HYBRID-CNES-CLS18-CMEMS2020 MDT dataset is used (Mulet *et al.*, 2021). The spatial  
222 resolution of this dataset is  $0.125^\circ \times 0.125^\circ$ . Errors associated with this dataset are largely  
223 caused by the input satellite altimetry data and can be up to 10 cm in some areas. The MDT  
224 at the shoreline is illustrated in the Appendix Fig. A1.

225 The Copernicus 30m DEM (European Space Agency, 2021) is used to create a high-resolution  
226 global coastline. This is used to define the RFA output points at approximately 1 km intervals  
227 along the global coastline (excluding Antarctica), resulting in over 3.4 million points.

228 Finally, in addition to GTSM-ERA5, we use the COAST-RP dataset from Dullaart *et al.* (2021)  
229 to validate the RFA methodology. COAST-RP uses the same hydraulic modelling framework  
230 as GTSM-ERA5 but simulates extra-tropical and tropical surge events separately using  
231 different forcing data. In areas prone to TC activity, synthetic TCs representing 3,000 years  
232 under current climate conditions are used from the STORM dataset (Bloemendaal *et al.*,  
233 2020). These synthetic TC model runs have been validated against observed IBTrACS-forced  
234 model runs, and found to show differences in ESLs at the 1 in 25 year return level of less  
235 than 0.1 m at 67% of the output locations in TC prone areas (Dullaart *et al.*, 2021). In regions  
236 impacted only by extra-tropical storms, a 38-year timeseries of ERA5 data is used (Hersbach  
237 *et al.*, 2020). The surge levels from each set of simulations are probabilistically combined  
238 with tides to result in a global database of dynamically modelled storm-tides.

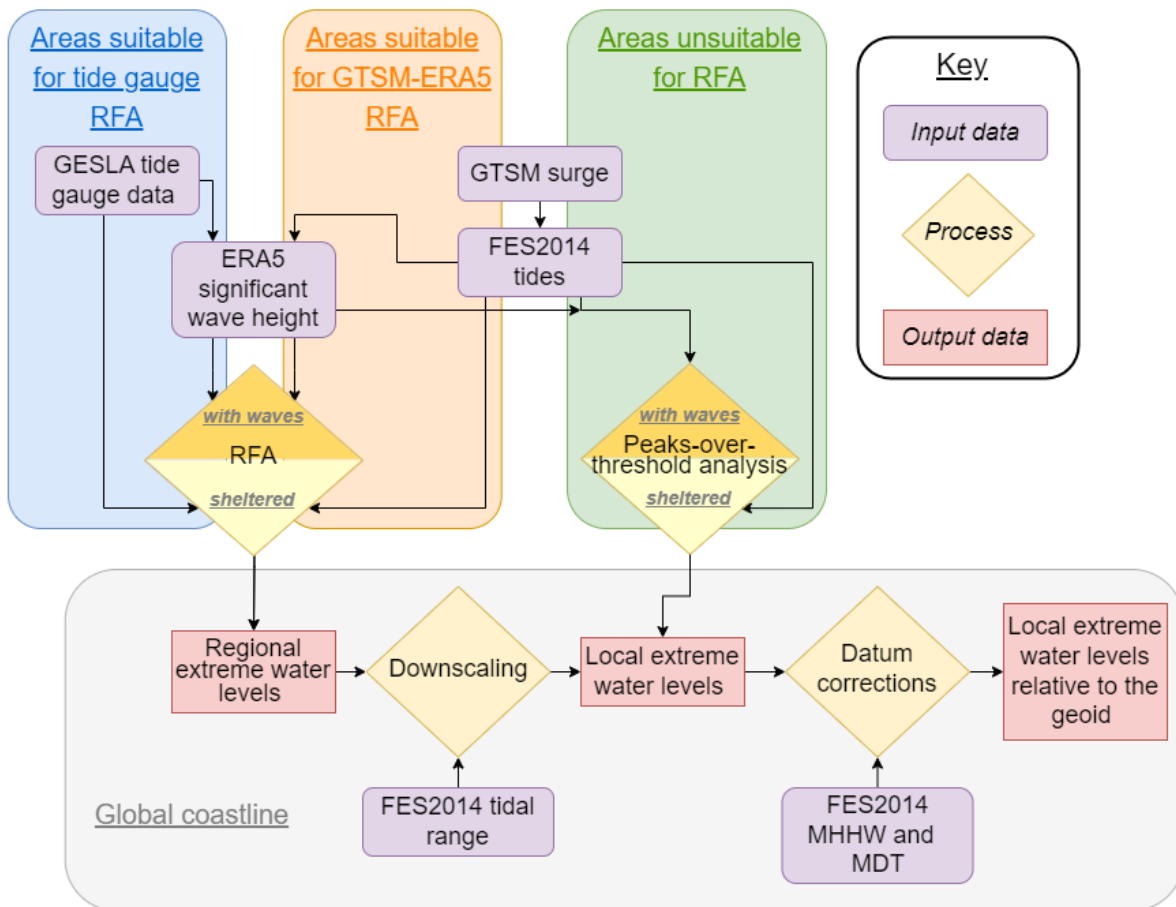

239

### 240 3. Methods

241 The first objective of this study is to develop and apply an RFA approach globally,  
242 encompassing still water levels and wave set up. In Section 3.1 we describe the methods  
243 used to process the data used in this study. In Section 3.2 we layout the global application of  
244 the RFA approach using observational and modelled data. The methods used to validate the  
245 results are explained in Section 3.3.

246 An overview of our methodology is illustrated in Fig. 1. This study broadly follows the  
247 methodology of Sweet *et al.* (2022) and applies an RFA to both tide gauge and GTSM-ERA5

248 records. As such, the terms ‘water level record’ and ‘record location’ are used to describe  
249 both tide gauge records and GTSM-ERA5 data. The method can be summarised in five key  
250 steps: (i) collation and pre-processing of tide gauge, GTSM-ERA5, FES2014, and ERA5 Hs  
251 data; (ii) spatial discretisation of water level records into regions; (iii) application of the RFA  
252 to regional water level records (in areas unsuitable for an RFA (because there are less than 3  
253 gauges in a region, or the regional water levels records are heterogenous), a peaks-over-  
254 threshold analysis of individual GTSM-ERA5 water level records is used); (iv) conversion  
255 (downscaling) of RFA exceedance levels to local exceedance levels at the output coastline  
256 points, using FES2014 tidal range (in areas unsuitable for an RFA, nearest-neighbour  
257 interpolation is used to assign local exceedance levels); and (v) correction of bias and  
258 datums to convert water levels to geoid mean sea level, using FES2014 mean higher high  
259 water and global MDT (HYBRID-CNES-CLS18-CMEMS2020). The final section of the methods  
260 (vi) describes the validation techniques. These steps are described in detail below.

262

263 *Figure 1: Schematic flow diagram detailing the data sources and processes involved in producing a global set of extreme*  
 264 *water levels*

265 **3.1 Data processing**

266

267 The GESLA-3 dataset was filtered to sample appropriate input data by removing duplicates,  
 268 gauges located in rivers (away from the coast), and gauges that fail quality control checks  
 269 carried out by the authors of the dataset (such as suspected datum jumps). The surge  
 270 component of GTSM-ERA5 at each record location is isolated from the water level  
 271 timeseries using a tide only simulation and superimposed upon a tidal timeseries created  
 272 with FES2014, as the FES2014 tidal elevations performed better than those of GTSM in  
 273 initial testing against in-situ observation. The decision to use tides from FES2014 is further  
 274 supported by the conclusion from Muis *et al*, (2020), in which they state “It appears that  
 275 biases increase in regions with a high tidal range, such as the North Sea, northern Australia,  
 276 and the northwest of the United States and Canada, which could indicate that GTSM is  
 277 outperformed by the FES2012 model that was used to develop the GTSR dataset.” Tidal

278 timeseries were also computed at each of the coastline output locations for use in  
279 downscaling the regional outputs, and in the bias and datum corrections of the local ESL.

280 Wave setup is the static increase in water level attributed to residual energy remaining after  
281 a wave breaks (Dean & Walton, 2010), and therefore is only observed in areas exposed to  
282 direct wave action. In this study, wave setup is approximated as 20% significant wave height  
283 ( $H_s$ ) from the ERA5 reanalysis, following the recommendation from the review of numerous  
284 laboratory and field experiments (Dean & Walton, 2010) and previous related studies (Bates  
285 *et al.*, 2021, Vousdoukas *et al.*, 2016). Wave setup is assigned to the nearest record location  
286 using a nearest-neighbour approach. Wave setup is assumed to be absent in sheltered  
287 areas (e.g., bays and estuaries). To account for this, the global coastline is classified as either  
288 sheltered or exposed, and the final extreme water levels are drawn from an RFA that is  
289 processed with or without wave setup added in. To classify the coastline, each coastline  
290 point is evaluated to determine if it is exposed from a minimum  $22.5^\circ$  angle over a fetch of  
291 50km. A total of 16 equal angle transects are drawn, extending 50km from each coastline  
292 point. If two or more adjacent transects do not intersect with land, the coastline point is  
293 considered exposed. Applying wave setup using this approach is an obvious simplification  
294 that has been used for the ease of global application. In reality wave setup is impacted by  
295 local bathymetry and coastal geometry, as well as local wind and wave conditions. There are  
296 other more complex methods for estimating wave setup that incorporate some aspects of  
297 bathymetry and coastal geometry, such as Stockdon *et al.* (2006).

