Abstract. In this study, we utilized a high-resolution (4 km) convection-permitting Weather Research Forecasting (WRF) simulation spanning a 13-year period (2000-2013) to investigate the climatological features of Low-level Jets (LLJs) over North America. The 4-km simulation enabled us to represent the effects of orography and the underlying surface on the boundary layer winds better. Focusing on the continental US and the adjacent border regions of Canada and Mexico, this study not only identified several well-known large-scale LLJs such as the southerly Great Plains LLJ and the summer northerly California coastal LLJ, but also the winter Quebec northerly LLJ which gets less focus before. All these LLJs reach the strongest in the night time in the diurnal cycle. Thus, the different thermal and dynamic mechanisms forming these three significant LLJs are investigated in this paper: Inertial oscillation theory dominates in Great Plain LLJ, California coastal LLJ is formed by the baroclinic theory, whereas the Quebec LLJ is associated with both theories. Moreover, the high-resolution simulation revealed climatic characteristics of weaker and smaller-scale LLJs or low-level wind maxima in regions with complex terrains, such as the northerly LLJs in the foothill regions of the Rocky Mountains and the Appalachian during the winter. This study provides valuable insights into the climatological features of LLJs in North America and the high-resolution simulation offers a more detailed understanding of LLJ behavior near complex terrains and other smaller-scale features.

22 1. Introduction

23 A low-level jet (LLJ) is described as the fast-moving air ribbon located in the lower atmosphere most of the time
24 (Bonner, 1968; Rife et al., 2010). Many of the world's LLJs have been studied, such as the Great Plains LLJ over the
25 central US (Bonner, 1968; Zhong et al., 1996), the Somali LLJ over eastern Africa (Munday et al., 2021), and the
26 South American LLJ over the east Andes Mountains (Montini et al., 2019). Other studies extend beyond in-land LLJs
27 to encompass offshore coastal LLJs such as the California LLJs (Parish, 2000) and North African Coastal LLJ (Soares
28 et al., 2018). A kind of mesoscale weather system, an LLJ has a relatively small vertical range of usually only a few
29 hundred meters, but its width can reach several hundred kilometers. LLJs are closely related to precipitation and even
30 extreme events, and they can transfer abundant water vapor to the downwind regions, providing favorable dynamic
31 conditions for rainfall (Walters and Winkler, 2001; Hodges and Pu, 2019). Meanwhile, researchers have long been
32 interested in investigating their features, because LLJs also affect various processes such as wind power development,
33 air pollution transportation, and urban heat islands: the wind turbines would be influenced by positive wind shear and
34 downward entrainment from the LLJs above them, assisting in extracting energy from the strong wind belt inside LLJs
35 (Gadde and Stevens 2021; Ma et al., 2022). LLJ-related horizontal transportation is beneficial to pollutant removal
36 (Sullivan et al. 2017). The LLJs can enhance the turbulent mixing in the boundary layer thereby decreasing the
37 atmospheric stability, helping pollution diffusion, and weakening urban heat island intensity (Hu et al., 2013).

38 Since the mid-20th century, scientists have used regular rawinsonde observations to investigate the characteristics of
39 LLJs. Applying rawinsondes to investigate the Great Plains LLJ in the central US, Bonner (1968), Mitchell et al.
40 (1995), and Walters et al. (2008) studied its distribution, seasonal activity, horizontal and vertical structure, and diurnal
41 features and established the climatology of the Great Plains LLJ during warm seasons. As well as rawinsondes, radar
42 systems and wind profilers are useful tools for characterizing LLJs. Frisch et al. (1992) observed a typical LLJ process
43 using Doppler weather radar in North Dakota and identified that the friction on the surface of the boundary layer is
44 important in the early stages of LLJ development. Using long-term wind profiler measurement, Miao et al. (2018)
45 interpreted the climatology of LLJs in Beijing and Guangzhou, concluding that the frequency values of LLJs in these
46 two cities are 13.0% and 4.9%, respectively. Moreover, Smith et al. (2019) used the Plains Elevated Convection at
47 Night (PECAN) observations to conduct high-quality measurements of nocturnal LLJs with wide spatial and temporal
48 resolutions. They found that sudden changes in LLJ structure typically result from the spatial evolution of the LLJ.

49 However, there are some disadvantages of observational research that should be noted. First, regular rawinsonde data
50 only contain measurements at two daily time points (00 UTC and 12 UTC), which cannot fully capture LLJs' diurnal
51 variations. The time density of observations is therefore coarse, and coastal areas lack regular high-density
52 measurements, making the study of coastal LLJs challenging (Mitchell et al., 1995). Second, heterogeneities in the
53 rawinsonde records, such as variations in station locations, radiosonde types, and archiving procedures, may also
54 complicate the use of these observations in climate research. Third, rawinsonde measurements taken at a single point
55 are not able to capture horizontal shear and environmental conditions (Chen et al., 2005). Although observation
56 platforms such as radar, PECAN, or lidar which investigate the atmosphere as low as 300 m, can compensate to some
57 extent for this lack of observational data. as well as lidar that investigates the atmosphere as low as 300 m, these
58 approaches are still limited by the spatial coverage of their measurement platforms (Smith et al., 2019).

59 Because of these problems with observational methods, researchers have chosen reanalysis datasets as an alternative
60 for investigating LLJs. Reanalysis data have relatively better spatial and temporal coverage than rawinsonde
61 measurements, incorporate observations into the preliminary model simulations, provide more comprehensive
62 variables through assimilation, and contain broader domains. Rife et al. (2010) highlighted the global distribution of
63 identified nocturnal LLJs using reanalysis data with a horizontal grid spacing of 40 km, and even successfully
64 extracted some previously unknown jets, like Tarim nocturnal LLJ in northwest China, Ethiopia nocturnal LLJ, and
65 Namibia–Angola nocturnal LLJ. Doubler et al. (2015) applied the North American Regional Reanalysis (NARR)
66 dataset (~32 km) to generate long-term LLJ climatology in North America. Consistent with previous records,
67 Doubler's results supplemented the description of some smaller-scale LLJs. Similarly, Montini et al. (2019) compared
68 and validated the performance of five different reanalysis datasets in identifying LLJs. Their results showed the 38-
69 year climatology of South American LLJs with ERA-Interim data (~79 km).

70 Scientists have also conducted studies based on numerical simulations, which can more accurately represent LLJs than
71 reanalysis data sets, especially in the vertical direction, thereby yielding new insights into LLJs' features. Tang et al.
72 (2017) used an ensemble of dynamically downscaling regional climate simulations to generate the climatology of
73 Great Plains LLJ and predicted that the LLJ will occur more frequently during the nighttime in spring and summer in
74 mid-21st century. Jiménez-Sánchez et al. (2019) conducted a simulation for LLJs over the Orinoco River Basin by
75 dynamic downscaling of the Weather Research and Forecasting model (WRF). The simulation represented the jet

76 streaks better than previous studies within a broader region of wind enhancement and illustrated more detailed diurnal
77 evolution. Nevertheless, most general numerical simulations still represent the convective processes by the
78 parameterization scheme, which generates uncertainty in the results. These issues can be addressed by using
79 convection-permitting models with grid spacing under 5 km that adequately simulate the convections and other small-
80 scale processes (Liu et al., 2017, Li et al., 2019, Kurkute et al., 2020). Convection-permitting modeling describes the
81 underlying surface more accurately than coarse-resolution simulations and reanalysis data and shows ability in
82 investigations of LLJs near complex mountain areas. Du and Chen (2019) analyzed the LLJs over southern China by
83 using 4-km WRF model and revealed a solid relationship between the mesoscale lifting of LLJs and the convection's
84 initiation. They also highlighted the importance of coastal terrain. Overall, the finer-resolution tools tend to show more
85 comprehensive and precise results, offering detailed and accurate references to LLJs.

86 The formation mechanisms of LLJs have been studied extensively by researchers. In explaining the diurnal cycle
87 feature of the Great Plains LLJ, the inertial oscillation theory proposed by Blackadar (1957) and Stensrud (1996)
88 suggests that the LLJ is related to the friction change in the boundary layer. During the night, the jet-core wind is
89 enhanced after decoupling with near-surface friction. Holton (1967) and Parish (2000) developed the thermal wind
90 adjustment theory, which suggests that the horizontal pressure gradient changes because the atmosphere over sloping
91 terrain is warmer or because sea-land contrast influences the diurnal cycle of wind. Additionally, LLJs can also be
92 formed due to synoptic system forcing, as proposed by Uccellini et al. (1987) and Saulo et al. (2007). However,
93 convection-permitting models can help explain how LLJs form because they have precise descriptions of weather
94 systems and underlying orography. Using 4-km simulations, Fu et al. (2018) and Zhang et al. (2019) analyzed the
95 evolution of LLJs over mountainous areas in eastern and southwestern China, respectively. They concluded that
96 inertial oscillation plays a prominent role in and is responsible for the local precipitation peak at a certain time. Besides,
97 Shapiro et al. (2016) argued that the formation of some LLJs may not be impacted by a single factor and that a unified
98 theory analysis is thus required. Thus, a dataset that offers more information must be very popular. All these studies
99 have shown that convection-permitting models, with both finer coverage and resolutions, are a powerful tool for LLJ
100 characteristics research.

