14
15 **Abstract** Anthropogenic non-methane volatile organic compounds (VOCs) in the United Kingdom
16 have been substantially reduced since 1990, in part attributed to controls on evaporative and vehicle
17 tailpipe emissions. Over time other sources with a different speciation, for example alcohols from
18 solvent use and industry processes, have grown in both relative importance and in some cases in
19 absolute terms. The impact of this change in speciation and the resulting photochemical reactivities
20 of VOCs are evaluated using a photochemical box model constrained by observational data during
21 a summertime ozone event (Birmingham, UK), and apportionment of sources based on the UK
22 National Atmospheric Emission Inventory (NAEI) data over the period 1990-2019. Despite road
23 transport sources representing only 3.3% of UK VOC emissions in 2019, it continued as the sector
24 with the largest influence on local O₃ production rate (P(O₃)). Under case study conditions, the 96%
25 reduction in road transport VOC emissions that has been achieved between 1990 – 2019 has likely
26 reduced daytime P(O₃) by ~1.67 ppbv h⁻¹. Further abatement of fuel fugitive emissions was modeled
27 to have had less impact on P(O₃) reduction than abatement of VOCs from industrial processes and
28 solvent use. The long-term trend of increased emissions of ethanol and methanol have somewhat
29 weakened the benefits of reducing road transport emissions, increasing P(O₃) by ~0.19 ppbv h⁻¹ in

30 the case study. Abatement of VOC emissions from multiple sources has been a notable technical
31 and policy success in the UK but some future benefits (from an ozone perspective) of the phase out
32 of internal combustion engine passenger cars may be offset if domestic and commercial solvent use
33 of VOCs were to continue to increase.

34

35 **1. Introduction**

36 Elevated tropospheric ozone (O_3) has been a long-standing pollutant of concern in the rural
37 and sub-urban environment and is now becoming more prevalent in urban centers as primary NO
38 traffic emissions reduce (Sicard, 2021). As an important tropospheric oxidant and greenhouse gas
39 (Kumar et al., 2021), exposure to O_3 also increases risks of mortality from respiratory diseases and
40 adversely impacts on crop productivity (Lefohn et al., 2018). O_3 is mainly formed through
41 photochemical reactions involving the oxidation of volatile organic compounds (VOCs) in the
42 presence of nitrogen oxides (NO_x , $NO_x=NO+NO_2$) (Calvert et al., 2015). The release of VOCs arises
43 from a wide range of activities, including unburned fuel or partially combusted products in exhaust,
44 from solvents used in industry and numerous other diffuse domestic and commercial sources (He et
45 al., 2019). Effective policies to mitigate ozone pollution rely on an accurate estimate of both
46 emissions and speciation of O_3 precursors.

47 The challenge in reducing O_3 lies in its non-linear relationship with its precursors since
48 individual VOCs have unique capacities for forming ozone. Decades of modelling studies have
49 established regimes where reductions in NO_x or VOCs emissions would be preferentially beneficial
50 to mitigate O_3 – so-called NO_x -limited or VOC-limited regimes (Ivatt et al., 2022; Seinfeld and
51 Pandis, 2016). Abatement of VOCs sources is important in VOCs-limited areas since decreasing the
52 emissions can effectively reduce the local O_3 production rate and help limit O_3 peak concentrations
53 (Gaudel et al., 2020). The wide range of sources, including many that are diffuse and occur indoors,
54 and differing photochemical reactivities further complicates O_3 reduction strategies. Different mixes
55 of sources and speciation can lead to a need for localized policies. For example, short-chain alkanes
56 and alkenes with high hydroxyl radical reactivity emitted from on-road transportation in China, have
57 been reported as being responsible for 26% of national O_3 formation (Wu and Xie, 2017). A field
58 observation study in Delhi, India reported that the O_3 production in that city was most sensitive to

59 monoaromatics, followed by monoterpenes and alkenes during a post-monsoon period in 2018
60 (Nelson et al., 2021). Another study at urban sites in Seoul, South Korea concluded that the O₃
61 production was controlled by C>6 aromatics and isoprene during a summer O₃ episode in 2016
62 (Schroeder et al., 2020). There is therefore no ‘one size fits-all’ policy in terms for which sources
63 and sectors to target for optimal O₃ abatement efforts.

64 Policy and regulation aimed at improving air quality in many countries including the United
65 States, the United Kingdom and Europe have led to decades of falling VOCs emissions (Lewis et
66 al., 2020; Coggon et al., 2021). This reduction can be substantially attributed to the successful
67 technical implementation of tailpipe exhaust after-treatment technology for gasoline vehicles
68 controls on evaporative emissions from vehicles including during re-fueling and a more widespread
69 set of efforts to control industrial emissions (Winkler et al., 2018). Despite these successes, O₃
70 remains a pollutant of concern; whilst peak concentrations during O₃ events have reduced in the UK,
71 increases in the long-term urban background O₃ concentrations have been observed since the 1990s
72 (Department for Environment, Food & Rural Affairs, 2023). A variety of explanations have been
73 given to account for the increase including a rising northern hemisphere background O₃, increasing
74 methane which contributes to both global radiative forcing and enhances O₃ production (Tarasick et
75 al., 2019; Abernethy et al., 2021), the increases in non-vehicular sources of VOCs emissions
76 (McDonald et al., 2018; Yeoman and Lewis, 2021), and the reduction of NO_x in VOCs-limited urban
77 areas leading to greater O₃ production efficiency (Diaz et al., 2020).