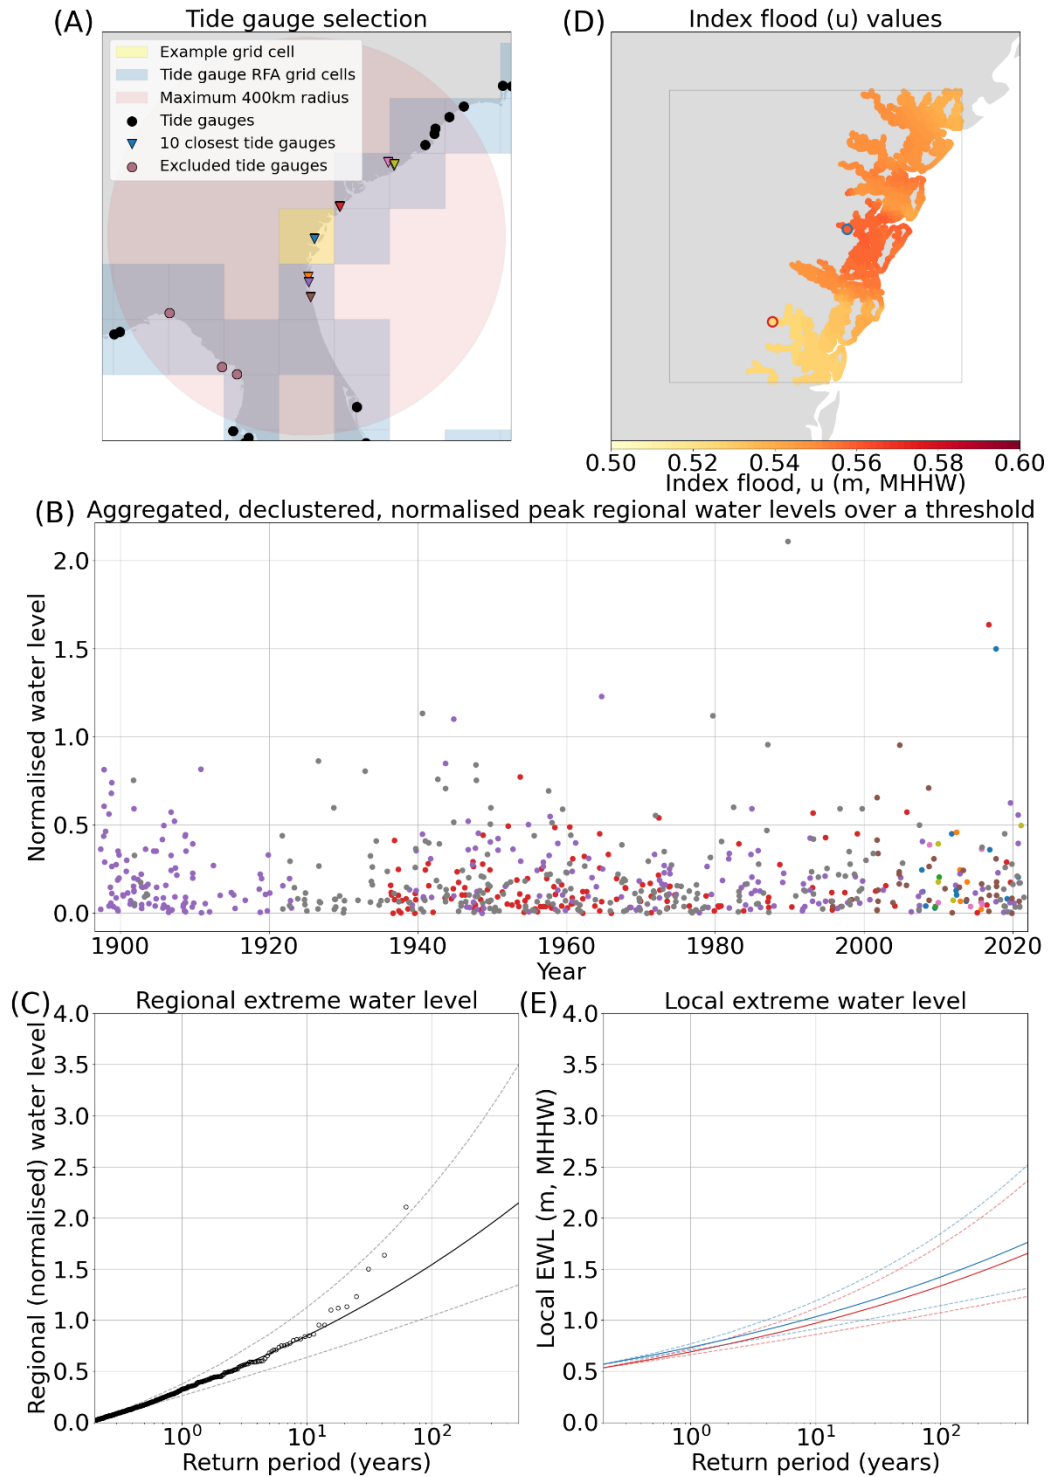

298 To process the RFA with wave setup, daily maximum wave setup is added to the daily  
299 highest water levels. Where tide gauge records fall outside of the temporal range of the  
300 ERA5 data, a copula-based approach was used to fit a simple statistical model between daily  
301 peak water levels and daily max  $H_s$ , providing a prediction of the daily max  $H_s$ . The RFA is  
302 then executed as described below. Tide gauges are assumed to be located in sheltered  
303 regions, such as bays and estuaries, thus tide gauge records are not impacted by wave  
304 setup.

### 305 3.2 Spatial discretisation of water level records into regions

306

307 Water level records are spatially clustered to form a potential pool from which regional  
308 exceedance levels can be characterised. To do this, the global coastline is divided into  $1^\circ$  by

309 1° grid cells, which are used as the regions to apply the outputs for each RFA. All record  
310 locations within a 400km radius (same as Hall *et al.* (2016) and Sweet *et al.* (2022)) of the  
311 grid cell centroid that have at least 10 consecutive years of good (>90% completeness) data  
312 are identified (minimum of 3 water level records, maximum of 10 (same as Sweet *et al.*  
313 (2022))). This step is illustrated in Fig. 2A. Record locations which are geographically within  
314 range, but are separated by a large expanse of land, and thus likely forced by different  
315 storm patterns are removed from the record location selection. To achieve this, a line is  
316 drawn between the grid cell centroid and each record location. The land intersected by the  
317 line is divided, and the areas of land on either side of the line are summed. A ratio of the  
318 length of the line to the area of land segmented by the line is then calculated. A threshold of  
319 100 was empirically evaluated using expert judgement based on a number of test cases,  
320 above which records are removed from the grid cell analysis. This approach ensures that, for  
321 example, record locations located on the east coast of Florida (e.g., Mayport) are not  
322 grouped with those on the west coast (e.g., Cedar Key) when characterising regional growth  
323 curves, despite the relatively short straight-line distance between them. Fig. 2A exemplifies  
324 three tide gauges which have been excluded from possible selection despite lying within a  
325 400km radius to the grid cell centroid as the land that separates them is considerably large  
326 when compared to the distance. This spatial discretisation of regions results in a total of  
327 836 tide gauge records (with a mean record length of 17 years) and 18628 GTSM-ERA5  
328 records for use in the application of the RFA.

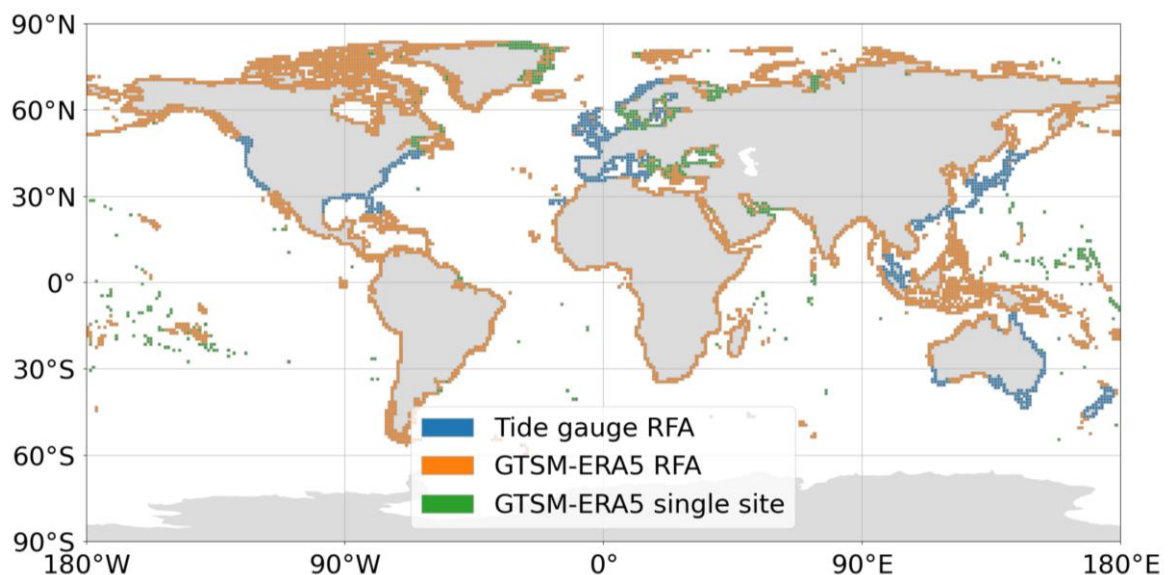

329

330 *Figure 2: Illustrating a selection of the steps through the RFA. (A) The 1° by 1° grid cells along the East Coast of the US,*  
 331 *along with the locations of the tide gauges, and the tide gauges selected for the RFA of the example grid cell. The tide*  
 332 *gauges excluded from possible selection by the distance/land area ratio are also indicated. (B) The aggregated, declustered,*  
 333 *normalised peak regional water levels over a threshold for each of the tide gauges used in the example grid cell. The colours*  
 334 *indicate peak water levels from the individual tide gauges in the region. (C) The regional extreme water levels, ascertained*  
 335 *by fitting a Generalised Pareto distribution to the data displayed in panel (B). (D) The index flood values of the example grid*  
 336 *cell, found by linearly interpolating the u value from the two closest tide gauges, and scaling by tidal range. The locations of*  
 337 *two coastline points used to produce local extreme water levels in panel E are also highlighted. (E) The local extreme water*  
 338 *level at two shoreline points inside the example grid cell, each with different index flood values as indicated in panel D.*

339 The RFA is preferentially applied to tide gauges in areas where the gauge density is sufficient  
340 (minimum 3 gauges within a 400km radius, same as Hall *et al.* (2016) and Sweet *et al.*  
341 (2022)). Outside of these areas, the RFA is implemented using data from GTSM-ERA5. In  
342 some regions, the density of homogenous record locations from GTSM-ERA5 is also too low  
343 for the RFA to function, in which case the ESL exceedance probabilities are interpolated  
344 from a single site peaks-over-threshold analysis of the nearest GTSM-ERA5 record location.  
345 The geographical locations of these areas are shown in Fig. 3. From the 5,975 global coastal  
346 grid cells, ESLs at 851 are computed using tide gauge data, 4,555 are calculated using an RFA  
347 of GTSM-ERA5 data, and 569 are calculated using GTSM-ERA5 data from the nearest record  
348 location.