101 In this study, we utilize the 4-km convection-permitting WRF simulation (Liu et al., 2017) to analyze the features of
102 low-level jet systems across North America, improving the spatial and temporal resolutions. Section 2 introduces the

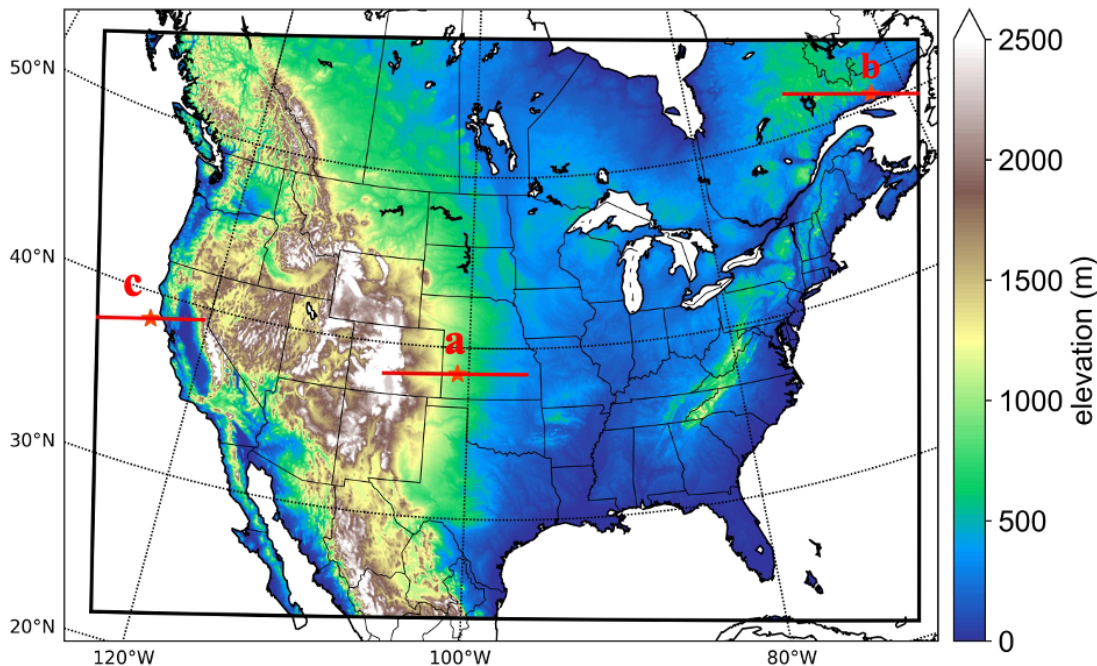

103 model configuration and the criteria for LLJ identification, Section 3 presents the characteristics of LLJ frequencies
104 in North America, and Section 4 illustrates the analysis of the background and mechanisms in several LLJ cases.
105 Finally, Section 5 provides the discussion and conclusion.

106 **2. Model configuration and methods**

107 **2.1 WRF setup**

108 This study utilized a convection-permitting Weather Research and Forecasting (WRF) dataset (Liu et al. 2017, Data
109 available at: <https://rda.ucar.edu/datasets/ds612.0/>) with a horizontal resolution of 4 km over North America, without
110 nesting. The domain covers the entire continental US, Southern Canada, and Northern Mexico, as illustrated in Figure
111 1. The simulation provides three-dimensional data at a temporal resolution of 3 hours, resulting in 8-time steps per
112 day. In the vertical direction, the data have 51 eta levels and can reach 50 hPa. It should be noted that there are five
113 layers under 500-m height and nine layers under 1 km are outputted above ground level, which means the WRF has a
114 better ability than other coarse modelling, to capture the LLJs occurring in the boundary layer. Considering the
115 computational cost for high-resolution modelling, this simulation period spans from 1st October 2000 to 30th
116 September 2013, and the six-hourly ERA-Interim reanalysis dataset of 0.7° resolution was used as input for the climate
117 simulation, the vertical layer depth of the forcing ERA-Interim data under 5 km is about 0.3-1.4 km (Hoffmann &
118 Spang, 2022). Even though the version is older, the ERA-Interim dataset still has been maturely applied in the climate
119 modelling study and accumulating a wealth of related cases and experiences (Liu et al., 2017, Li et al., 2019). Besides,
120 it is noted that 13 years is shorter than the normally defined climatology, but considering the computational cost of
121 high-resolution simulation, it is still a balanced compromise. This shorter period length was also utilized to analyze
122 the climate features of other weather events (Liu et al., 2017, Ma et al., 2022). The simulation did not apply any
123 cumulus parameterization scheme due to the fine horizontal grid spacing, but other sub-grid scale processes were
124 parameterized by various physical schemes: the rapid radiative transfer model (RRTMG) (Iacono et al., 2008) was
125 used for simulating longwave and shortwave radiations, the Yonsei University (YSU) scheme was used for
126 representing the planetary boundary layer (Hong et al., 2006), and the Noah-MP model was used for computing surface
127 processes (Niu et al., 2011). In this study, the planetary boundary layer scheme is retained. Nonetheless, it should be

128 noted that this would introduce uncertainties to the simulation in the vertical direction, especially in regions with
129 complex topography.

130
131 **Figure 1. Study domain of this convection-permitting model. The colors represent the elevation. The red lines and stars**
132 **show the positions of investigated cross-section and jets in Section 4.**

133
134 **2.2 Methodology**

135 Using the threshold criteria proposed by Bonner (1968), this study identifies LLJs from the vertical wind profile of
136 each grid point in the model output data. LLJs are present when the following conditions are met: (1) the height of the
137 LLJ core maximum wind speed is below 3 km above the ground level (AGL); (2) the maximum wind speed is greater
138 than or equal to 12 m s⁻¹; (3) from the height of the wind maxima to the height of the next minimum value or 3-km
139 height (whichever is lower), the velocity of winds drop by at least 6 m s⁻¹; (4) the wind speed drops by at least 6 m s⁻¹
140 below the level of wind maxima. On the other hand, the investigation of LLJs is normally conducted with different
141 jet-core wind directions. Pu and Cook (2010) studied the West African Westerly Jet, this zonal LLJ can help transport
142 water vapor from the Atlantic to Africa, this LLJ is related to the westward extension of the continental thermal low
143 pressure over Africa in summer. Thus, the LLJ research should refer to the local climatologic or geographic features.
144 Considering the importance of the meridional LLJ for heat and water vapor transport over North America, as well as

145 the direction of the Rockies, this study addresses LLJ frequencies in different meridional directions. According to
146 Walter et al. (2008) and Doubler et al. (2015), the criteria for identifying different meridional LLJs are as follows: for
147 southerly LLJs (S-LLJs), the jet-core wind direction is between 113° and 247° ; for northerly LLJs (N-LLJs), the jet-
148 core direction is between 293° and 67° . These criteria are also used in this study.