78 The UK National Atmospheric Emissions Inventory (NAEI) for VOCs has shown increases in
79 the relative contribution of solvent usage and the food & wine industry to total national VOCs
80 emission over 1990-2019, and steady growth in the relative importance of OVOCs within the overall
81 speciation (Lewis et al., 2020). In North America and Europe cities, OVOCs emitted from volatile
82 chemical products (VCP) can outweigh fossil fuel sources for urban VOCs. Modelling results
83 showed that the additional OVOCs from VCP emissions were the most important species for urban
84 O₃ production, increasing the daily maximum O₃ mixing ratio by as much as 10 ppbv in Los Angeles
85 and 11 ppbv in New York (Coggon et al., 2021; Qin et al., 2021). Substantial OVOCs emissions can
86 come from unexpected places. For example, alcohols emitted from use of windshield fluid are now
87 estimated to be a larger VOC source from road transport than VOC from the tailpipe in the UK
88 (Cliff et al., 2023). From the perspective of O₃ pollution, the benefit of substantial reductions on

89 vehicle emissions, whilst there has been a parallel increasing role for non-industrial solvent usage
90 remains unclear. What effect this shift in speciation is having on ozone chemistry is less well studied.
91 One challenge has been the lack of routine measurement of OVOCs in most national air quality
92 monitoring networks (Air Quality Expert Group, 2020).

93 In this study we evaluate the effects of changing speciation on urban ozone chemistry, using
94 recent field measurements of O₃ and its key precursors such as NO_x, CO, speciated VOCs and
95 OVOCs in Birmingham, UK during August 2022. We combine this with changing speciation and
96 relative amounts of VOCs based on long-trends in the NAEI. The sensitivity of *in-situ* production
97 and OH reactivities of the measured O₃ precursors are investigated by constraining the observational
98 data sets to a zero-dimensional chemical box model. By incorporating the detailed NAEI VOCs
99 emission inventories over the period of 1990-2019 into the model, O₃ formation in Birmingham is
100 used as a case study to quantify the impacts of the real-world changes in VOCs sources on urban O₃
101 production rate. The relative importance of different VOCs functional group classes to O₃
102 production are also evaluated. The results help understand impacts of decades of abating different
103 VOCs-emitting sectors on urban O₃ production, and outline the implications for future O₃ control
104 strategies.

105

106 **2. Materials and Methods**

107 **2.1 Field observations**

108 The observations are taken from the Birmingham NERC Air Quality Supersite during August
109 2022. This is located on the University of Birmingham (52°27'20.2"N 1°55'44.3"W) campus. The
110 site has been in operation for many years, and represents an urban background environment. It is
111 influenced by transport emissions from nearby arterial roads and residential emissions from
112 surrounding area. There are no significant industrial activities within a 4km radius of the site.

113 Continuous measurements of NO, NO₂, CO, CH₄, VOCs, O₃, along with meteorological
114 parameters including air temperature and pressure, relative humidity, wind speed and direction were
115 made. Briefly, NO and NO₂ were measured by a chemiluminescence-based T200 analyzer (Teledyne
116 API, U.S.A.) and the T500U Cavity Attenuated Phase Shift (CAPS) analyzer (Teledyne API,
117 U.S.A.). The concentration of NO_x was then the statistical sum of NO and NO₂. The mixing ratio of

118 CO were measured by a laser absorption spectroscopy Multi-species Continuous Emissions
119 Monitoring instrument (Enviro Technology Service Ltd., UK) (Li et al., 2020). Manual calibration
120 and span checks for the above instruments were performed every 3 days, and automatic zero
121 calibration was set on daily bases. O₃ was measured by an O₃ analyzer (Model 49i, Thermo Fisher
122 Scientific Inc., U.S.A.) with a minimum detection limit (MDL) of 1.0 ppbv. Meteorological
123 parameters including air temperature and pressure, and relative humidity were obtained from a
124 weather station WS300-UMB weather station (Luff GmbH, Germany). Additionally, Wind speed
125 and direction were measured by a 3-axis ultrasonic anemometer (Gill Instruments Ltd., UK) over
126 the campaign.

127 A gas chromatography-flame ionization detection (GC-FID) analysis system (7890A, Agilent
128 Technologies, U.S.A.) was used to quantify 38 individual VOCs species. Details on instrument
129 settings and quality assurance/quality control methods can be found in (Warburton et al., 2023).
130 Briefly, the GC-FID system utilizes dual detectors: one detector for C₂ – C₆ non-methane
131 hydrocarbons (NMHCs); the other detector for remaining C ≥ 7 hydrocarbons, and polar species
132 such as ethers, ketones, and alcohols. Ambient samples were dried at –40 °C using a water trap and
133 then preconcentrated on a carbon adsorbent at the lowest temperature the unit could achieve, always
134 lower than -115 °C. Once a 0.5L sample had been collected, a pre-concentration trap was warmed
135 slightly from -80 °C to purge trapped atmospheric CO₂. The trap was then heated to 190 °C for 3
136 minutes with a counter flow of helium thermally desorbing the concentrated VOCs onto focusing
137 micro-trap held at lower than -115 °C. The analytes were flash heated and passed onto a VF-WAX
138 column. The unresolved analytes (C₂ – C₆ NMHCs) were then transferred into a Na₂SO₄-deactivated
139 Al₂O₃ porous-layer open tubular (PLOT) column via a Deans switch, for separation and detection
140 by the first FID. The Dean switch then diverted the analytes onto a fused silica internal diameter to
141 balance column flows and subsequently transfer the VF-WAX column- resolved species into the
142 second FID. Generally, quantification of C₂-C₆ hydrocarbons was completed by the first FID using
143 4 ppbv gas standard cylinders (the National Physical Laboratory, Teddington, UK). Quantification
144 of C ≥ 7 hydrocarbons and OVOCs was completed by the second FID using effective carbon number
145 (ECN) with reference to toluene. In this study, the concentration of total VOC (TVOC) was defined
146 as the statistical sum of concentrations of measured individual species, but this is not meant to infer
147 that this represents the total reactive carbon in air, which would always be greater than this value