349

350 *Figure 3: This map shows the global distribution the areas in which the tide gauge RFA is used, the GTSM-ERA5 RFA is used,*  
351 *and the areas which are interpolations of single site analysis from GTSM-ERA5.*

### 352 3.3 Application of the RFA

353

354 Tide gauge records are referenced to different vertical datums, so to ensure consistency, the  
355 mean over the most recent 19-year epoch is subtract from the water level record, and the  
356 timeseries is linearly detrended to the centre year of the most recent available epoch (2002-  
357 2020), resulting in 2011. GTSM-ERA5 records are referenced to MSL over the period of  
358 1986-2005, and so the timeseries are linearly detrended to reference the same tidal epoch  
359 as the tide gauge records, centred on 2011. Within each cluster of gauge (or model) records,

360 the water level time series are resampled to hourly resolution and converted to mean  
361 higher high water, defined as the mean daily highest water level over a 19-year epoch, to  
362 account for differences in tidal range between record locations. In the case of records with  
363 fewer than 19 years of data available the maximum continuous epoch is used instead.

364 Daily highest water level is determined from the hourly time series of each measured or  
365 modelled record. The time series are then declustered using a 4-day storm window to  
366 ensure event independence. This window length was used by Sweet *et al.*, 2020 and Sweet  
367 *et al.*, 2022, and is a similar length to the storms that cause surge events in the UK\_ (Haigh *et*  
368 *al.*, 2016). The index flood  $u$ , defined as the 98th percentile of the declustered daily highest  
369 water levels (Sweet *et al.*, 2022), is used as the exceedance threshold at which to normalise  
370 the water level at each record location, as follows:

$$371 \quad \text{Normalised water level} = (\text{Observed exceedance water level} - u) / u \quad (\text{eq. 1})$$

372 The normalised datasets are then aggregated and further declustered to ensure only one  
373 peak water level is retained for each regional event. This is shown in Fig. 2B for an example  
374 grid cell. Following Hosking and Wallis (1997), a statistical heterogeneity test (H) is  
375 undertaken to ensure the homogeneity of the region. If the H-score is less than 2, then the  
376 region is considered sufficiently homogenous. If the H-score is greater than 2, then the  
377 furthest water level record from the grid cell centroid is removed from the region, and the  
378 test re-run. This process is repeated until the H-score is less than 2. In a minority of cases,  
379 the heterogeneity test fails due to an anomalous record that lies within the closest 3  
380 sampling locations to the grid cell centroid. In this instance the test is rerun, except after the  
381 furthest record is removed, all the remaining records are sequentially removed and  
382 replaced, until the H-score is less than 2.

383 After the region is confirmed to be homogenous, a Generalised Pareto distribution is fitted  
384 to the aggregated, declustered, normalised regional water levels using a penalised  
385 maximum likelihood method to estimate regional extreme water levels (REWLs). This is  
386 illustrated at an example in Fig. 2C. This is repeated for the aggregated regional water levels  
387 for each 1° by 1° grid cell. While theoretically correct, applying distribution fits to real world  
388 data can sometimes give unrealistic results, particularly in the estimation of the lower  
389 frequency space. In these cases, growth curve optimisation is undertaken to ensure the

390 output local extreme water levels are plausible in real world scenarios. To ensure  
391 consistency, an empirical threshold of 0.35 for the shape parameter is used to determine  
392 which curves will generate unrealistic extreme water levels. The empirical threshold of the  
393 shape parameter is determined based on expert judgement of plausible real world  
394 maximum surge heights in the low frequency events. To correct these curves, where this  
395 threshold is exceeded, we use the shape and scale parameters of the nearest grid cell which  
396 has a shape parameter less than 0.35. In total, 34 grid cells had their shape and scale  
397 parameters adjusted, mostly concentrated in the Gulf of Mexico and Japan.

### 398 3.4 Downscaling to local extreme water levels

399

400 Local extreme water levels (LEWLs) are then estimated from the regional growth curves  
401 using the following relationship:

$$402 \quad LEWL = (REWL * u) + u \quad (eq. 2)$$

403 for each coastal point along the coastline contained within the grid cell represented by the  
404 REWL. The index  $u$  is estimated at the coastline points using an inverse distance weighting  
405 interpolation of the  $u$  values for the two closest record locations, scaled by tidal range. This  
406 deviates from the methodology set out by Sweet *et al.* (2022), in which they recommend  
407 drawing  $u$  values from a linear regression of  $u$  against tidal range values from record  
408 locations across a region. We found this approach led to significant differences in LEWLs at  
409 record locations when compared to single site analysis of water level records, and hence  
410 have modified the methodology. Fig. 2D exhibits an example of the index flood for every  
411 shoreline point in an example grid cell. Tidal ranges are calculated as the difference  
412 between mean higher high water and mean lower low water. Tidal harmonics from FES2014  
413 are used to predict mean higher high water and mean lower low water at each coastline  
414 point. The index flood,  $u$ , is used to downscale the REWLs, which represent the ESL  
415 characteristics of the entire grid cell. LEWLs are output in the format of return levels for a  
416 range of exceedance probabilities. Two example LEWL curves are shown in Fig. 2E, which  
417 have been computed using different index flood values, as indicated in Fig. 2D.

### 418 3.5 Bias and datum corrections

419

420 The last stage of the LEWL calculation involved characterisation and removal of bias in the  
421 high frequency portion of the exceedance probability curves, relative to a single site analysis  
422 of water level records (within which we expect the high frequency water levels to be  
423 accurately modelled). Other surge RFA studies also concluded that the approach generally  
424 yields higher estimated surge heights when compared to single site analysis, because during  
425 the regionalisation process an extreme event that occurred in one location is assumed to  
426 have the same probability of occurring at another location within the homogeneous region.  
427 (Bardet *et al.*, 2011; Sweet *et al.*, 2022). Bias is quantified based on the divergence in the 1-  
428 in-1-year return period at each tide gauge/GTSM-ERA5 location and the corresponding  
429 LEWL predictions. This bias is used as a correction term and is removed from the LEWLs. As  
430 the density of the coastline points is much greater than the density of the tide  
431 gauges/model output locations, the correction term is interpolated across all coastal LEWL  
432 points based on correlation between monthly values of the 99<sup>th</sup> percentile of tidal  
433 elevations produced over a 3-year period centred on 2011, computed using FES2014 at the  
434 tide gauge/GTSM-ERA5 location and neighbouring coastline points. The mean bias  
435 correction across all gauges is 8 cm.

436 Datum corrections are applied to ensure the LEWLs are correctly referenced to a vertical  
437 datum which can be used for hazard assessment applications, such as inundation modelling.  
438 Inundation models utilise digital elevation models, which typically reference a geoid as the  
439 vertical datum. The output water levels from the RFA are transformed from mean higher  
440 high water to Mean Sea Level (MSL) by adding the approximation of mean higher high water  
441 (above MSL) from the FES2014 simulations to each of the boundary condition points. The  
442 corrected MDT dataset from (Mulet *et al.*, 2021) is applied to convert water levels from MSL  
443 from the FES2014 model to the 'MSL' of a commonly used geoid, EGM08.

### 444 3.6 Validation methods

445

446 In this section we define a range of validation techniques used to address objectives 3 and 4.  
447 To validate the RFA ESLs against tide gauge records from GESLA (objective 3), a comparison  
448 is made against ESL exceedance probabilities calculated at the individual tide gauges used to  
449 inform the RFA. To quantify the degree to which the RFA approach improves the estimation

450 of ESL exceedance probabilities compared to single site analysis (objective 4), two  
451 assessments are made.

452 Firstly, the divergence between GTSM-ERA5 RFA ESL and GTSM-ERA5 single site ESL for the  
453 entire global coastline are quantified. These are then contrasted against the differences  
454 between return levels from GTSM-ERA5 (Muis *et al.*, 2020) and COAST-RP (Dullaart *et al.*  
455 2021). The comparison can then identify regions in which the historical ESLs are poorly  
456 represented due to the limited record lengths.

457 Secondly, a leave-one-out cross validation is undertaken using GTSM-ERA5 data. Leave-one  
458 out-cross validation aims to address the common issues involved with validating statistical  
459 models. One common method to validate models is split-sample validation, in which the  
460 data is split into two groups, a training set and a validation set, which are generally 70% and  
461 30% of the data respectively. The model is then trained on the larger set and validated  
462 against the smaller set. The drawbacks of this method include a highly variable validation  
463 error, due to the selection of the training and validation sets, as well as a validation error  
464 bias caused by training the model on only 70% of the available data (James *et al.*, 2013).

465 Instead of using a 70/30 split of the data, leave-one-out cross validation uses a larger  
466 proportion of the data to train the model, while validating against a smaller sub-sample, but  
467 repeats this process multiple times to generate a robust validation. To do this, we identified  
468 1000 grid cells which use 10 GTSM-ERA5 records for the RFA and contain 3 GTSM-ERA5  
469 record locations inside the grid cell (and therefore the RFA can be used to directly estimate  
470 ESLs at the record locations). One of the GTSM-ERA5 records from inside the grid cell is  
471 removed from the RFA process, and the REWL is calculated using the 9 remaining gauges.  
472 The LEWL is then predicted at the record location which has been left out, using the index  
473 flood,  $u$  at the record location. These LEWLs are then contrasted with a single site analysis of  
474 the water level record that was removed from the RFA. The process is then repeated for the  
475 2 other GTSM-ERA5 record locations which lie within the grid cell. This means each of the  
476 1000 models is being tested three times, against 90% of the available data, thus giving a  
477 more robust realisation of the model when trained on 100% of the data.