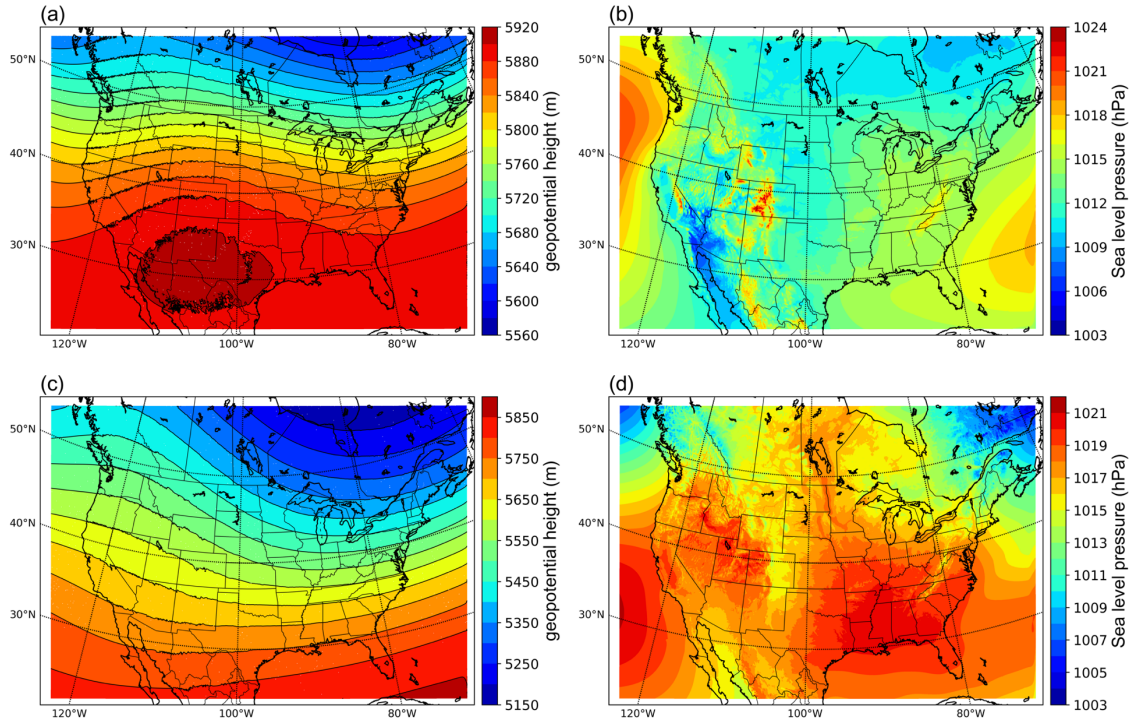

149 Based on the identification criteria above, we determined if the LLJ existed at each grid point and consequently
150 counted the occurrences of S-LLJs and N-LLJs. We also calculated the frequencies of LLJs in different seasons or
151 time steps. The frequency is defined as the percentage of the total number of occurrences for the selected accumulation
152 period. We generated the frequency distribution maps for LLJs in North America, which are illustrated in Section 3.

153 **3. The patterns of North American LLJs**

154 **3.1 Analysis of atmospheric circulation**

155 This study adopts model data to capture the climatological features of LLJs in North America. Considering the
156 relationship between LLJs and synoptical systems, we evaluated the ability of the convection-permitting model to
157 simulate the background atmospheric circulation. Figure 2 depicts the simulated multi-year analysis of geopotential
158 heights at 500 hPa and sea-level pressure isobars for summer and winter. In summer, at a height of 500 hPa (Figure
159 2a), In summer, the model depicts a trough in the east of the continental US, a ridge over the Rocky Mountains, and
160 the upper-air subtropical anticyclone crossing the southern US. At sea level (Figure 2b), the model captures the Azores
161 High-Pressure area in the Atlantic Ocean and the Hawaiian High-Pressure area in the Pacific.

162 In winter, the contours at the pressure value of 500 hPa (Figure 2c) show stronger fluctuating characteristics: the
163 eastern trough and western ridge over the continent strengthen, and the polar vortex extends to the northern US, while
164 most of North America is controlled by a cold high-pressure system. In addition, the subtropical anticyclone is too
165 weak to be found within the study domain. On the other hand, most of North America is controlled by a cold high-
166 pressure system at sea level (Figure 2d), and parts of the Icelandic Low and Aleutian Low appear on both east and
167 west of Canada, even though their centers are not captured in the domain. To summarize, the convection-permitting
168 model can simulate the features of semi-permanent centers of atmospheric circulations in North America, thus
169 demonstrating its strength in identifying the LLJs in this area.

170
 171 **Figure 2. Multi-year patterns of atmospheric circulations simulated by the convection-permitting model: (a) summer 500**
 172 **hPa geopotential height; (b) sea-level pressure in summer; (c)-(d) the same variables but in winter.**

173

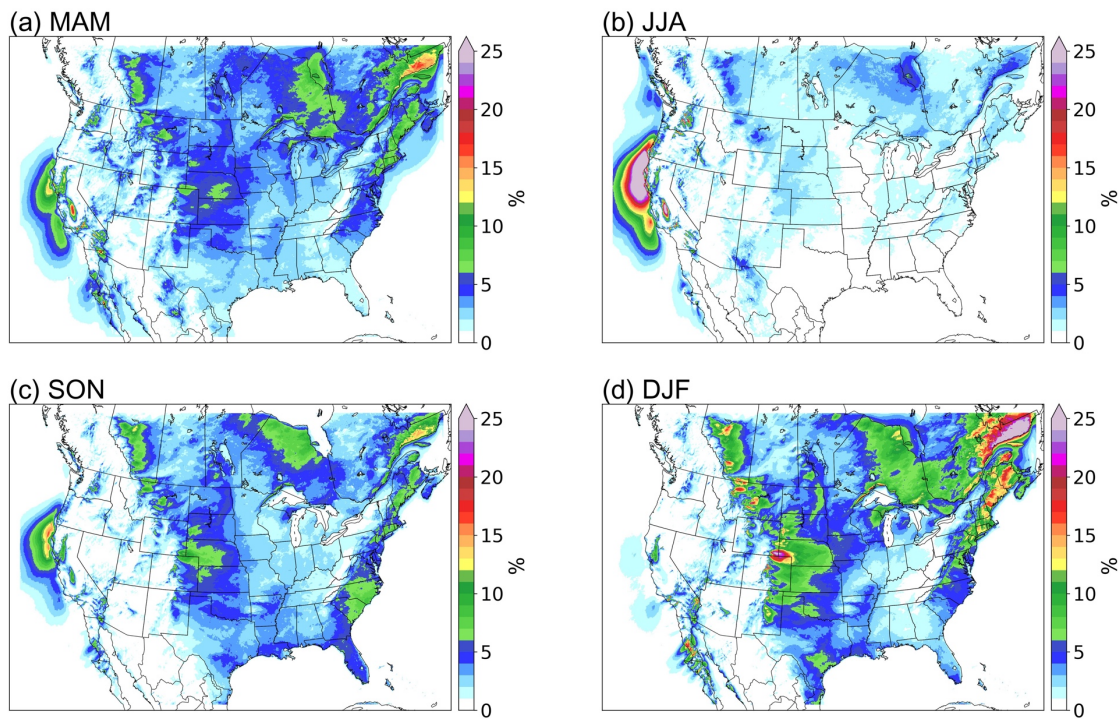

174 3.2 Seasonal variations of LLJs

175 3.2.1 Northerly LLJs

176 Figure 3 illustrates the seasonal frequency distribution of Northern Low-Level Jets (N-LLJs). The frequency is defined
 177 as the ratio of the total number of LLJ occurrences to the total number of time steps in each season. Notably, the
 178 California coastal LLJ peaks during the summer months (June, July, and August (JJA)), where frequencies exceed 25%
 179 over a broad area stretching from the southern Oregon coast to central California. In these regions, frequencies above
 180 5% can even extend into the Pacific Ocean near northern Baja California. However, transitioning from summer to
 181 autumn (September, October, and November (SON)), there is a sharp decline in the frequency of this LLJ, dropping
 182 to only 5%-15% within the core region, predominantly along the northern California coast. In winter (December,
 183 January, and February (DJF)), occurrences are sparse, at approximately 1%-2%.

184 Conversely, various N-LLJ phenomena are more prevalent during the colder seasons. These jets primarily occur near
 185 the eastern slopes of significant terrains such as the Rocky Mountains, Appalachian Mountains, and the Quebec

186 Labrador Plateau. High frequencies ($>10\%$) are observed from western Alberta to Oklahoma during winter, with hot
187 spots sporadically located in Alberta, Montana, Wyoming, and Colorado, where frequencies reach about 20%,
188 particularly between Colorado and Wyoming. In more than 25% of the wind profiles analyzed, N-LLJs were
189 identifiable. Along the Eastern US coast, N-LLJs predominantly stretch from Maine to South Carolina with peak
190 frequencies of approximately 15%-20%. In eastern Quebec, N-LLJs are most frequent in winter, exceeding 25%. The
191 simulation also detects the presence of N-LLJ in about 10% of the time steps over Hudson Bay. Notably, the
192 frequencies of all aforementioned N-LLJs significantly diminish in spring, becoming scarcely detectable in summer
193 with frequencies mostly under 5%.

194
195 **Figure 3. Seasonal occurrence frequency of N-LLJs.** Frequency shown here is calculated by counting the number of
196 occurrences of LLJs in each three-hourly time step and then dividing the total number of LLJs in each season by the number
197 of time steps in that season.