148 due to unmeasured species. Later in this study we broadly group species according to their chemical
149 function groups, summing into alcohols, ketones, alkanes, alkenes, aromatics, aldehydes, and
150 alkynes.

151 The GC-FID system responses were regularly checked by running direct calibration sequences
152 using the 4 ppbv gas standard cylinders. It was verified there was no FID-response drift over the
153 analyzing period for this study. Additionally, carbon-wise FID responses for all reported species
154 were calculated to verify the use of ECN as a quantification method. Table S1 lists which species
155 were directly calibrated, and which used equivalent carbon numbers for quantification. Table S2
156 shows effective carbon numbers of species which used carbon-wise responses.

157 2.2 National emission inventory for VOCs

158 Estimates of UK anthropogenic VOC emissions are taken from the NAEI. The NAEI uses a
159 combination of UK-specific methods and default methods as recommended in the European
160 Monitoring and Evaluation Programme (EMEP)/European Environment Agency (EEA) Emission
161 Inventory Guidebook (European Environment Agency, 2016). Further details can be found in (NAEI,
162 2021). The VOC inventory is also disaggregated into inventories for each individual VOC species
163 and details of the speciation process and assumptions can be found in (Passant, 2002) and (Lewis et
164 al., 2020).

165 Methods to estimate emissions can be divided into two groups: those using emission factors,
166 and those using 'point source' emissions data reported to regulators by the operators of individual
167 industrial sites. The emission factor methods require UK activity data, for example consumption of
168 paint, consumption of a fuel, production of steel or vehicle kilometers travelled. The activity data is
169 then combined with an emission factor which expresses the total VOC emission that is expected per
170 unit of a given activity. Most total VOC emission factors are taken from the internationally applied
171 EMEP/EEA Emission Inventory Guidebook and so are not necessarily UK-specific. The factors for
172 road transport are directly calculated for the UK and a particularly detailed approach is used to
173 estimate emissions using emission factors from the Guidebook for many different vehicle types and
174 emission standards, fuels and road types combined with detailed transport activity from the UK
175 Department for Transport. Government statistics cannot always provide the necessary activity data
176 for other sectors, so industry data are used instead. For instance, NAEI data on consumption of
177 products containing organic solvents are from industry sources. The alternative point source method

178 can be used for source categories where emissions data can be obtained for all sites within the sector,
179 and this limits the method to source categories such as crude oil refining, steel production and
180 chemicals production. The emissions data reported by the operators of these sites can be based on
181 emissions monitoring, although this is not always the case and emissions might instead be estimated,
182 for example, using emission factors.

183 The NAEI produces updates to the inventory for total VOC mass emissions by source sector
184 each year to achieve a consistent historic time-series reflecting trends in UK emissions. Emissions
185 of individual VOC species are estimated using source-specific speciation profiles which show the
186 mass fraction of each species, or in some cases groups of species, emitted by the source (NAEI,
187 2021; Passant, 2002). Over 600 individual VOC species or species groups are included in the
188 speciation, based on sources in industry, regulators and in some cases literature sources and
189 databases such as the USEPA SPECIATE database. The speciated inventory tends to be more
190 uncertain than the estimation of total mass of VOC emissions. The inventory for total VOC mass is
191 updated annually, whereas the speciation profiles are only periodically updated when new
192 information becomes available. Thus, trends in a particular species for a sector are a reflection of
193 changes in total VOC emissions for the sector and do not normally reflect any changes over time in
194 the speciation profile of the sector which may have occurred.

195 2.3 Photochemical box model

196 The framework for evaluating effects of changing VOCs speciation is a 0-D Atmospheric
197 Modelling chemistry box model (Wolfe et al., 2016), driven by the Version 3.3.1 of the Master
198 Chemical Mechanism (MCM v3.3.1) (Saunders et al., 2003; Jenkin et al., 2003). The model can be
199 effective in identifying the instantaneous *in-situ* O₃ sensitivity to changes in individual VOCs. The
200 measured concentrations of 38 VOCs species, NO_x, and CO, along with air temperature and pressure,
201 and relative humidity were averaged to a time resolution of 1-hour to constrain the model. A 3-day
202 model spin-up, with each 24-hour model run constrained by the observational data, was performed
203 in order to initialize the unmeasured compounds and transient radicals. The modelled outputs on the
204 4th day were taken as representing steady state of the photochemistry.