478

## 479 4. Results

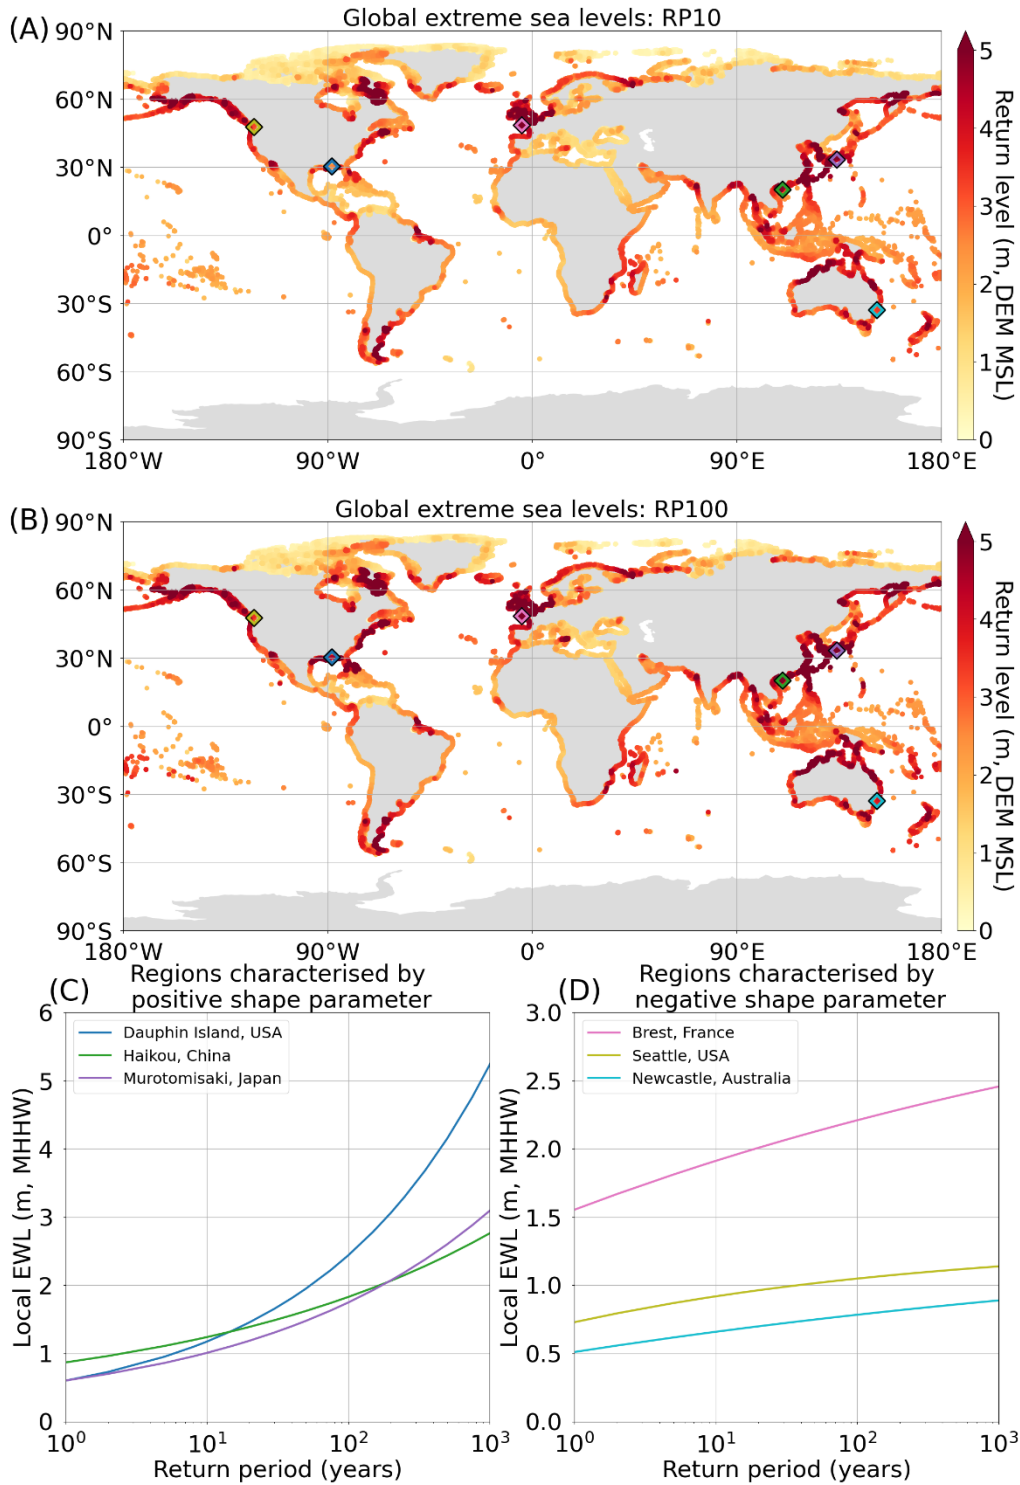

480 The results section is divided into four sub-sections. Section 4.1 presents the results of the  
481 global application of the RFA, showing both the global view of two return periods and the  
482 return levels for selected sites around the world. Section 4.2 illustrates how the RFA  
483 methodology improves the characterisation of rare extreme events using Cyclone Yasi  
484 (objective 2). In section 4.3 we validate the RFA against estimates of ESL from GESLA tide  
485 gauges (objective 3). Finally, in section 4.4 we quantify the improvements made by using an  
486 RFA approach when compared to a single site analysis of water levels (objective 4).

487

### 488 4.1 Global application of RFA

489 The final ESL exceedance probabilities (including wave setup) created at high resolution  
490 around the global coastline are displayed in Fig. 4, for the 1-in-10 and 1-in-100-year return  
491 periods. Both the 1-in-10 year (Fig. 4A) and 1-in-100 year (Fig. 4B) return periods show  
492 similar spatial patterns, with 1-in-100-year return periods exhibiting greater increases as  
493 expected in areas prone to TC activity (e.g., the Gulf of Mexico, Australia, Japan, and China).  
494 ESLs are higher in regions with large tidal ranges such as the Bay of Fundy, the Patagonia  
495 Shelf, the Bristol Channel in UK, the northern coast of France, and the northwest coast of  
496 Australia. The return levels for 6 select tide gauge locations, 3 of which are characterised by  
497 a positive and 3 of which are characterised by negative shape parameter from the  
498 Generalised Pareto distribution are shown in Fig. 4C and 4D respectively, relative to mean  
499 higher high water. The locations of the 6 tide gauges are indicated in both Fig. 4A and 4B.  
500 Regions exhibiting positive shape parameters are typically prone to TC activity and  
501 associated surge and wave events. As a result, these regions experience more significant  
502 increases in return levels at higher return periods than regions with negative shape  
503 parameters. Regions characterised by negative shape parameters have different drivers of  
504 ESL events, for instance extra-tropical storms surges or tide dominated ESLs (Sweet *et al.*,  
505 2020).

506

507

508 *Figure 4: The final global RFA results output at approximately 1km resolution along the entire global coastline (excluding*  
 509 *Antarctica) for RP10 (A) and RP100 (B). Return levels are referenced to DEM MSL, and so represent surge, waves and tide.*  
 510 *Return levels (relative to mean higher high water) for 6 tide gauges in regions characterised by either positive or negative*  
 511 *shape parameter of the Generalised Pareto distribution are shown in panels (C) and (D) respectively. The locations of the 6*  
 512 *tide gauges are indicated by the diamonds plotted on both panels (A) and (B).*