198 3.2.2 Southerly LLJs

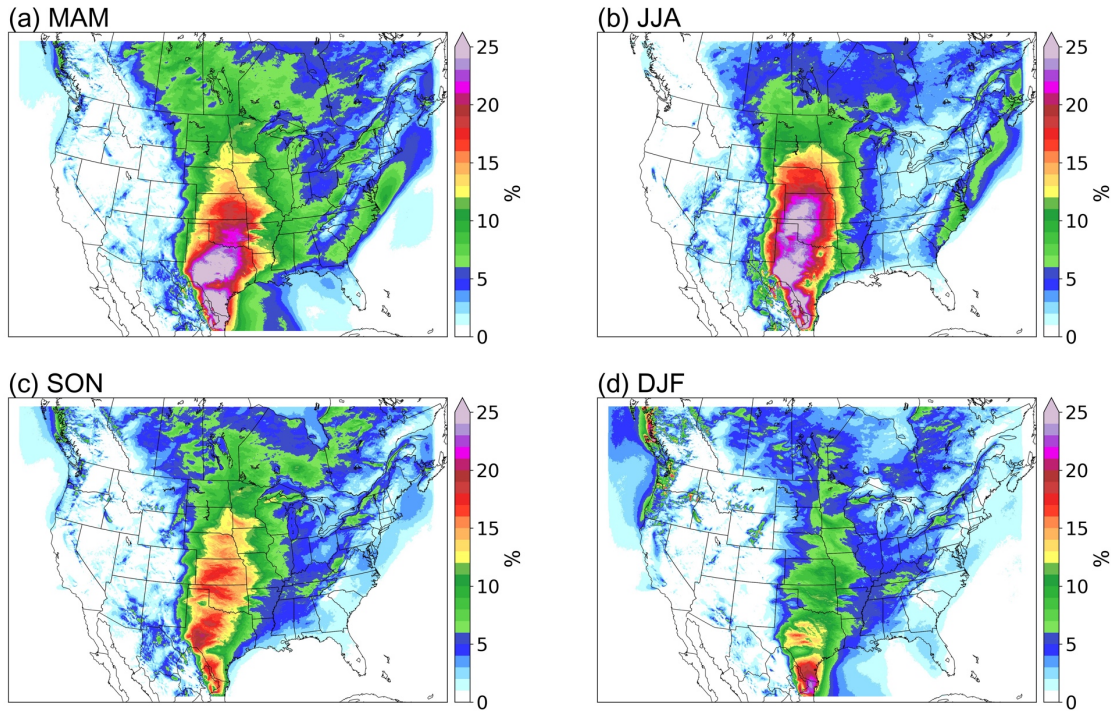

199 As to the patterns of S-LLJs in different seasons (see Figure 4), during winter, frequencies exceeding 10% are observed
200 across a vast area spanning from south Texas and the western Gulf of Mexico to southern Iowa, depicted as a deep
201 green area in Figure 4d. The greatest frequencies of S-LLJs ($>20\%$) are found along the border between northeastern

202 Mexico and the United States. In addition, about 15% of the simulated wind profiles in south-central Texas are
203 identified as S-LLJs (red clusters). In the spring (March, April, and May), the frequency expands significantly in >10%
204 of areas, with clear S-LLJ distributions detected in Manitoba, Saskatchewan, and other parts of Canada. The highest
205 frequencies are still found in the Texas-Mexico area, where the magnitude of these frequencies increases to over 25%.
206 This region (colored purple) also extends northward to occupy most of Texas. In winter, S-LLJs with occurrence
207 frequencies of above 15% extend to near Colorado and Nebraska.

208 By summer, the area with frequencies greater than 10% no longer reaches to the central Canadian prairie provinces.
209 The S-LLJs over the western Gulf of Mexico become nearly indiscernible in modeled data, with frequencies
210 approaching 0%. Conversely, the area with frequencies exceeding 25% expands northward and is segmented into three
211 distinct parts: along the northeast Mexico-Texas border, west-central Texas, and the central US Great Plains (western
212 Oklahoma and southern Kansas). Regions where over 15% of wind profiles are identified as S-LLJs also spread from
213 Colorado to near South Dakota.

214 In the fall, the magnitude of the frequency of S-LLJs decreases dramatically in the central US Plains and Texas. The
215 frequency still maintains a level greater than 15% in most areas, but with a maximum frequency of only 20% and
216 sporadically located in southwest Texas. The frequencies greater than 10% again expand northward and eastward in
217 this season, reaching Manitoba and Ontario.

218 Additionally, several smaller-scale S-LLJs are evident on the seasonal S-LLJ distribution map. In spring, a narrow
219 region of S-LLJs with a frequency greater than 5% along the eastern side of the Appalachians extends from Georgia
220 through the western Atlantic to southern Nova Scotia. Near eastern Maryland over the Atlantic, the frequency of S-
221 LLJs can exceed 10%. This narrow frequency belt persists through summer with the same coverage, though the
222 frequency magnitude diminishes, and the presence of frequencies greater than 10% is no longer visible. In winter, a
223 region where S-LLJ frequency exceeds 5% stretches from southwest Oregon to the west coast of British Columbia,
224 Canada. However, by spring, S-LLJs with frequencies above 5% occur solely over the ocean west of British Columbia,
225 and in summer, S-LLJs are virtually undetectable in this region.

226

227 **Figure 4. Seasonal frequency of S-LLJs.**

228 To summarize, for the LLJ systems that have been investigated by many researchers, the convection-permitting WRF
 229 model performs well in observing the Great Plains S-LLJ and California coastal N-LLJ during the summer. But as to
 230 the winter LLJs that lack attention, it is essential to compare and validate the occurrence and features revealed by
 231 WRF simulation. Therefore, the ERA5 reanalysis dataset is applied in this study for capturing the LLJs in winter using
 232 the same criterion. Appendix after the text shows the results of the comparison between ERA5 and WRF simulation.

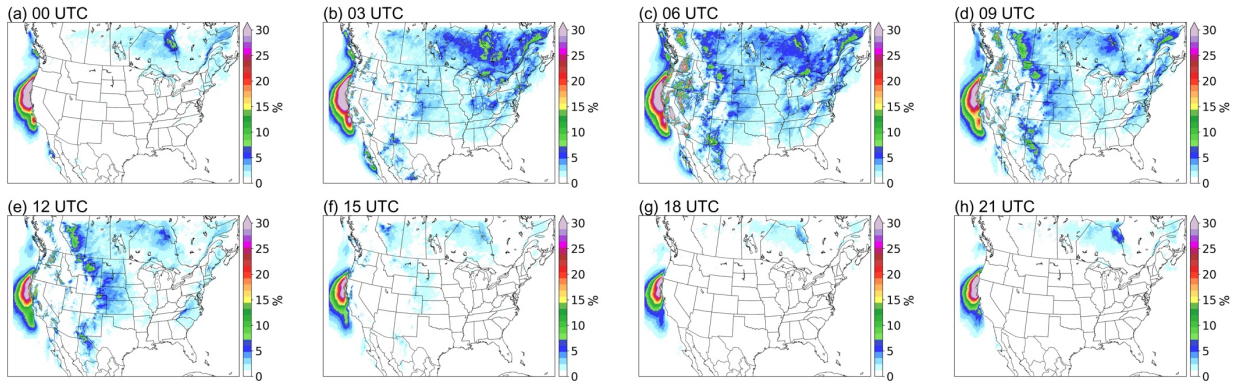

233 **3.3 Diurnal variations of LLJs**

234 To show the diurnal features of the LLJs, we selected summer and winter as the representative seasons because S-
 235 LLJs and N-LLJs occur most frequently in these seasons, respectively. Below, the descriptions are divided into N-
 236 LLJs and S-LLJs.

237 **3.3.1 Northerly LLJs**

238 The California coastal N-LLJ is the most highlighted low-level jet system in this region in summer. As seen in Figure
 239 5, it occurs throughout the day over the eastern Pacific Ocean from Oregon to the California coast. Figure 5 also shows
 240 that the California Coastal N-LLJ has diurnal characteristics: from 21 UTC (1 pm LST in California), the low-level

241 jet begins to develop, with a N-LLJ frequency of >30%, expanding until it reaches its maximum at 03 UTC – 06 UTC.
242 Then the high-frequency coverage of the California coastal LLJ gradually shrinks, reaching the minimum at 18 UTC
243 and only existing off the northwest coast of California.

244

245 **Figure 5. Diurnal frequency of N-LLJs in the summer (JJA).**

246 In winter (Figure 6), three types of N-LLJs over the Hudson Bay Lowlands, the eastern slopes of the Quebec Labrador
247 Plateau, and the Appalachians display similar diurnal fluctuations. All three N-LLJs reach their highest frequency at
248 03 UTC (10 pm EST) and their lowest at 18 UTC (1 pm EST). The only difference among the three types is that the
249 smallest frequency of the Quebec N-LLJ still endures at a level of greater than 15%, while the other two N-LLJs
250 mostly have frequencies of about 5%. The smallest frequency (~5%) of N-LLJs occurs downstream of the Rocky
251 Mountains (over Alberta, Montana, and Kansas) at 21 UTC. In the subsequent development stage, the changes in the
252 sporadic hot spots distributed near the eastern boundary of the Rocky Mountains are more significant. As seen in
253 Figure 6, frequency starts growing from 00 UTC and then peaks at 12 UTC, especially the wind maxima located in
254 Colorado, Wyoming, and Kansas, where the highest frequency can be >25%.