205 Photolysis rates were calculated as a function of solar zenith angle (Saunders et al., 2003):

$$206 \quad J = l(\cos \chi)^m \exp(-n \sec \chi) \quad (1)$$

207 Where J is the photolysis rate in s⁻¹; l , m , n are constants derived from radiative transfer model

208 runs for clear sky condition at an altitude of 0.5 km and literature cross sections/quantum yields; χ
 209 is the solar zenith angle in radians.

210 The net production rate of O₃ ($P(O_3)$) is calculated by the difference of the production rate of
 211 O₃ and the destruction rate of O₃, as in Equation (2):

$$\begin{aligned}
 P(O_3) = & (k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_2_i+NO}[RO_2][NO]) - \\
 & (k_{O^1D+H_2O}[O^1D][H_2O] + k_{O_3+OH}[O_3][OH] + k_{O_3+HO_2}[O_3][HO_2] \\
 & k_{NO_2+OH}[NO_2][OH] + \sum_i k_{RO_2_i+NO_2}[RO_2][NO_2])
 \end{aligned} \quad (2)$$

213 Where the former part is the rate of O₃ production, representing by rate of NO oxidation by
 214 HO₂ and RO₂ radicals; the latter part is the destruction rate of O₃, calculating by the sum of the rate
 215 of O₃ photolysis, the rates of the reactions with OH and HO₂ radicals, and the rates of NO₂ loss
 216 through reactions with OH and RO₂ radicals.

217 The sensitivity of O₃ to its precursors is quantified by the index of relative incremental
 218 reactivity (RIR) (Liu et al., 2022b), as in Equation (3):

$$RIR = \frac{\Delta P(O_3)}{P(O_3)} \times a^{-1} \quad (3)$$

220 Where RIR is the Relative Incremental Reactivity in %/%, $\Delta P(O_3)/P(O_3)$ is the ratio of the
 221 change in O₃ production rate to the base O₃ production rate; a is the reduction percentage in the
 222 input concentration of O₃ precursors – a factor that allows for the effects of changing absolute
 223 amounts of VOCs to be evaluated. Here a value of 30% was adopted for a .

224

225 3. Results and Discussion

226 3.1 Observation overview

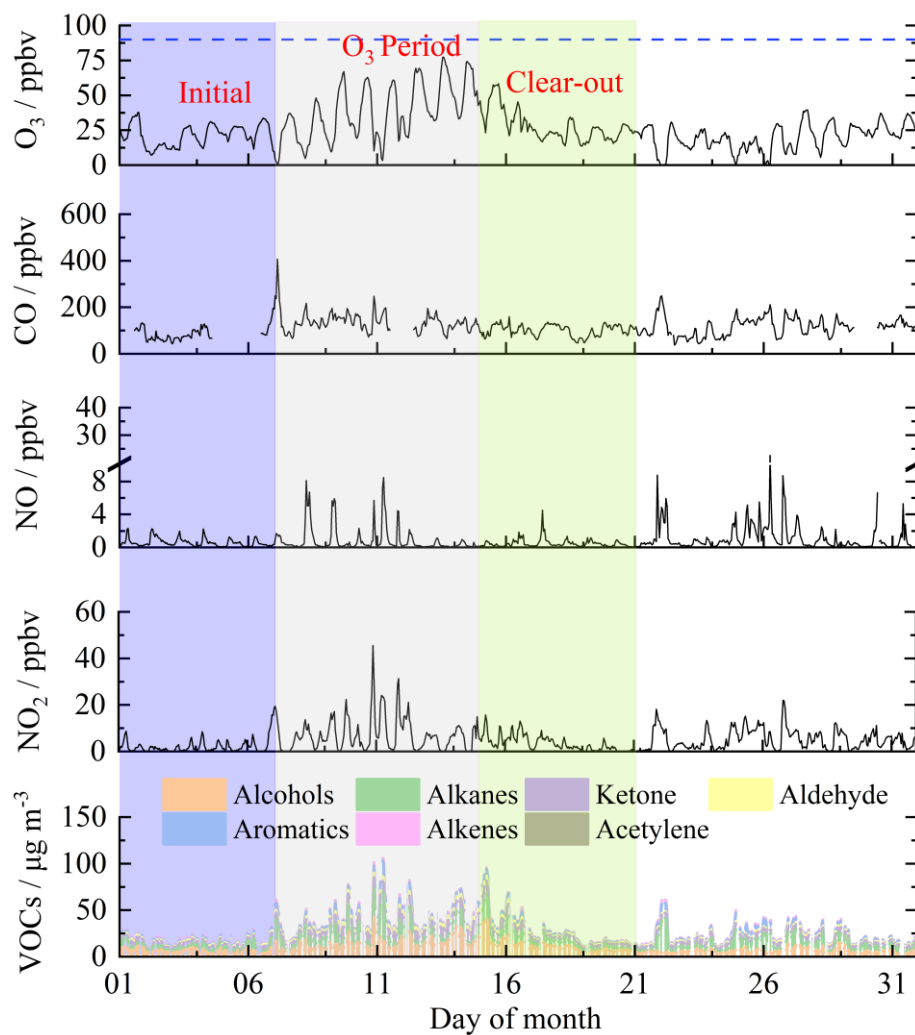

227 The time series of O₃ and its precursors during August 2022 are shown in Figure 1, subdivided
 228 into periods that will be referred to as ‘initial period’, ‘O₃ period’, and ‘clear-out’. The three periods
 229 covered 1st August-21th August 2022. Each period included one full week to avoid
 230 weekday/weekend differences in NO_x and VOCs concentrations impacting differently when O₃
 231 production was compared between the three periods (de Foy et al., 2020). Ozone showed a generally
 232 increasing trend from 1st to 14th August and then returned to relatively low concentrations after 15th
 233 August 2022. The daily maximum 8 h average O₃ concentrations (MDA8h O₃) during the O₃ period
 234 exceeded the WHO guideline value (100 µg m⁻³), ranging from 111 to 153 µg m⁻³. The elevated O₃

235 during the middle of the month corresponded to more intense photochemical formation under hot
236 weather conditions (32.7 °C in maximum) and higher concentrations of O₃ precursors (Table S3).