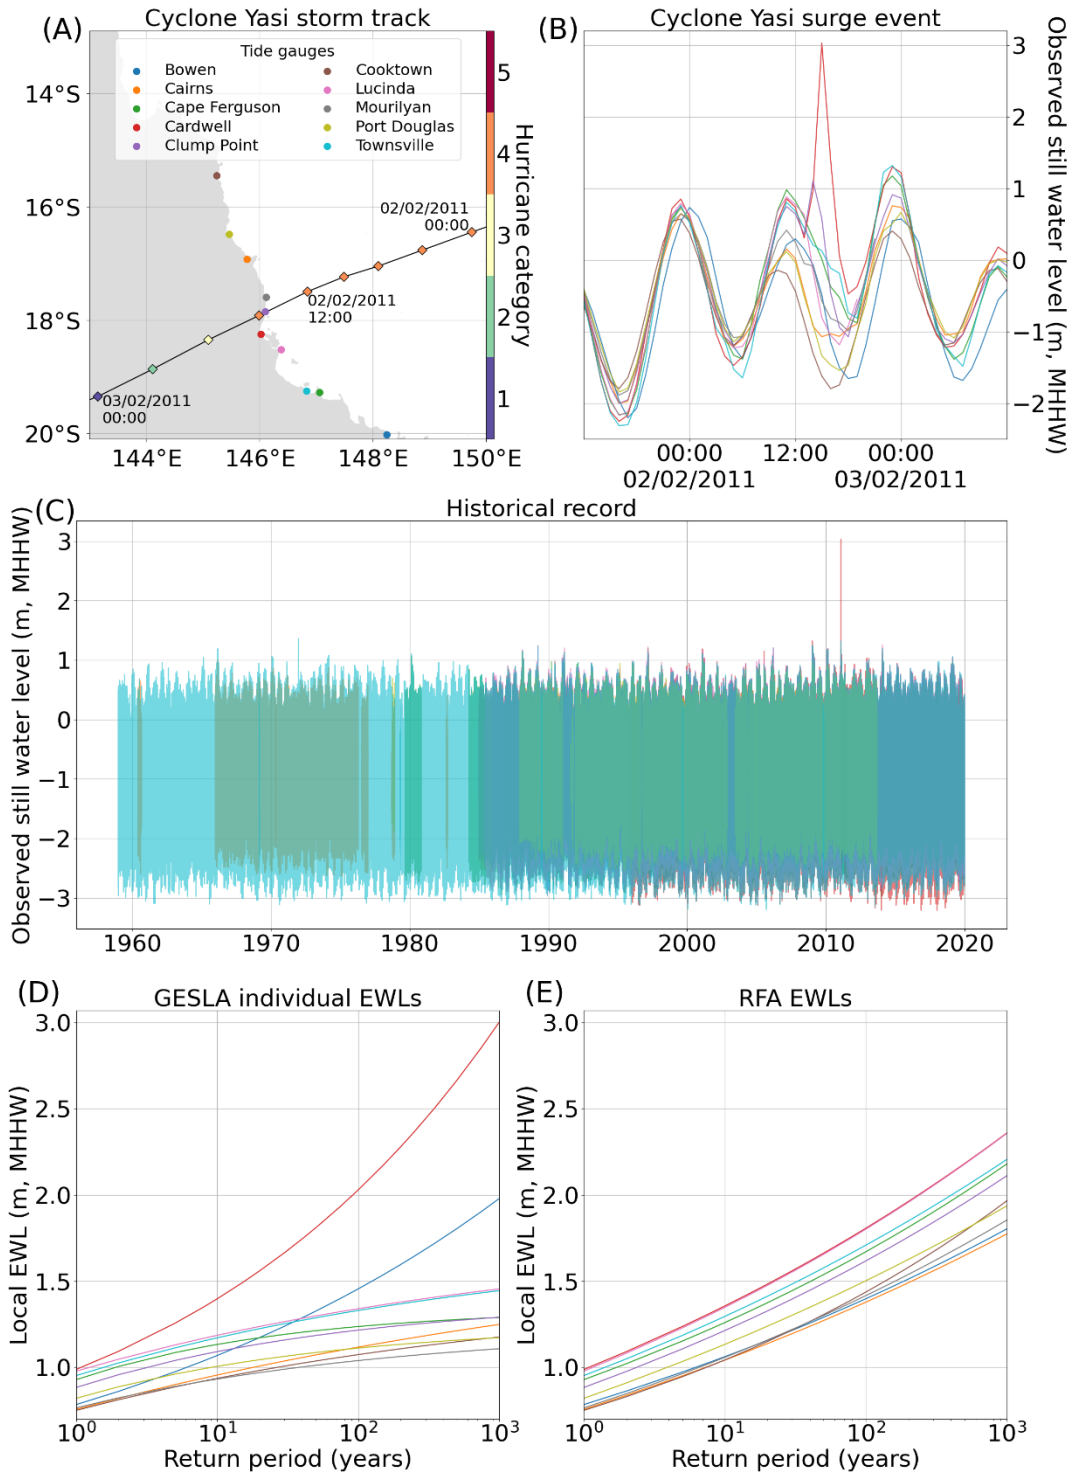

513

## 514 4.2 Tropical Cyclone Yasi

515 Our second study objective is to illustrate how the RFA methodology previously described  
516 can draw on few, rare events, to provide more realistic representation of low frequency ESL  
517 exceedance probabilities across a region, using the case study of cyclone Yasi which  
518 impacted the Australian coastline in 2011. Cyclone Yasi made landfall on the North-eastern  
519 coast of Australia, in the Queensland region, between 14:00 and 15:00 UTC on the 2nd of  
520 February 2011. It is the strongest cyclone to have impacted the region since 1918, with  
521 possible windspeeds of 285km/h and minimum record pressure centre of 929 hPa (Australia  
522 Bureau of Meteorology, 2011). When it made landfall, Yasi was a category 4 storm on the  
523 Saffir-Sampson scale. The path and strength of the storm are shown in Fig. 5A.

524 The total water levels, relative to mean higher high water, for all the tide gauges in the  
525 region are shown in Fig. 5B. Cardwell had the highest surge, and highest total water level, by  
526 a considerable margin compared to neighbouring tide gauges, receiving a surge of over 3m  
527 above mean higher high water. Clump Point also showed a definitive but less substantial  
528 surge signal, whereas the other gauges showed much smaller surge effects or even no surge  
529 at all. The historical water level records of all the gauges in the regions are included in Fig.  
530 5C. The tide gauges span different temporal ranges, and many have years which are  
531 incomplete. The longest record is at Townsville, which started in the late 1950s. Despite this  
532 record, the largest event is cyclone Yasi by over 1.5m (at Cardwell).

533 Based on this historical record, no other surge event of this magnitude has impacted this  
534 section of coastline since the records began. There are, however, records of other historic  
535 extreme events that predate tide gauges affecting the region. For example, Cyclone Mahina,  
536 which made landfall in Princess Charlotte Bay (approximately 100km north of Cooktown) in  
537 1899, reportedly had a surge height approaching 10m (Needham *et al.*, 2015). The idea that  
538 this stretch of coastline is at risk of TC generated ESLs is further supported by STORM, a  
539 dataset of 10,000 years of synthetic hurricane tracks (Bloemendaal *et al.*, 2020). IBTrACS  
540 shows just eight category 4 and 5 hurricanes impacting this 700km stretch of coastline  
541 between 1980 and 2022 (shown in the Appendix Fig. A2; Knapp *et al.*, 2010). In contrast, the  
542 STORM dataset has 333 events affecting the area, producing a more continuous spread of  
543 landfall locations along the coastline. In addition, large surges are sometimes not captured  
544 in this region due to the lack of gauges in rural areas (Needham *et al.*, 2015).

545

546 *Figure 5: Tropical Cyclone Yasi: (A) The storm track of cyclone Yasi, covering a 24-hour period over the landfall event. The*  
 547 *locations of the 10 closest tide gauges along the Queensland coast are also included. Times are in UTC. (B) The observed*  
 548 *water level timeseries for the same 24-hour period at each of the 10 tide gauges in the region. Times are in UTC. (C) The*  
 549 *entire historical record of all 10 gauges in the region. (D) The return period curves of individual gauges fit with Generalised*  
 550 *Pareto distribution. (E) The return period curves at the gauge locations from the RFA.*

551 The return period curves, calculated by fitting a Generalised Pareto distribution to the  
 552 peaks-over-threshold water levels at each individual tide gauge, for each of the 10 gauges in

553 the region, are shown in Fig. 5D. As expected, Cardwell has the largest return levels and the  
554 steepest curve. All the other gauges, except Bowen, exhibit negative shape parameters,  
555 characterised by a decreasing gradient of the return period curves. In a region which is  
556 prone to TCs, this is a dangerous underestimation of the risk from cyclone induced surges. In  
557 some coastal ESL studies, ESLs are calculated at each gauge, and then interpolated along the  
558 coastline, such as in the UK (Environment Agency, 2018). In this case, that approach would  
559 lead to a gross disparity from the actual risk of storm surges to coastal communities in the  
560 area.

561 In contrast, Fig. 5E shows the return period curves estimated from the RFA at the tide gauge  
562 locations. All of the curves now have positive shape parameters, characterised by increasing  
563 gradients of the curves. The curves of Cardwell and Bowen have been reduced somewhat,  
564 while all the other curves have been increased significantly. This demonstrates the  
565 regionalisation process, by which the extreme event at Cardwell can be used to propagate  
566 the risk along the coastline to areas which have not had an extreme event on record, or  
567 have short, incomplete, or non-existent tide gauge records. This reinforces the key strengths  
568 of the RFA, namely: (1) the ability to spatially account for rare extreme events, (2) the use of  
569 short and incomplete tide gauge records to produce robust parameter fits, and (3) the  
570 ability to downscale the results into regions which aren't covered by tide gauges at all.