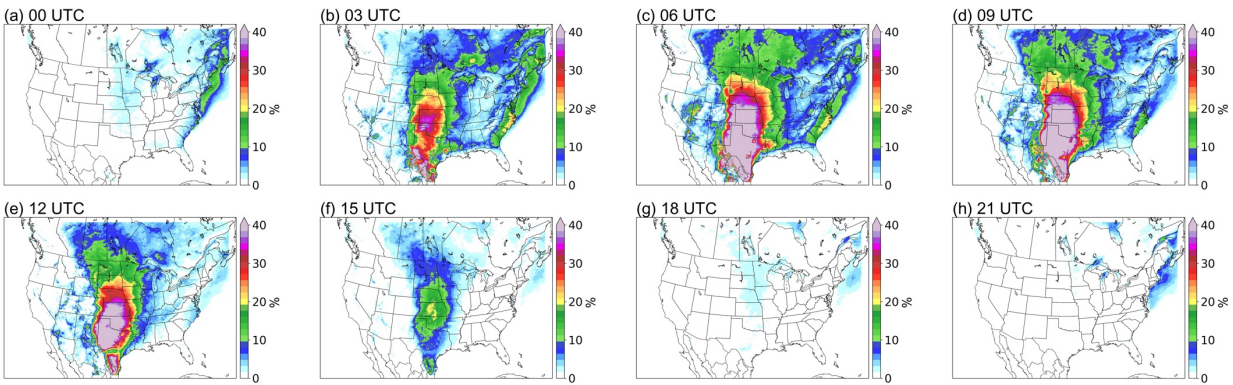

255

256 **Figure 6. Diurnal frequency of N-LLJs in winter (DJF).**

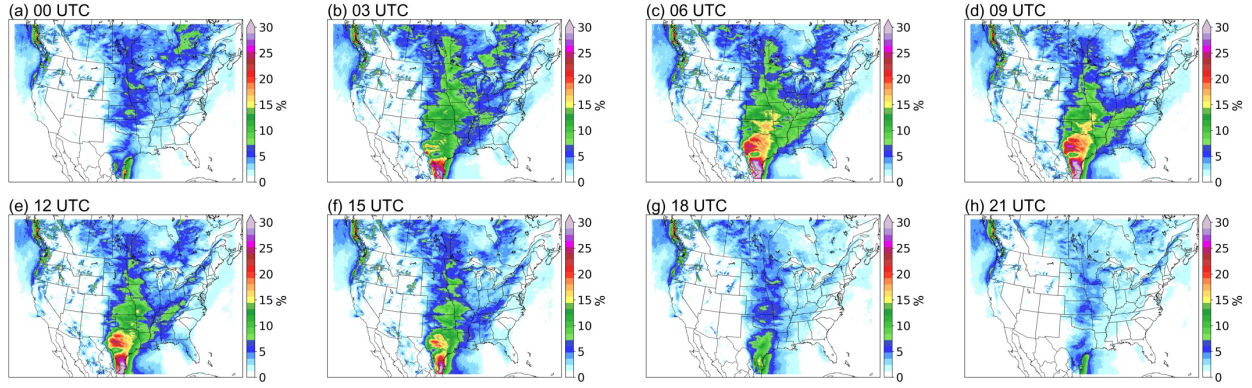

257 **3.3.2 Southerly LLJs**

258 In summer, the Great Plains S-LLJ occurs more frequently than in other seasons, and its diurnal variability is also the
259 strongest in this season (see Figure 7). At noon local time and in the afternoon (18 UTC – 00 UTC, 12-18 CST), almost
260 no S-LLJs occur over the central US (frequency <5% or about 0%). In contrast, the Great Plains LLJ begins to develop
261 at 03 UTC, when a frequency of over 25% extends from Mexico to Kansas. It reaches maximum strength at midnight
262 (06 UTC – 09 UTC, 00 – 03 CST), when the frequency reaches over 30% and the high-frequency coverage enlarges
263 to the Dakotas, the border of the eastern Rocky Mountains, and western Minnesota, Missouri, and Louisiana. Summer
264 S-LLJs are also active in southern Canada at night and in the early morning. In Saskatchewan, Manitoba, and central
265 Ontario (03 UTC – 12 UTC, as shown in Figure 7), S-LLJs are found with frequency >15%. In the eastern US and
266 Atlantic, S-LLJs occur most frequently at midnight (03 UTC – 06 UTC).

267
268 **Figure 7. Diurnal frequency of S-LLJs in summer (JJA).**

269 For the cold season (Figure 8), even though the Great Plains LLJ is the most inactive based on the description in
270 section 3.2, it still has a clear diurnal variation. Compared with the results in summer, the diurnal cycle of Great Plains
271 LLJ in winter is not that pronounced: It mainly occurs over the western Gulf of Mexico and southern Texas, with the
272 frequency in the afternoon (18 UTC – 21 UTC) declining to 5-10%. The S-LLJ develops from 03 UTC, gradually
273 generating two high-frequency (20%-25%) centers in mid- and southeastern Texas at 06 UTC – 12 UTC. As for the
274 S-LLJ near Vancouver Island, it is hard to see the diurnal variability: There is only a slight magnitude growth of
275 frequency from the afternoon (00 UTC) to the evening (06 UTC), and the coverage is almost the same.

276

277 **Figure 8. Diurnal frequency of S-LLJs in winter (DJF).**

278

279 **4 Formation and evolution mechanisms of various LLJs**

280 Section 3's results illustrate the occurrence frequency of LLJs over North America, particularly their seasonal and
 281 diurnal features. To explain the mechanisms, the inertial oscillation theory from Blackadar (1957) is used. Using this
 282 theory, we start from the horizontal momentum equations and divide the actual horizontal wind u/v into two
 283 components—geostrophic wind u_g/v_g and ageostrophic wind u_a/v_a :

284
$$\frac{d(u_g + u_a)}{dt} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + f(v_g + v_a) \quad (1.1)$$

285
$$\frac{d(v_g + v_a)}{dt} = -\frac{1}{\rho} \frac{\partial P}{\partial y} - f(u_g + u_a) \quad (1.2)$$

286

287 In which ρ is air density, P is pressure, and f is the Coriolis parameter. Assuming the horizontal pressure gradient is
 288 fixed, the geostrophic wind is a constant as well, which means $\frac{du_g}{dt} = \frac{dv_g}{dt} = 0$:

289
$$\frac{du_a}{dt} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + f(v_g + v_a) \quad (2.2)$$

290
$$\frac{dv_a}{dt} = -\frac{1}{\rho} \frac{\partial P}{\partial y} - f(u_g + u_a) \quad (2.2)$$

291

292 When the definition of geostrophic wind $u_g = -\frac{1}{\rho f} \frac{\partial P}{\partial y}$ and $v_g = \frac{1}{\rho f} \frac{\partial P}{\partial x}$ is combined, the equation (2) is:

293
$$\frac{du_a}{dt} = f v_a \quad (3.1)$$

294
$$\frac{dv_a}{dt} = -f u_a \quad (3.2)$$

295

296 If $\frac{d}{dt}$ is taken to both sides of the equations (3), then we get $\frac{d^2 u_a}{dt^2} = -f^2 u_a$, and $\frac{d^2 v_a}{dt^2} = -f^2 v_a$, thereby:

297
$$u_a = c_1 \cos(ft) + c_2 \sin(ft) \quad (4.1)$$

298
$$v_a = c_2 \cos(ft) - c_1 \sin(ft) \quad (4.2)$$

299

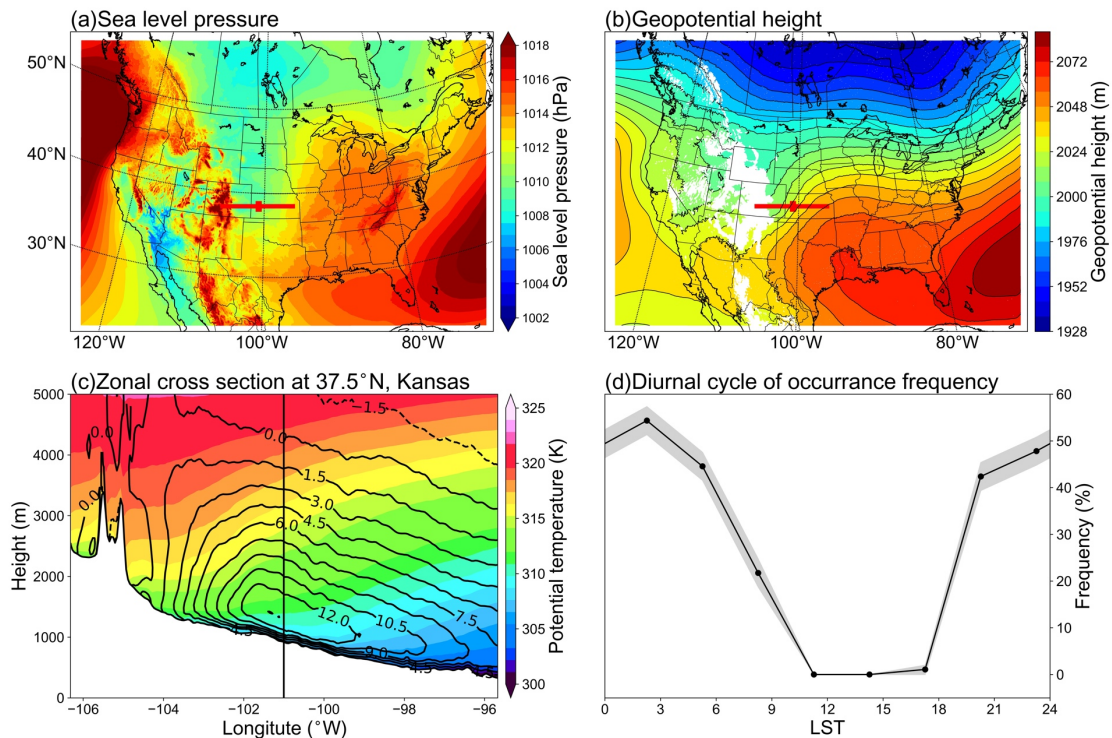

300 Therefore, according to the equations (4), the ageostrophic wind should theoretically have a circle-pattern variation
301 and the vector must rotate clockwise with a period of $2\pi/f$ (Blackadar, 1957; Van de Wiel et al., 2010). Under the
302 condition of a constant geostrophic wind—when the ageostrophic vector rotates from the opposite to the same
303 direction of geostrophic wind—the wind transitions from subgeostrophic to supergeostrophic. This change occurs
304 because of decoupling with surface friction effects, then the wind gets unbalanced.

305 Other theories also help explain the formation of LLJs, such as the sloping-terrain thermodynamic mechanism (Holton,
306 1967) and background synoptic system forcing (Uccellini et al., 1987). To understand the characteristics of the LLJs
307 in this study, three typical cases are analyzed: Great Plains S-LLJ, Quebec N-LLJ, and California coastal N-LLJ. The
308 locations for extracting data are shown in Figure 1 (solid lines and stars a, b, c).

309 **4.1 Great Plains S-LLJ**

310 As Section 3's results show (see Fig. 7), the Great Plains S-LLJ typically occurs in summer and more frequently at
311 night. To investigate its associated meteorological condition, this study extracts all the Great Plains S-LLJ cases occurs
312 at the jet core in JJA. The jet core is defined by where the mean meridional wind is the strongest on the cross-section,
313 and it locates at star A (shown in figure 1). The mean sea-level pressure and 800 hPa geopotential height are shown
314 in Figure 9a and 9b, respectively. The background large-scale circulations indicate that, at all the time points when
315 the Great Plains S-LLJ occurs, the range of the subtropical anticyclone extends east of the Great Plains at both ground
316 and low-level atmosphere. A high-pressure ridge is located near the gulf coast of Mexico and Texas (Figure 9b). Thus,
317 clearly, the zonal pressure/geopotential gradient in the central US guides the dominant southerly winds around this
318 region. The cross-section in Figure 9c illustrates a strong baroclinicity and shows that the isentropic line incline moves
319 from east to west, as is typical for the sloping-terrain heating effect (Holton, 1967). This effect generates an upslope
320 wind on the east side of the slope, and the airstream gradually turns northward due to the Coriolis force, creating the
321 southerly LLJs. On the other hand, as can be seen in the frequency cycle in Figure 9d, at noon local time (at the

322 selected point-a in Figure 1), the frequency of the Great Plains LLJ is very low (close to 0%), rising to more than 40%
 323 after 18 LST even if the radiation is not at the day's peak.

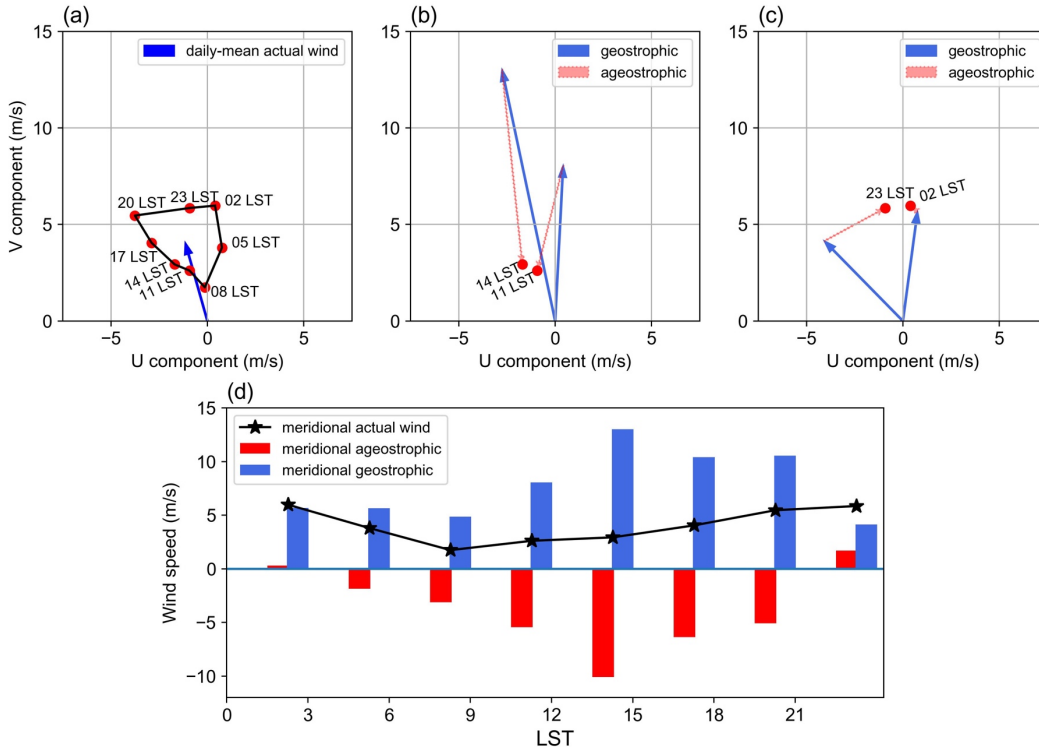

324
 325 **Figure 9. Background circulations of the Great Plains S-LLJ in JJA: (a) sea-level pressure, (b) geopotential height of 800**
 326 **hPa, (c) cross section including meridional winds (lines) and potential temperature (shading), and (d) diurnal cycle of**
 327 **frequency, with the shaded 95% confidence intervals. The red lines and points in (a) and (b) show the position of cross-**
 328 **section and chosen jet core, the vertical line in (c) shows the zonal location of the chosen jet core.**

329 To explain the nighttime enhancement of S-LLJ, we analyzed the wind vectors using inertial oscillation theory. To
 330 show more significant diurnal variation, all the time points, including the LLJs that did not occur, were considered.
 331 Figure 10a is the hodograph of jet-core winds at point-a near the Great Plains, and their temporal mean is computed
 332 at 3-hourly intervals in summer. It is noted here that the “jet-core” means the position where LLJ occurs horizontally
 333 the most frequently on the cross-section. Compared with the mean actual wind (blue arrow), the deviation at each
 334 local time shows a clear clockwise rotation. The wind speed begins increasing after 17 LST. Nevertheless, the analysis
 335 for Figure 9 indicates the sloping heating effect, meaning that the geostrophic wind is not fixed.

336 Thus, to obtain the ageostrophic winds, we computed the geostrophic components by pressure gradient and subtracted
 337 them from the actual airflow. According to the aforementioned definition of geostrophic wind, u_g and v_g are

338 calculated by the horizontal pressure gradient $\frac{\partial P}{\partial y}$ and $\frac{\partial P}{\partial x}$, respectively. By choosing four grids surrounding point-a, we
339 first interpolated the pressure value to the same level as the LLJ core height. Then, we adopted the central difference
340 equation $\frac{\Delta P}{\Delta x} = \frac{P_{i+1} - P_{i-1}}{x_{i+1} - x_{i-1}}$ or $\frac{\Delta P}{\Delta y} = \frac{P_{i+1} - P_{i-1}}{y_{i+1} - y_{i-1}}$ to obtain the pressure gradients at point-a, where i is the index of the grid
341 point at point-a.