237 The diurnal profile of NO and NO₂ in the three periods generally showed a bimodal pattern,
238 albeit less pronounced in the initial and clear-out periods (Figure 2). The two peaks likely arise as
239 a consequence of increased traffic volumes at the start and end of the day, coupled to boundary layer
240 height changes in the early morning and into the evening (Lee et al., 2020). The average
241 concentrations of NO₂ during 05:00-10:00 were 10.8 ppbv in the O₃ period, which was considerably
242 higher than the concentration of 3.9 ppbv in the initial period and 3.4 ppbv in the clear-out period.
243 The low level of NO in the O₃ period highlights the rapid consumption of NO via photochemical
244 processes. The oxidation of CO is an important source of HO₂ in the atmosphere (Chen et al., 2020),
245 here in the range of 82.5 to 134.2 ppbv with little difference between periods. The diurnal profiles
246 of O₃ peaked at 15:00, with maximum hourly concentrations of 31.6, 67.2, and 30.4 ppbv in the
247 initial, O₃, and clear-out periods, respectively. Slight decreases in O₃ were observed during
248 nighttime (00:00-05:00), indicating enhanced NO titration effects.

249 The detailed VOCs composition in the three periods is presented in Figure S1. Concentration
250 of TVOC were 19.4 ± 8.4 , 48.0 ± 18.8 , and 23.5 ± 12.5 $\mu\text{g m}^{-3}$ in the three periods, respectively.
251 Alcohols, represented mainly by methanol and ethanol, were the predominant group that contributed
252 40.3% - 47.4% of over measured VOCs mass. This was followed by alkanes (21.4%-24.6%) and
253 ketones (16.3%-17.3%). Contributions of aldehyde (acetaldehyde), aromatics, alkenes, and
254 acetylene were low, ranging from 1.0% to 9.4% of total mass. Average mixing ratio of the top 10
255 species in selected periods at Birmingham Supersite are listed in Table S4. The top 10 species were
256 represented by methanol, acetone, ethanol, acetaldehyde, and C₂ – C₄ alkanes across initial period,
257 O₃ period, and clear-out period. The top individual species contributing to the total VOCs were
258 methanol (10.3% – 33.6%) and acetone (15.5% – 17.1%), regardless of the subdivided periods. The
259 results highlight large emissions of ethane, propane, n-butane, and i-butane associated with Natural
260 Gas (NG), Liquefied Petroleum Gas (LPG), and propellant use, fuel combustion and evaporation.
261 Ambient VOCs largely influenced by combustion-related sources (i.e., vehicle exhaust and coal
262 combustion) generally show alkane-dominated composition (Wu and Xie, 2017). Here, the
263 composition and amount of VOCs observed were most likely influenced by non-combustion
264 processes such as volatile chemical product usage and industrial processes (Gkatzelis et al., 2020).

265 Methanol was the most abundant VOC with an average concentration of 4.1 ppbv, followed by
 266 acetone (2.0 ppbv), ethane (1.9 ppbv), ethanol (1.8 ppbv), and acetaldehyde (1.0 ppbv). The average
 267 ratio of ethene/ethane was 0.2 ± 0.1 over the campaign, considerably lower than seen in polluted
 268 locations, e.g. Hong Kong (China) (0.7 ± 0.1) (Wang et al., 2018) and Seremban (Malaysia) (1.1)
 269 (Zulkifli et al., 2022).

270
 271 Figure 1. Time series of O₃, CO, NO, NO₂, and VOCs groups at the Birmingham Supersite. The
 272 blue dash line denotes the national standard (90 ppbv) for hourly O₃ concentration.
 273

274

275 Figure 2. Diurnal variations of O₃, NO, NO₂, and CO during the initial (a), O₃ period (b), and
 276 clear-out period (c). The shaded areas represent standard variations.

277

278 The general diel profiles for all selected VOCs, except for ethane, showed bimodal pattern
 279 (Figure S2). Concentrations were much higher during the night, and lower in the day, due to they
 280 were subject to photochemical losses during the daytime. The bimodal pattern is less apparent for
 281 methanol and acetone, as they are abundant species originating from many anthropogenic sources
 282 in urban areas. For example, methanol was the most abundant species measured at a roadside in UK
 283 using Thermal Desorption-Gas Chromatography coupled with Flame Ionization Detection (TD-GC-
 284 FID) (Cliff et al., 2023). A separate study on gasoline and diesel vehicle exhausts reported methanol
 285 and acetone were the largest OVOCs emitted (Wang et al., 2022). Gkatzelis et al. (2021) conducted
 286 Positive Matrix factorization (PMF) analysis based on observed VOCs dataset in New York City,
 287 and concluded that acetone was the second most abundant species in measurements and was mostly
 288 attributed to volatile consumer product emissions (90%). (See Section 3.3 for further discussions
 289 for anthropogenic sources of OVOCs).