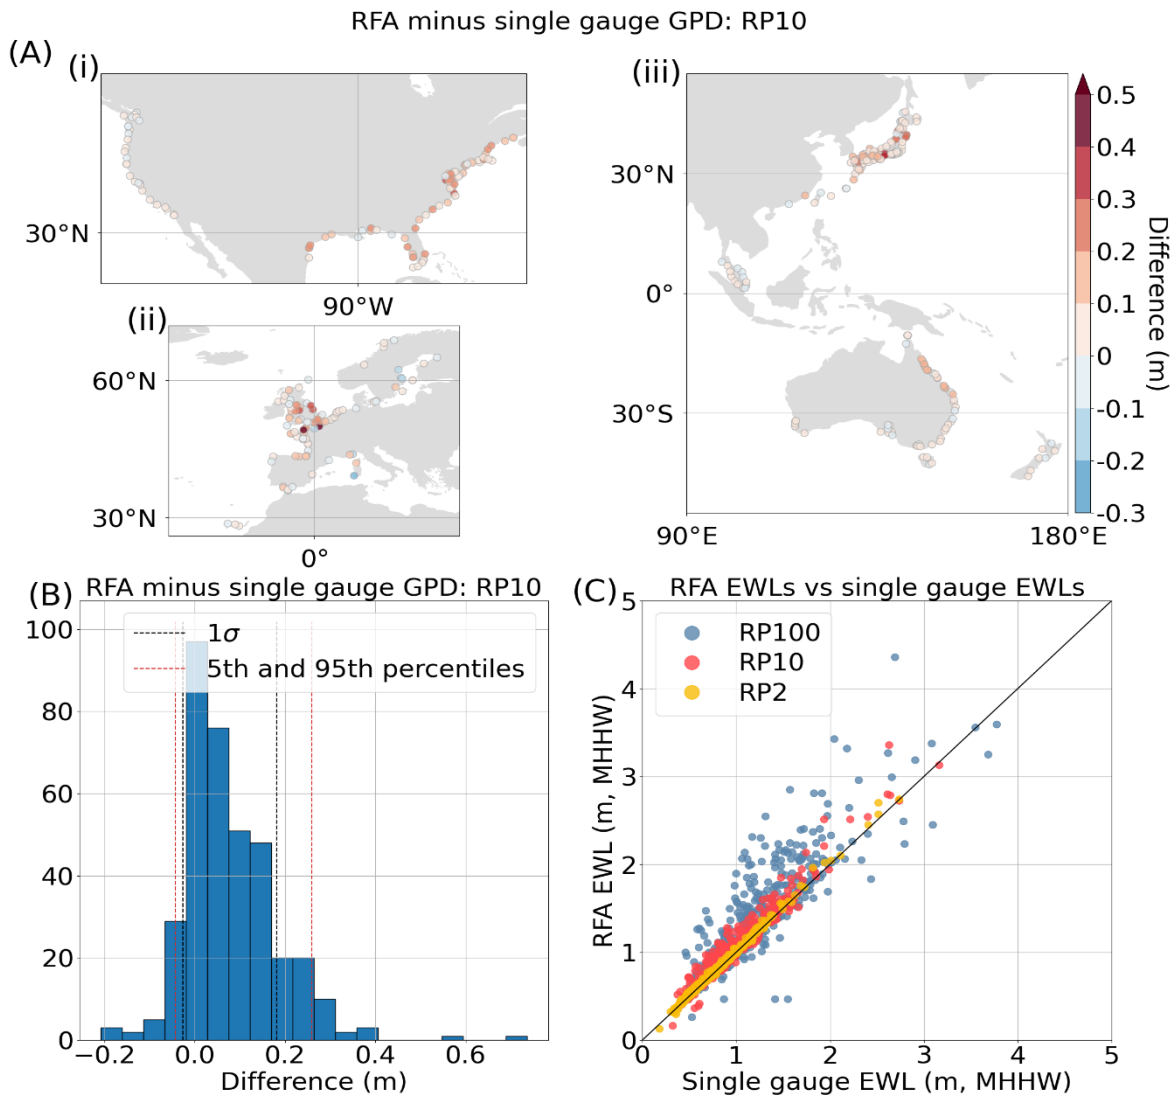

### 571 4.3 Comparisons with GESLA

572 The third objective is to validate ESLs calculated using our RFA against those calculated  
573 directly from the measured GESLA-3 global tide gauge database. Contrasting the RFA results  
574 with ESL exceedance probabilities calculated through a Generalised Pareto distribution fit at  
575 individual tide gauges yields promising results. Fig. 6A shows the spatial distribution of the  
576 difference at the 1-in-10-year return period for Europe, the United States, and the East  
577 Pacific. In areas impacted by TCs (e.g., the Gulf of Mexico, North-Eastern Coast of Australia,  
578 and Japan) we broadly see that the RFA has increasing return levels across most gauges.  
579 Increases in the 1-in-10-year return level are also observed in areas usually associated with  
580 extra-tropical storms (e.g., Europe), suggesting gauges in these regions also suffer from  
581 under sampling of rare surge events. Extreme surge events can be undersampled for two  
582 reasons. Firstly, by their very nature, they are rare and might never have occurred at a

583 specific location. Secondly, as a result of a scarcity of in-situ tide gauges, surges can occur  
584 and remain unrecorded.

585 In all areas shown in Figure 6A, some gauges show decreases in the return levels. This could  
586 be driven by either shape parameter limiting (to prevent unrealistically large water levels),  
587 an anomalously large number of events impacting the gauge, or due to a single anomalously  
588 large event impacting the gauge, which is then smoothed out through the regionalisation  
589 process, as was the case in Cardwell, Australia (Fig. 5E). Of the gauges shown in the Fig. 6A,  
590 only 5 had limited shape parameters, which were located in the Gulf of Mexico. The  
591 distribution of the differences at RP10 is shown in Fig. 6B with a positive skew, detailing the  
592 5<sup>th</sup> and 95<sup>th</sup> percentiles as -8cm and 27cm respectively. The spread of the data increases  
593 across the three selected return periods (1-in-2, 1-in-10 and 1-in-100 year) presented in in  
594 Fig. 6C, as well as the mean bias, which increased from 2 cm in the 1-in-2 year return level,  
595 to 21cm in the 1-in-100 year return level.

596

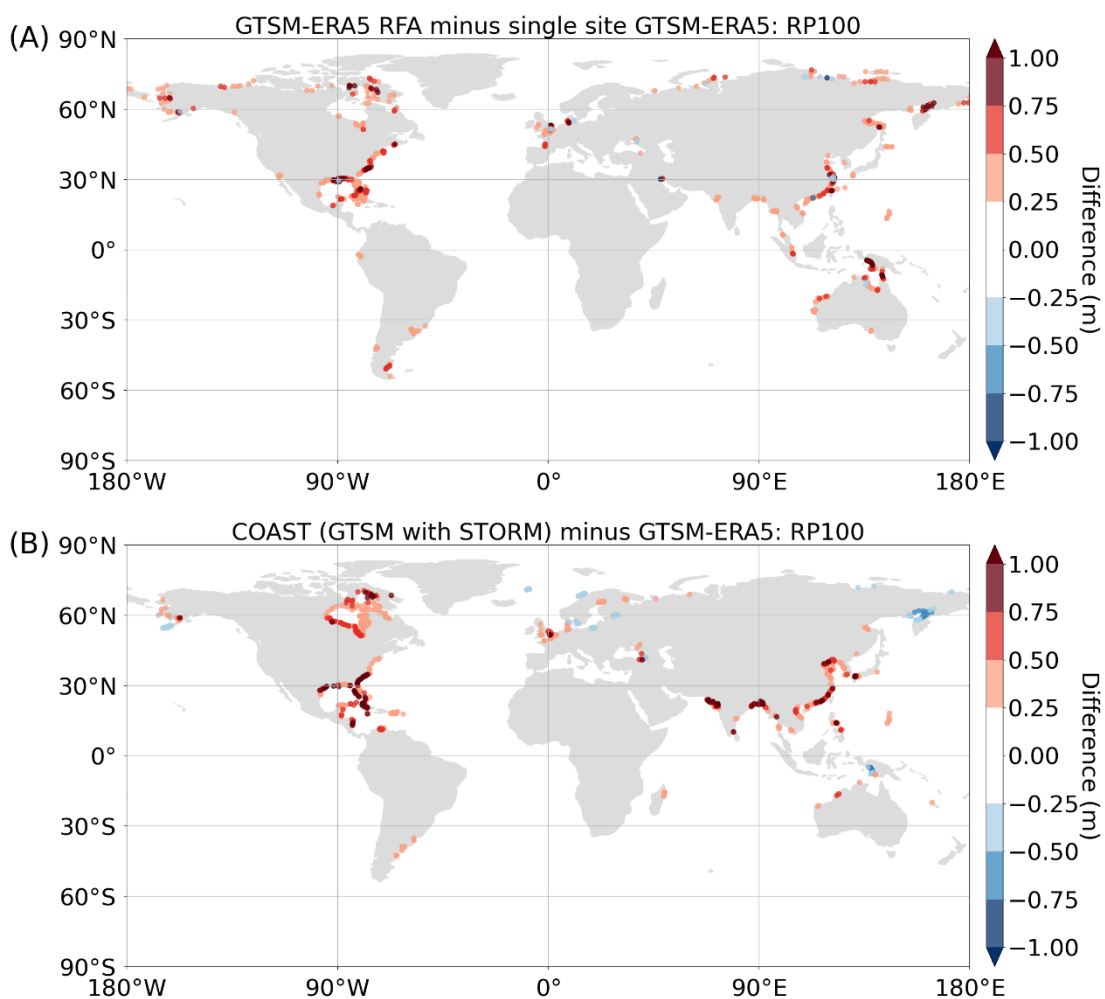

597 *Figure 6: Comparison of RFA water levels against extreme water levels calculated at individual gauges from GESLA by fitting*  
 598 *a Generalised Pareto distribution to peaks-over-threshold water levels. (A) The spatial distribution of the difference at RP10*  
 599 *for (i) the contiguous US, (ii) Europe, (iii) Japan, Malaysia, Australia and New Zealand, (B) a histogram of the distributions of*  
 600 *difference at RP10, including the locations of the 5<sup>th</sup> and 95<sup>th</sup> percentiles and 1 standard deviation from the mean, and (C) a*  
 601 *scatter plot of EWLs (RP2, RP10, RP100) from the RFA and the EWLs calculated using a single site Generalised Pareto*  
 602 *distribution fit. The black line indicates a 1:1 perfect fit.*

603

#### 604 4.4 Quantifying the increases made by the RFA when compared to single site 605 analysis

606 The fourth objective is to quantify the increases made to ESL exceedance probabilities in TC  
 607 prone areas by the RFA, when compared to a single site analysis. Figure 7A shows the  
 608 deviation in the 1-in-100-year return period between the GTSM-ERA5 RFA carried out across  
 609 the global coastline, and a single site peaks-over-threshold analysis of GTSM-ERA5 water  
 610 level records. Only differences greater or less than 0.25 m and -0.25 m respectively, are

611 plotted. There are evident increases to RFA ESLs in areas prone to TCs. The Gulf of Mexico,  
 612 the East Coast of the US, Southern China, and the North-East Coast of Australia show the  
 613 largest increases. Sporadic negative differences are also observed in Fig. 7A, which are  
 614 driven by a smoothing of ESL exceedance probabilities at locations which have experienced  
 615 anomalously high ESL compared to the local region. From this we see that the RFA is capable  
 616 of incorporating the influence of TCs that were not present in the historical record, but  
 617 statistically could occur as indicated by the regional characteristic.