342 Figures 10b and 10c display geostrophic wind vectors (blue arrows) and ageostrophic vectors (pink) at noon and
343 midnight. The southerly geostrophic flows are much stronger in the afternoon (10b) than at midnight. The ageostrophic
344 winds flow mostly in the opposite direction, limiting the actual wind speed. At night (10c), the geostrophic wind
345 direction rotates clockwise from that of the afternoon as the pressure gradient changes. Considering the relative
346 positions of blue and pink vectors at 23 LST and 01 LST, ageostrophic flow has rotated roughly 150 degrees to
347 enhance the geostrophic winds, thereby creating a super-geostrophic state. Although the inertial oscillation theory can
348 help explain some aspects of wind behavior, the real situation is more complex than initially thought. Figures 10b and
349 10c indicate that by 02 LST, the wind is almost entirely geostrophic with only negligible ageostrophic perturbations.
350 This suggests that the diurnal changes in the geostrophic wind and pressure gradient may provide a complicating
351 background that prevents the inertial oscillation theory from fully prevailing. While the inertial oscillation theory can
352 provide valuable insights, it should not be relied upon as the sole explanation for LLJs at the Great Plains. Instead, a
353 more comprehensive understanding of atmospheric dynamics is necessary to fully comprehend the behavior of the
354 wind, particularly when dealing with diurnally changing conditions. Figure 10d compares different meridional wind
355 components' amplitudes. The geostrophic wind contributes significantly to the southerly wind during the day, peaking
356 at 14 LST (blue bars). The northerly ageostrophic wind (red bars) is highest during the day, indicating the strongest
357 negative impact from friction. The meridional ageostrophic component decreases and eventually reverses at 23 LST,
358 showing a process from sub- to super-geostrophic status. In summary, the thermodynamic circulation near the slopes
359 of the Great Plains contributes to the strong southerly airflow, while the inertial oscillation plays a critical role in
360 forming the nocturnal southerly LLJ.

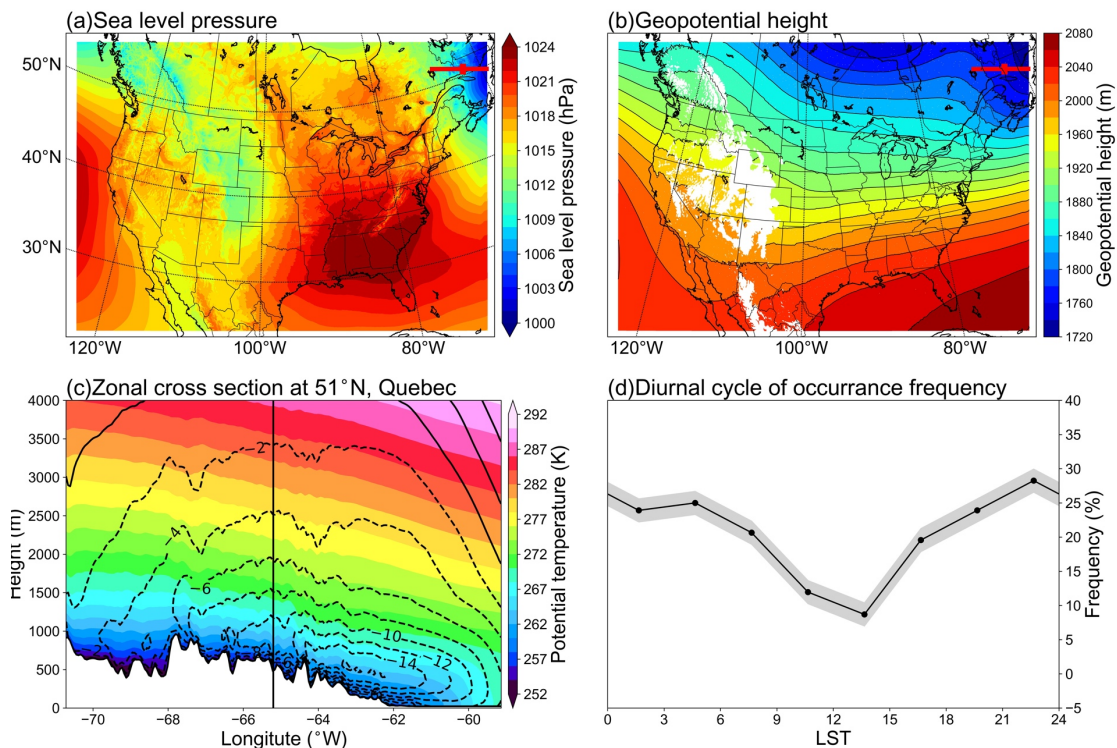

361
 362 **Figure 10. (a) Hodograph of jet-core winds for the Great Plains S-LLJ every 3 hours over the whole JJA (red dots – solid**
 363 **line) and the daily averaged actual wind velocity (blue vector); vectors of mean jet-core geostrophic winds (solid blue) and**
 364 **ageostrophic winds (dashed red) at (b) 11/14 LST and (c) 23/02 LST; (d) diurnal cycles of meridional components of actual**
 365 **(black line), geostrophic (blue bars), and ageostrophic winds (red bars).**

366
 367 **4.2 Quebec N-LLJ**

368 Similarly, for the Quebec N-LLJ that is typically observed in winter, we selected all the LLJ cases at point-b (see the
 369 position in Figure 1) in DJF to generate the background circulation pattern. The background large-scale circulations
 370 indicate that the northeastern coast of Canada lies to the west of a strong surface low-pressure system (Figure 11a),
 371 while in the lower troposphere, a ridge on the east side of Hudson Bay occupies the Labrador Plateau (Figure 11b).
 372 This combination brings the northerly momentum to the downstream eastern coast. In fact, the background circulation
 373 is consistent with the shallow baroclinic structure of Quebec N-LLJ in winter, that is, the thermal difference between
 374 relatively warm sea and cold land. The cross-section in Figure 11c shows the thermodynamic structure of this N-LLJ:
 375 A well-defined low-level jet core is located above land and close to the coastline (approximately 63°W). With a
 376 maximum wind speed of more than 16 m s⁻¹ and a height of about 400 m, the jet core is located above the mixed layer

377 under the warm air covering and on the land side. Notably, the steep isentropic lines slope towards the ocean and
 378 finally sink at the position of 60°W. The onshore isentropic lines are flat and dense above the LLJ core, which means
 379 the environment is quite stable. This is helpful to maintain the structure of the LLJ, when vertical motion is inhibited,
 380 and horizontal wind is enhanced. Compared with the sloped isentropic lines in the Great Plain S-LLJ case (Figure 9c),
 381 the stability over Great Plain is not as high as in this case, so this difference in stability helps explain the variation in
 382 wind speeds between these two cases.

383 In addition, the diurnal cycle of frequency (Figure 11d) shows that the diurnal signal and peak frequency of Quebec
 384 N-LLJ are much weaker than the Great Plains S-LLJ, becoming weakest at noon and peaking at midnight, which is
 385 consistent with the results reported in Section 3. This diurnal variation can be explained by the baroclinicity near this
 386 region: At night in winter, the land temperature drops faster than the ocean temperature due to radiative cooling,
 387 enhancing the land-sea contrast and thereby the thermal wind above. The gentle slope on the east of the Labrador
 388 Plateau could generate the slope heating effect in the daytime. In this way, the related temperature gradient from east
 389 to west offsets the land-sea thermal difference.