290 3.2 Observation-based O₃ formation sensitivity

291 The *in-situ* O₃ formation sensitivity was examined via reaction rates of ozone precursors and
 292 OH radical (OH reactivities, ($k(\text{OH})$)) and RIR scales of ozone precursors, along with the chemical
 293 budgets of O₃ formation and loss. In initial and clear-out periods. $k(\text{OH})$ exhibited consistent diurnal
 294 patterns, ranging from 2.4 to 5.9 s⁻¹ (Figure S3). In the O₃ period, $k(\text{OH})$ reached 9.0 and 8.7 s⁻¹ at
 295 approximately 07:00 and 20:00, respectively. A rapid increase in $k(\text{OH})$ was observed in the early

296 morning (00:00-06:00). VOCs and model generated species represented 60.5%, 65.7%, and 56.7%
297 of the total $k(\text{OH})$ in the three periods, respectively. NO_x and CO only contributed 10.2% -27.9% to
298 total $k(\text{OH})$. Among of the VOCs groups, alcohols exhibited the largest $k(\text{OH})$ in all periods,
299 accounting for 5.0% - 6.9% of the total $k(\text{OH})$. The diurnal production and loss of O_3 are shown in
300 Figure S4. The oxidation and photolysis of VOCs promoted the production of RO_2 , and $\text{NO}+\text{RO}_2$
301 contributed 47.7% of the O_3 production pathways in the O_3 period and 36.2% and 39.8% in initial
302 and clear-out periods, respectively. Considering O_3 destruction, $\text{OH}+\text{NO}_2$ was the most important
303 pathway during morning (08:00-12:00), accounting for 73.5%, 55.4% and 59.4% of the O_3
304 destruction pathways in the three periods. The dominant $\text{OH}+\text{NO}_2$ contribution to O_3 destruction
305 suggested that the *in-situ* O_3 productions in all three periods was sensitive to VOCs emissions to
306 some extent.

307 In order to understand contributions of O_3 formation from direct emissions and secondary
308 formations of OVOCs, we developed two modelling scenarios: (1) all OVOCs species were
309 constrained to observed mixing ratio; (2) all OVOCs species were unconstrained. (2) allowed
310 secondary formations of OVOCs by oxidations of their precursor VOCs. As shown in Figure S5,
311 secondary formations of OVOCs had little impact on O_3 formation in all periods. The simulation of
312 O_3 production using the box model without constraining observed OVOCs slightly underestimated
313 average daily maximum O_3 mixing ratio and $\text{P}(\text{O}_3)$, compared to the scenario with all observed
314 OVOCs species constrained. The underestimation for average daily maximum mixing ratio of O_3
315 was 4.8%, 6.9%, and 5.1% in initial period, O_3 period, and clear-out period, respectively. In this
316 case, the underestimation of average daily maximum $\text{P}(\text{O}_3)$ was 5.1%, 6.0%, and 9.3% in the three
317 periods, respectively. The results demonstrated that in the Birmingham case study, primary
318 emissions of OVOCs played central role in the *in-situ* ozone production.

319 The relative incremental reactivity of NO_x , CO, and anthropogenic VOCs (AVOCs, all
320 measured VOCs except for isoprene) are shown in Figure 3. The *in-situ* O_3 production was most
321 sensitive to anthropogenic VOCs with the highest positive RIR values (0.44 - 0.49). This is as
322 anticipated given earlier analyses demonstrating their role in determining $k(\text{OH})$ and O_3 production.
323 The low RIR (0.03 - 0.07) for CO in all three periods indicated a minor contribution of CO oxidation
324 to O_3 production. The high RIR (0.24) for NO_x was only observed in the O_3 period. Acetaldehyde
325 showed the highest positive RIR (0.17 - 0.19) among the AVOCs, suggesting that the photolysis and

326 oxidation of acetaldehyde was a limiting factor for O₃ formation. The important role of carbonyl
 327 compounds in atmospheric photochemistry has also been reported in previous studies, contributing
 328 up to 59.3% to the O₃ formation in ambient environments in China, the United States, and Brazil
 329 (Qin et al., 2021; Liu et al., 2022a; Edwards et al., 2014). Alkanes and alcohols exhibited lower RIR
 330 values (0.02 - 0.04), despite their high mass concentrations.

331

332 Figure 3. Modelled RIRs for (a) major O₃ precursors and (b) the AVOCs groups during
 333 photochemically active daytime (08:00-16:00) in the selected periods. (AVOCs: anthropogenic
 334 VOCs, all measured VOCs except for isoprene)

335

336 3.3 Emission inventory-informed O₃ production sensitivity tests

337 The trends in anthropogenic VOCs emissions from 1990 to 2019 estimated by the NAEI are
 338 shown in Figure S6. Over the period, the annual national emissions decreased by ~69.0% from 2,941
 339 kt in 1990 to 911kt in 2019. The reduction is partly attributed to more stringent controls for gasoline
 340 vehicle emissions, both tailpipe and evaporative/fugitive. In 2019, VOCs emissions from on-road
 341 transport and fuel fugitive losses accounted for only 3.3% and 13.7% of the total mass of VOCs
 342 emissions, compared to 29.1% and 26.9% in 1990. Efforts have also been directed towards
 343 controlling industrial processes, commercial solvent usage, and combustion emissions, resulting in
 344 reductions of 66.8%, 48.9%, and 20.7%, respectively over the period. However, contributions from
 345 solvent usage to total VOCs emissions over 1990-2019 showed only modest reductions in the 1990s
 346 and 2000s and indeed small increases in the most recent years (Figure 4(b)). This slight growth in
 347 solvent usage is due to increasing emissions from solvent use in consumer products such as
 348 decorative products, aerosols, personal-care products, and detergents (NAEI, 2021). Solvent usage
 349 had become the largest contributory sector (33.7%) to VOCs emissions by 2019, followed by

350 industrial processes (16.0%).