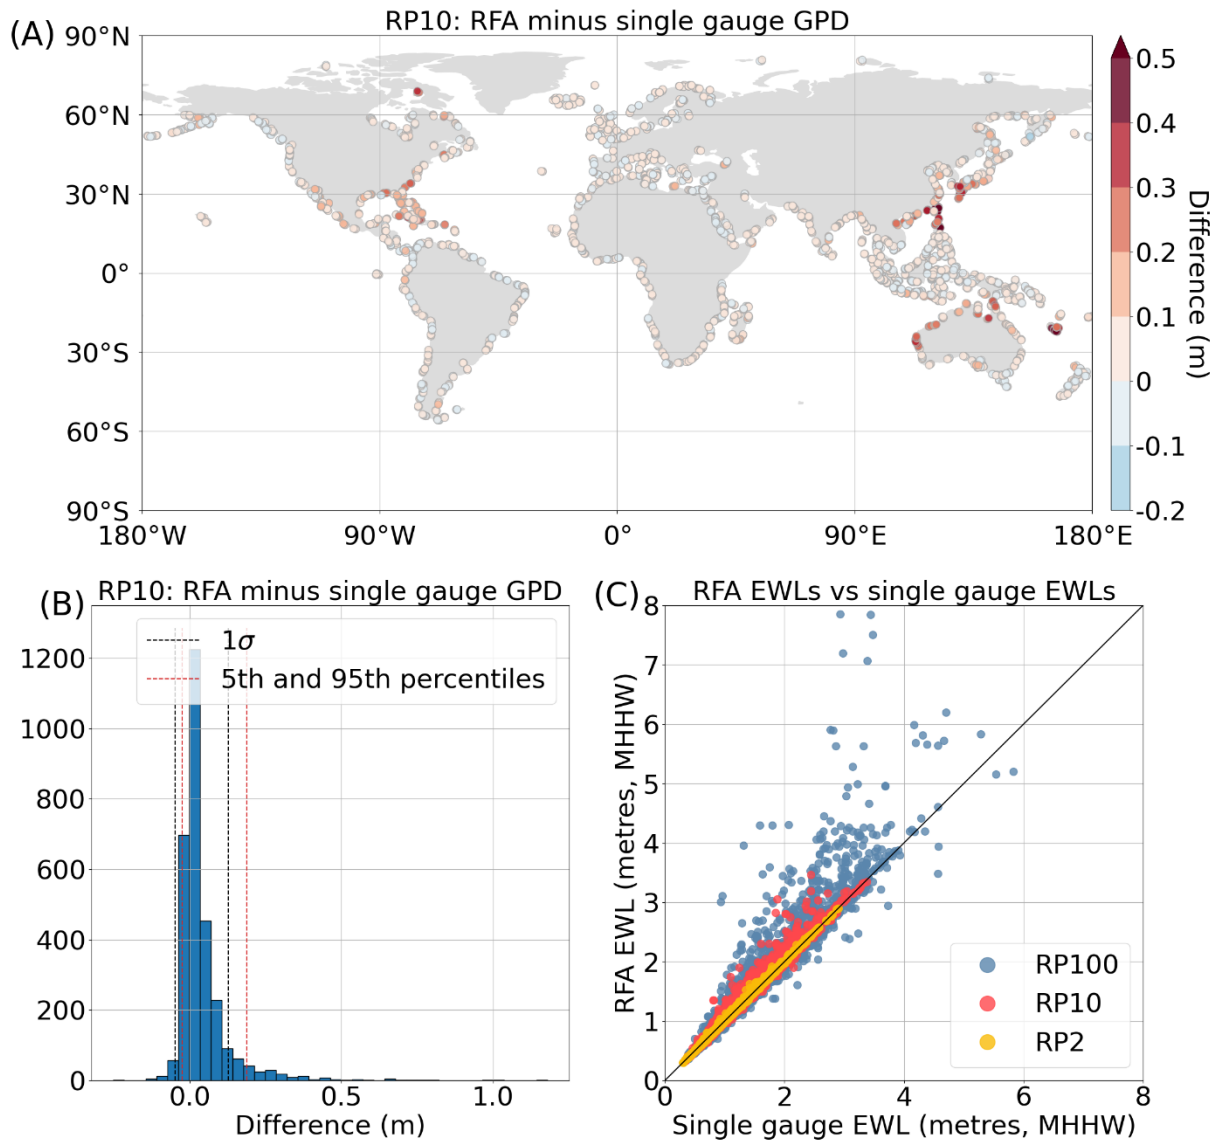

618

619 *Figure 7: The spatial distributions of: (A) the differences between the GTSM-ERA5 RFA 1-in-100-year return period (RP100)*  
 620 *and the RP100 of single site GTSM-ERA5 data fit with a Generalised Pareto distribution to the peaks-over-threshold water*  
 621 *levels; and (B) the differences in RP100 published by the COAST-RP (GTSM forced with STORM) paper (Dullaart et al., 2021)*  
 622 *and RP100 published by the original GTSM paper (Muis et al., 2020). Only differences greater or less than 0.25 m and -0.25*  
 623 *m, respectively, are plotted.*

624 These findings can be supported by the results shown in Fig. 7B, which shows the  
625 differences between COAST-RP and GTSM-ERA5. COAST-RP is GTSM forced with STORM  
626 (10,000 years of synthetic TCs) in areas prone to TC activity, instead of ERA5 (Dullaart *et al.*,  
627 2021). The areas of positive difference highlight locations where COAST-RP is greater than  
628 GTSM-ERA5, and so give an indication of the areas in which the synthetic hurricanes make  
629 landfall. These patterns are broadly similar to those of the RFA, shown in Fig. 7A. However,  
630 there are two areas which stand out for being poorly characterised by the RFA, namely: the  
631 Bay of Bengal and the western Gujarat region of India. Large differences are also observed  
632 in Hudson Bay, Canada, however we suspect these discrepancies are the result of  
633 differences in the approach to modelling extra-tropical regions, as TCs do not make landfall  
634 here.

635 Figure 8 shows the results of the leave-one-out cross validation of the global coastal LEWLs.  
636 In general, the RFA tends to increase return levels due to the regionalisation process. These  
637 findings match those of (Sweet *et al.*, 2020, Sweet *et al.*, 2022) upon which our approach is  
638 based. This is evident throughout the world, with the majority of gauges exhibiting increases  
639 of less than 5 cm at the 1-in-10-year return period (Fig. 8A). The central 90th percentile  
640 band of the data for the 1-in-10-year return period ranges from -3 to 18 cm, as shown in Fig.  
641 8B. However, the spread of the data is more pronounced at the higher return periods, as  
642 shown in Fig. 8C. Some regions of the world have greater increases, in the order of 30 – 40  
643 cm for the 1-in-10 year return period. These gauges are mostly concentrated in TC basins,  
644 namely the Caribbean, the Gulf of Mexico, Japan, China, the Philippines, plus the East and  
645 West Coasts of Australia. This demonstrates the process by which the RFA better represents  
646 extreme rare events that are typically under sampled in the historical record. By drawing on  
647 all the events captured by gauges across the region, the RFA reveals that there is greater risk  
648 of extreme events by considering their potential occurrence in areas that, by chance, have  
649 not been previously impacted as observed in historical records. Similarly, oversampling is  
650 clearly evident at 1-in-100-year return periods, for which nearly a third of locations show  
651 decreases in ESL exceedance probabilities compared to the single site analysis. The  
652 magnitude of these decreases tend to be much smaller than the increases seen.

## 661 5. Discussion

662 The ESL exceedance probabilities dataset that is presented in this paper is the first global  
 663 dataset, to our knowledge, to be derived using an RFA approach, using a synthesis of  
 664 observed and modelled hindcast data. The resulting data is output at high resolution (~1  
 665 km) along the entire global coastline (excluding Antarctica), includes wave setup, and better

666 captures the coastal flood risk from TCs. This approach is notable for being computationally  
667 inexpensive compared to more traditional approaches for deriving ESL exceedance  
668 probabilities via hydrodynamic modelling.

669 As previously discussed in the introduction section, relying solely on observational records  
670 to estimate ESL exceedance probabilities can significantly bias results. To fit robust  
671 parameter estimates and obtain confident exceedance probabilities sufficient for informing  
672 flood risk managers, long term and consistent high quality observational records are needed  
673 (Coles, 2001). While some tide gauge and wave records span numerous decades, many  
674 records only cover a handful of recent decades (e.g., 10-30 years) or have significant gaps in  
675 their historical records. This often means quality data is excluded from analyses as their  
676 records are too short to produce robust parameter estimates. Furthermore, gauges are  
677 relatively sparse, especially in less populated areas and developing nations. While surges  
678 and waves typically impact large regions, peak water levels are usually only observed over  
679 smaller areas (i.e., a single bay, estuary or beach). As a result, measured records can easily  
680 miss the maximum of an extreme event, thus mischaracterising extreme water levels of the  
681 event. As such, rare extreme events that characterise the upmost tails of the distributions of  
682 ESLs, such as TCs, are repeatedly under sampled in the historic record, in both frequency  
683 and magnitude.

684 By using an RFA approach, we demonstrate how we have improved these issues. The RFA  
685 can be viewed as a space-for-time approach, where long historical records (which give  
686 robust parameter estimates) are substituted for a collection of shorter records that cover a  
687 larger area. The volume of data (and subsequent extreme events) is retained, but the  
688 individual records can be much shorter. In this study, records as short as 10 years have been  
689 utilised. Furthermore, the regionalisation process works to overcome the issues with gauge  
690 density by disseminating the hazard presented by rare extreme events, as shown using the  
691 Cyclone Yasi example. From the 10 gauges in the region, the only record to have captured  
692 an historic extreme surge event of the magnitude observed during Cyclone Yasi was  
693 Cardwell, despite this section of coastline being at known risk to TC activity. A single site  
694 analysis of tide gauge data in this region would likely underpredict the real risk of ESLs  
695 generated by TCs in areas which haven't had a direct impact in the observational record. On

696 the other hand, the damping of the return levels in the RFA output at Cardwell and Bowen  
697 could mean an underprediction of the risk from surges in these locations.

698 Global hydrodynamic models that simulate tide and surge (e.g., GTSM) or waves have been  
699 developed to substitute observational records, especially in regions not covered by tide  
700 gauges. These models have been demonstrated to represent historic extreme events to a  
701 high degree of accuracy when forced using historical observational data pertaining to the  
702 event (Yang *et al.*, 2020). However, using these models for the characterisation of  
703 exceedance probabilities is limited by the availability of long term high-quality global  
704 reanalysis data, that captures the full extent of meteorological extremes that drive large  
705 surge events. The RFA aims to address this by using a space-for-time approach, however it  
706 is still limited by the bounds of the GTSM-ERA5 data. As demonstrated in Fig. 7, the  
707 distribution of increases to local return levels made by the RFA broadly follows the same  
708 patterns globally as the differences between COAST-RP and GTSM-ERA5. As TC hazard is  
709 typically underrepresented due to short records, it can be inferred that the increases  
710 observed across these regions are an improvement on a single site analysis.

711 While the RFA is capable of identifying areas of increased risk from TC activity, it is still  
712 constrained by the training data available. This is demonstrated in Fig. 7. Two distinct areas  
713 lack increased water levels in the RFA difference plot (Fig. 7A), namely: the Bay of Bengal  
714 and Northwestern coasts of India and Pakistan. ERA5, the forcing data used for GTSM-ERA5  
715 has been found to consistently underestimate TC intensity in both minimum sea level  
716 pressure and maximum windspeed (Dulac *et al.*, 2023). Consequently, the intensity of  
717 extreme events in GTSM-ERA5 in these regions could underrepresent the potential hazard  
718 from TC activity. If the maximums of extremes are not captured in the reanalysis data, then  
719 the full magnitude of the surge cannot be simulated by GTSM-ERA5. As such, the RFA will  
720 have smaller or fewer extremes with which to draw data from when characterising rare  
721 extreme events, therefore leading to a persistent underestimation of the return levels.

722 Coastal flood hazard mapping is usually carried out using inundation models that simulate  
723 the propagation of water over the coastal floodplain. To accurately capture the footprint of  
724 the surge on the land, inundation models require high-resolution boundary conditions at  
725 regular intervals along the coastline. The density of boundary condition points needs to be  
726 sufficient to capture local variability in ESLs along a coastline, which can be caused by

727 bathymetric and topographic features such as narrow channels, enclosed bays, barrier  
728 island and estuaries. The spatial resolution of tide gauges, even in the areas of highest gauge  
729 density, is insufficient for direct use in inundation modelling and therefore requires some  
730 form of interpolation and/or extrapolation. Similarly, while GTSM-ERA5, is run at a  
731 reasonably high coastal resolution, publicly available data is only output at approximately  
732 50km resolution outside of Europe, and therefore does not meet the standards necessary  
733 for coastal floodplain inundation modelling. Using the RFA to downscale the regional  
734 extreme water levels allows for the possibility of implementing tide gauge data and the  
735 outputs from GTSM-ERA5 as boundary conditions for subsequent inundation models. In  
736 addition, the downscaling process involves scaling the water levels by tidal range and thus  
737 enables dynamic characteristics of the surge, such as amplification at the head of estuaries,  
738 to be reproduced in the inundation models. This downscaling process is, however, limited  
739 by the resolution of the tide model used to obtain the tidal range values. In the case of this  
740 study, FES2014 is output at 1/16<sup>th</sup> of a degree (approximately 7km at the equator).

741 Ultimately, the future of delineating the flood hazard from TCs lies in multi-ensemble  
742 models using 100's of 1,000's of years' worth of synthetically generated storms forcing high-  
743 resolution tide-surge-wave models. However, the computational cost of running such  
744 simulations is enormous when compared to the cost of running an RFA on a relatively short  
745 hindcast record. In the same way, dynamically modelled waves are usually excluded from  
746 global simulations that consider exceedance probabilities due to the computational  
747 expense. At the same time, failing to considering the joint dependence of surge and waves  
748 can lead to an underestimation of ESL exceedance levels by up to a factor of two along 30%  
749 of the global coastline (Marcos *et al.*, 2019). This reinforces the significance of the RFA  
750 methodology in characterising global coastal flood risk.

751 Validating the RFA is nuanced, as assessing metrics compared with observed record is: (a)  
752 validating against the data used to build the RFA in the first place; and (b) not recognising  
753 the inadequacies of the tide gauge records that the RFA is attempting to mitigate. Leave-  
754 one-out cross validation highlights the strengths of the RFA, without succumbing to the  
755 shortfalls inherent in the observational record. The increased LEWLs in the regions prone to  
756 TC activity once again demonstrates the RFA's ability to spatially disperse the hazard of low  
757 probability extreme events across a region. It is worth noting that the leave-one-out cross

758 validation is the best possible representation of the RFA as only grid cells that use data from  
759 10 record locations are used, so each model is trained on the maximum amount of data  
760 possible. In some areas, the number of records used can be as low as three, and so the  
761 ability for the RFA to reproduce water levels in these regions could be compromised.

762 Applying the RFA as done in this study does have its limitations. Firstly, changing our  
763 definition of a homogeneous region would likely have a great impact on our results. In  
764 future iterations of this study, we recommend carrying out a sensitivity analysis to  
765 understand how using different maximum radii to select water level records impacts upon  
766 estimated extreme water levels within the region. Secondly, delineating the global coastline  
767 into 1° by 1° tiles and evaluating a different RFA for each tile results in some complex areas  
768 of coastline being summarised by a single regional growth function. Examples of this are  
769 seen in Japan, where exposed coastlines of the North Coast are contained in the same tile as  
770 a sheltered bay that is open to the South Coast. A solution to this would be to classify  
771 coastlines based on descriptors, as carried out by Sweet *et al.* (2020). These descriptors  
772 could include characteristics such as dominant forcing type, geographic location, and/or  
773 local coastal dynamics. The method used to incorporate wave setup is another constraint, as  
774 it has been greatly simplified for ease of global application. Improving upon this should also  
775 be a focus of future studies. Lastly, another limitation of the approach used in this study is  
776 the static shape parameter limiter. It is probable that the maximum shape parameter varies  
777 by location around the world, and that by implementing a fixed threshold globally we are  
778 perhaps limiting some of the most extreme events in some regions. Improving this section  
779 of the methodology is a high priority for future updates.

780 The outputs from the RFA should be supplemented with local knowledge wherever possible,  
781 and the uncertainties in the results should be considered before the data is used. The RFA is  
782 a powerful tool for estimating return levels in ungauged locations or in locations where the  
783 historical records are short or incomplete, but there are risks associated with both  
784 overpredicting and underpredicting surge heights. Underprediction can lead to complacency  
785 among coastal managers and the potentially dangerous assumption that communities are  
786 safe from surge risk. Conversely, overprediction can result in unnecessary cost for risk  
787 mitigation measures and potential economic loss driven by a lack of investment in a region  
788 deemed at risk. Disseminating the risk of TC generated surges over a region could lead to

789 overprediction in some locations, and so conducting sensitivity analyses to understand the  
790 robustness of findings is recommended, especially in the context of coastal management  
791 and safety assessments. The RFA has been developed in this study as a method for regional  
792 to continental to global scale risk analyses from globally available data, and not local  
793 studies. The results give a first order approximation of extreme water levels in ungauged  
794 locations. It is not expected that they would be used in the design for local flood defences,  
795 for example.

796 Going forward, the RFA framework developed in this study can be easily updated with the  
797 availability of new data. Possible next steps could also include using GTSM simulations of  
798 future climate scenarios, as well as measured wave data. To this end, a global wave dataset  
799 similar to GESLA would be instrumental in collating wave data from the numerous buoys  
800 globally. Future updates could also include an assessment of using different extreme value  
801 distributions, perhaps following the mixed climate approach of O'Grady *et al.*, (2022).

802 In the near future, we plan to use the global exceedance probabilities derived in this paper  
803 as boundary conditions for inundation modelling of the coastal floodplain of the entire  
804 globe, using the 2D hydraulic model LISFLOOD-FP (Bates *et al.*, 2010). This presents an  
805 exciting opportunity to provide an invaluable resource that will help to better quantify  
806 global coastal flood risk.

807

## 808 6. Conclusions

809 In this paper we have demonstrated an RFA approach utilising both measured and modelled  
810 hindcast records to estimate ESL exceedance probabilities, including wave setup, at high  
811 resolution (~1 km) along the entire global coastline (with the exception of Antarctica). Our  
812 methodology is computationally inexpensive and is more effective in accurately estimating  
813 the low frequency exceedance probabilities that are associated with rare extreme events,  
814 compared to approaches that consider data from single sites. We have demonstrated, using  
815 Cyclone Yasi (2011) which impacted the Australia coast, the ability of the RFA to better  
816 characterise ESLs in regions prone to TC activity. Furthermore, on the global scale we have  
817 exemplified how the RFA, when trained on relatively short reanalysis data, can reproduce  
818 patterns of increased water levels similar to those present in dynamic simulations of 10,000

819 years of synthetic hurricane tracks. The RFA methodology shown provides a promising  
820 avenue for improving our understanding of coastal flooding and enhancing our ability to  
821 prepare for and mitigate its devastating impacts. In the future, we plan to use the  
822 exceedance probabilities from this study as boundary conditions for an inundation model  
823 covering the global coastal floodplain.

## 1006 9. Code Availability

1007 The Python scripts used for handling the GESLA dataset can be downloaded for:

1008 <https://github.com/philiprt/GeslaDataset>

1009 The Conda package (Python) used for creating the FES2014 tidal timeseries can found at:

1010 <https://anaconda.org/fbriol/pyfes>

## 1011 10. Data availability

1012 GESLA tide gauge data is available at: <https://gesla787883612.wordpress.com/downloads/>

1013 GTSM data is available at: <https://cds.climate.copernicus.eu/cdsapp#!/dataset/sis-water-level-change-timeseries?tab=overview>

1015 ERA5 wave hindcast data is available at:

1016 <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=overview>

1017 FES2014 tidal heights can be downloaded from:

1018 <https://www.aviso.altimetry.fr/en/data/products/auxiliary-products/global-tide-fes.html>

1019 HYBRID-CNES-CLS18-CMEMS2020 is available at:

1020 <https://www.aviso.altimetry.fr/en/data/products/auxiliary-products/mdt/mdt-global-hybrid-cnescs-cmems.html>  
1021

1022 Copernicus 30m DEM is found at: <https://spacedata.copernicus.eu/collections/copernicus-digital-elevation-model>  
1023

1024 COAST-RP dataset is downloaded from: [https://data.4tu.nl/articles/\\_/13392314](https://data.4tu.nl/articles/_/13392314)

1025 The data produced in this study is available for academic, non-commercial research only. Please  
1026 contact the corresponding author for access.

## 1027 11. Author contributions

1028 T.C. was responsible for coding up the pre-processing the tide gauge and GTSM data, coding up the  
1029 RFA and validating the results. N.Q. pre-processed the wave data, including fitting the copula to  
1030 predict wave conditions for tide gauge records that extended beyond the hindcast period. J.G.  
1031 created the coastline output points using the Copernicus DEM. I.P. worked on the evaluating the  
1032 empirical shape parameter limiter. H.W. assisted in validating the output results from the RFA. S.M.  
1033 supplied the GTSM dataset and W.S. provided the RFA methodology which we applied globally. I.H.  
1034 and P.B. provided guidance and assistance throughout. T.C. prepared the manuscript with  
1035 contributions and editing from all co-authors.

## 1036 12. Competing Interests

1037 The authors declare that they have no conflict of interest.