351 As shown in Figure 4(a), the VOC speciation over the 1990-2019 period was dominated in mass
352 terms by contributions from alkanes and alcohols, the former decreasing as gasoline sources
353 declined, the other increasing as non-industrial solvent and food and drink industry processes
354 emissions followed a different pattern. Alkane emissions fell from 46.6% to 30.6% over the period.
355 Further reductions in alkane emissions are expected from policies for that phase-out sales of new
356 internal combustion engine vehicles in the UK (and in many other places) by 2035. Growth in the
357 relative contributions of alcohols was primarily driven by increases in emissions of methanol and
358 ethanol, and to a lesser extent in 1-butanol and 2-propanol (Figure 4(c)).

359
360 Figure 4. Contributions to annual national UK emissions of VOCs between 1990-2019 by: (a)
361 functional group; (b) by major emissions reporting sector; (c) for four individual alcohols in the
362 overall sub-class of alcohols; (d) for eight individual alkanes in the sub-class of all alkanes.

363

364 Figure S7 shows UK emission trends of individual species from different VOCs classes. These
365 highlight a national trend since 1990 of decreasing emissions of ethane associated with natural gas
366 leakage, toluene and propane associated with on-road petrol evaporation, as well as reductions of
367 benzene, ethene, and acetylene associated with tailpipe exhaust. Meanwhile, the reduced emissions
368 have been accompanied with increases in emissions of methanol and ethanol. The increase in
369 methanol is largely attributed to increased emissions from car-care products (i.e., non-aerosol

370 products). The increase in ethanol is due to increased domestic and industrial solvent usage.

371 The NO_x, CO, and VOC speciation within the NAEI for each of the six major emission sectors
372 was used to assign proportional sectoral contributions to the VOCs observed in Birmingham, and
373 hence to ozone production in the case study. (Table S5). The six sectors are: road transport (both of
374 on-road exhaust emission and evaporative losses of fuel vapor), industrial processes, combustion,
375 solvent usage, fuel fugitive, and agriculture emissions). This makes a key assumption that the VOCs
376 at the observation site are affected directly in the same proportion that VOCs are reported in national
377 amounts in the NAEI. We make this assumption since it provides a reasonable starting point for
378 understanding how each VOC sector may influence O₃ production during a case study event,
379 however ozone formation might be sensitive to differing regional distribution in speciation. The
380 attribution of VOCs sources based on the NAEI data can be thought of as representative for this
381 case study as a typical urban environment, but it might not hold for cities near large industrial VOC
382 sources (i.e., oil refinery and industrial production sites), since they can significantly affect
383 composition and chemical reactivity of ambient VOCs.

384 Figure S8 shows the modelled RIRs for these sources in the initial, O₃, and clear-out periods.
385 All the sources generally showed higher RIR values in the O₃ period. Road transport exhibited the
386 highest positive RIR values in all periods (0.30 - 0.36), followed by industrial process (0.06 - 0.09)
387 and solvent usage (0.05 - 0.07). Despite being a relatively minor contributor to the mass of national
388 VOCs emissions (only 3.3% of the total in 2019), road transport VOCs still played the most
389 important role in local ozone photochemical chemistry, in this case study.

390 Figure 5a shows the changes in P(O₃) during the O₃ period from 08:00 to 16:00 which might
391 arise as a result of reductions in the individual sectors described above. This is a ‘thought experiment’
392 where under 2019 general observed atmospheric conditions (e.g., for NO_x, CO and so on), each of
393 the VOC source sectors is then further reduced in isolation (from 2019 levels) and the effects on
394 ΔP(O₃) were evaluated. Based on these scenarios, reducing emissions from the individual sectors
395 all resulted in decreased P(O₃), as would be anticipated. Reducing ozone precursors arising from
396 road transport would lead to a decreased P(O₃) of ~1.71 ppbv h⁻¹ if that sector could be 100% abated
397 in the case study. This is expected because road transport is a source of photochemically reactive
398 VOCs, including aromatics, aldehyde, and short-chain alkanes/alkenes. Other sectors showed more
399 modest effects, with reductions in solvent-related VOCs the next most significant lever to control

400 ozone. Fully abating emissions of all industrial and solvent process emissions only resulted in a
 401 decreased $P(O_3)$ of ~ 0.35 ppbv h^{-1} , largely because they are dominated by ethanol and methanol
 402 with relatively low RIR values. Considering the real-world changes in VOC emissions over the
 403 period of 1990 to 2019, the very major reductions in road transport emissions have led to the largest
 404 effects in reducing $P(O_3)$ (Figure 5(b)). Whilst there have also been some very large reductions
 405 (94.6%) in fuel fugitive emissions, the impact on $P(O_3)$ reduction is modelled to have been relatively
 406 modest, being similar to industrial processes and solvent usage.

407
 408 Figure 5. (a) Changes in $P(O_3)$ in response to different reductions in VOCs, NO_x , and CO from
 409 different sectors for the Birmingham-case study condition. (b) Changes in $P(O_3)$ based on the NAEI
 410 estimated reductions in VOCs from different sectors between 1990 and 2019. The standard
 411 deviations represent variability in $\Delta P(O_3)$ during 08:00-16:00 LST in the O_3 period.

412
 413 Further model runs were performed to better understand the impacts of the shift between
 414 alkanes and alcohol species on $P(O_3)$, given trends showing decreasing alkanes emissions and
 415 increasing alcohol emissions between the 1990-2019 period (Figure 4). The modelled alkane
 416 concentrations in the case study were reduced by 10%, 30%, 50%, 70%, 90%, and 99%. This
 417 represents a downward trajectory in alkane emissions that would be anticipated as gasoline vehicles
 418 are slowly retired. Two further scenarios were then developed to sit alongside these reductions in
 419 alkanes. Firstly, the concentration of ethanol was increased to keep the overall total VOC
 420 concentrations in the model under case study conditions unchanged. Second, the concentration of
 421 both ethanol and methanol were scaled upwards to keep total VOCs concentration unchanged. As
 422 shown in Figure 6, reductions in alkanes alone resulted in decreased $P(O_3)$ to a maximum of ~ 0.26

423 ppbv h⁻¹ if fully abated. If that alkane reduction was balanced with increased ethanol and methanol,
424 then $\Delta P(O_3)$ is reduced by a maximum of 0.19 ppbv h⁻¹. If alkane reductions were balanced by
425 increasing ethanol alone, then $P(O_3)$ still decreases, but only up to 0.07 ppbv h⁻¹.

426
427 Figure 6. Reductions in $\Delta P(O_3)$ based on reducing alkanes (ALK) in the model (under case study
428 conditions), reducing alkanes but balancing the overall VOC amount with increased ethanol (blue
429 line) and reducing alkanes but balancing the overall VOC amount with increased ethanol and
430 methanol (green line).

431

432 Conclusion

433 In this study a typical high- O_3 event in Birmingham, United Kingdom was chosen as a case
434 study to investigate the impacts of changes to VOCs emissions and speciation on urban O_3
435 production. The *in-situ* O_3 formation sensitivity was split into three periods: initial, high O_3 , and
436 clear-out. Results from OH reactivity, O_3 budgets, and RIR index showed that O_3 formation in all
437 three periods was impacted by both VOCs and NO_x , but was more sensitive to anthropogenic VOCs.
438 The oxidation of alcohols and photolysis of acetaldehyde substantially contributed to *in-situ* O_3
439 formation, especially in the high O_3 period. The roles of anthropogenic VOC sources in urban O_3
440 chemistry were examined by integrating the NAEI speciation over the period of 1990-2019 into
441 photochemical box model scenarios. Despite road transport only contributing 3.3% of national
442 VOCs emissions in 2019 it still played the most important VOC role in the case study ozone
443 photochemistry, when inventory contributions were mapped onto observed VOCs. Sequentially the
444 observed VOCs were reduced by the fractional contributions and speciation in the NAEI for six

445 sectors to evaluate what impact abating different VOCs-emitting sectors would have on P(O₃).
446 Abating road transport VOCs in isolation would lead to a decreased P(O₃) by up to 1.67 ppbv h⁻¹,
447 but abating other sectors such as solvent use and fugitive fuels had noticeably smaller effects.
448 Despite emissions of VOCs from road transport falling very dramatically between 1990 and 2019,
449 it remains one of the most powerful means to further reduce ozone in this typical UK case study.
450 The wider shift in speciation reported in the NAEI from alkanes to alcohols was also examined
451 using scenarios where emission reductions for alkanes, were counterbalanced with increases in
452 alcohols, all simulated for the Birmingham case study conditions (e.g., for NO_x, CO and etc). Further
453 reducing alkanes from present day conditions to zero has a clear beneficial effect on reducing P(O₃)
454 by up to ~0.26 ppb hr⁻¹. However, this benefit would to a degree be offset should alcohol emissions
455 (for example from food and drink, and/or solvent use) increase to counterbalance those alkanes
456 reductions. Whilst simple alcohols are inherently less potent ozone-forming VOCs compared to the
457 mixture of VOCs from road transport, avoiding future growth in emissions remains important, since
458 they weaken the long-term benefits of road transport electrification and the phase out of internal
459 combustion engine vehicles.

460

461 **Data Availability**

462 Observational data including meteorological parameters and air pollutants used in this study are
463 available at https://github.com/nervouslee/Birmingham_CS.git. UK national emission inventory is
464 available at <https://naei.beis.gov.uk/>.

465

466 **Author Contribution**

467 Jianghao Li prepared the manuscript with contributions from all authors. Alastair C. Lewis helped
468 with modelling scenarios and revised the manuscript. Jim R. Hopkins contributed to measurement
469 of chemical species. Stephen J. Andrews contributed to scientific discussion on findings of this work.
470 Tim Murrells, Neil Passant and Ben Richmond contributed to the data of national emission inventory
471 data and revision on NAEI methodology. Siqi Hou, William J. Bloss, Roy M. Harrison, and Zongbo
472 Shi provided measurements of atmospheric pollutants used in this study, along with critical
473 discussion on revising the manuscript.

474