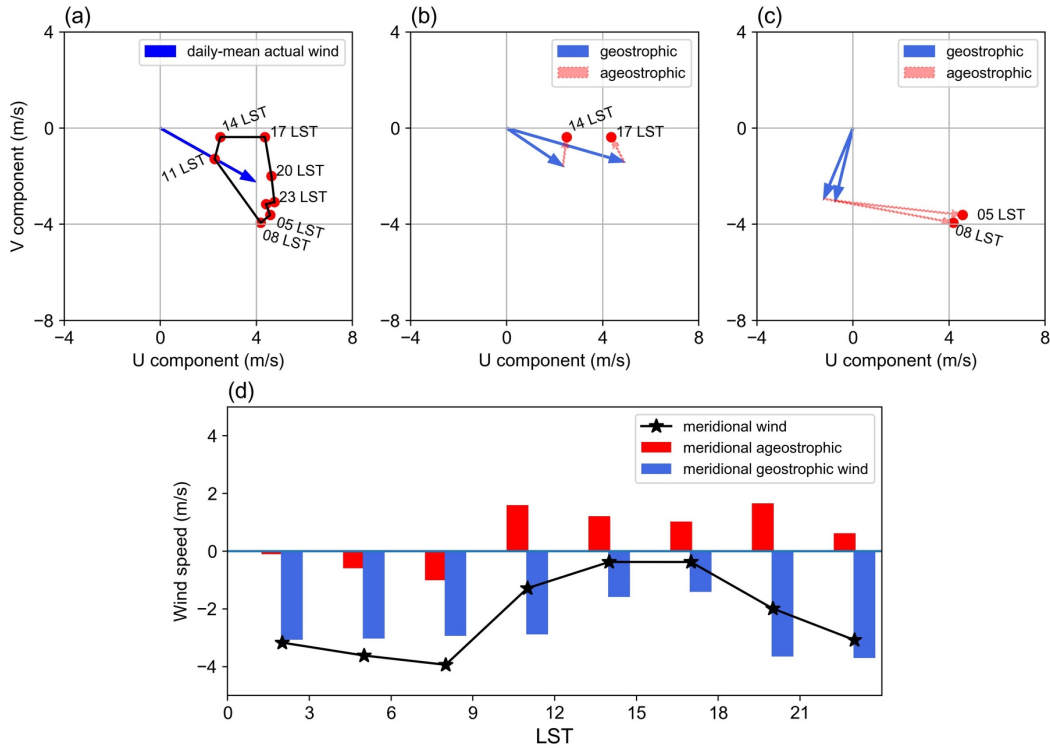

390
 391 **Figure 11. Background circulations of the Quebec N-LLJ in DJF: (a) sea-level pressure, (b) geopotential height of 800 hPa,**
 392 **(c) cross section including meridional winds (lines) and potential temperature (shading), and (d) diurnal cycle of frequency**

393 **with the shaded 95% confidence intervals. The red lines and points in (a) and (b) show the position of cross-section and**
394 **chosen jet core, the vertical line in (c) shows the zonal location of the chose jet core.**

395 As for the impact of inertial oscillation on the Quebec N-LLJ, the hodograph of averaged 3-hourly winds extracted at
396 point-b (Figure 12a) also illustrates a clear clockwise rotation of wind deviations compared with the daily mean (blue
397 arrow). Figure 12b and 12c show that the geostrophic and ageostrophic wind vectors contribute to the diurnal cycle in
398 the afternoon and morning, respectively. Even though the direction of geostrophic wind changes significantly, the
399 relative angles between ageostrophic and geostrophic arrows indicate that the ageostrophic flow rotates clockwise.
400 The geostrophic wind is weakened by ageostrophic wind in the afternoon (Figure 12b), whereas the supergeostrophic
401 state is generated in the morning (Figure 12c).

402 Focusing only on the meridional amplitudes validates this characteristic. In Figure 12d, the blue line that represents
403 the mean actual meridional wind has the same diurnal trend as the frequency variation in Figure 11d. The northerly
404 wind is weakest in the afternoon, peaking at night and in the early morning. Similarly, the variation of meridional
405 geostrophic flow has a consistent phase with the actual meridional wind, which is explained by the baroclinic structure
406 near the Quebec coast mentioned above. The meridional ageostrophic wind in this region also promotes the formation
407 of N-LLJ. The ageostrophic wind drags the geostrophic component in the afternoon, before reversing to a consistent
408 direction with the northerly geostrophic flow at night and in the morning. This trend is also the result of decreasing
409 friction after sunset. Therefore, the evolution of Quebec N-LLJ derives from both inertial oscillation and land-sea
410 thermal contrast in winter.

411

412 **Figure 12. (a) Hodograph of jet-core winds for the Quebec N-LLJ every 3 hours over the whole DJF (red dots – solid line)**

 415 **(black line), geostrophic (blue bars), and ageostrophic winds (red bars).**

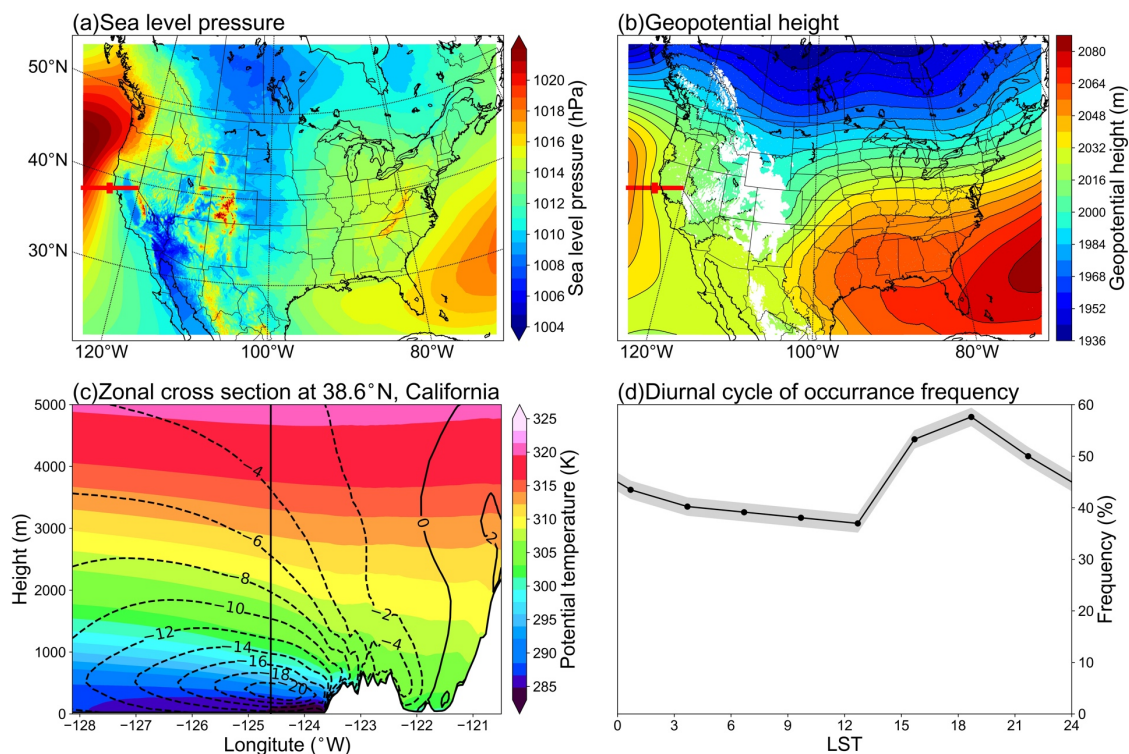

416

417 4.3 California coastal N-LLJ

418 The California coastal N-LLJ is similar to the one in Quebec, but it occurs more often in summer afternoons or
 419 evenings over the ocean. Figure 13a shows that a relatively strong high-pressure system is located on the east coast of
 420 the Pacific Ocean, trending NE-SW, although half of the structure is beyond the boundary of the domain. On the 800
 421 hPa isobaric surface in Figure 13b, there is also an anticyclone system in the same location, whose eastern contour is
 422 roughly parallel to the coastline, guiding the airflow to the south. Therefore, this pair is also forced by the thermal
 423 difference between land and sea, but contrary to the LLJ in Quebec, in summer, when the California LLJ occurs
 424 frequently, it has the characteristics of the cool sea-hot land. Figure 13b also shows that the isobars near Cape
 425 Mendocino are relatively strong, making the ridge of high pressure extend northeastward of the Cape. This extension
 426 is generally believed to occur due to pressure perturbation caused when northerly winds converge at this position after

427 being obstructed (Rahn and Parish, 2007). Regarding the cross-section structure shown in Figure 13c, the jet core is
 428 located at steep isentropic lines above the ocean at a height of 500 m. On the coast of California, the LLJ is close to
 429 the mountains. The maximum central wind speed of California coastal LLJ exceeds 20 m s⁻¹, whereas Quebec N-
 430 LLJ's max core wind is only about 14 m s⁻¹. Based on baroclinicity, the isentropic lines slope towards the continent
 431 and finally sink near the coastline.

432 The core wind speed in California's coastal LLJ is higher than that of Quebec's LLJ because the land-sea contrast is
 433 more significant in summer than in winter and the formed sea breeze front generates flow convergence under the
 434 blockage caused by the west coast mountains. On the other hand, the atmosphere over the sea is more stable because
 435 the isentropic lines are flatter and denser than Quebec's case, which also favors the development of LLJ. In contrast,
 436 the east coast of Quebec is relatively gentle, which may account for its lower wind speed. California's LLJ occurs
 437 frequently at each time step, and its diurnal signal is weaker compared, for example, to the signal in the Great Plain
 438 S-LLJ. As well, the California signal stays at frequency of over 35%. California's LLJ occurs most frequently at
 439 around 18 LST and starts to decline after sunset, which is generally consistent with the coastal baroclinicity.

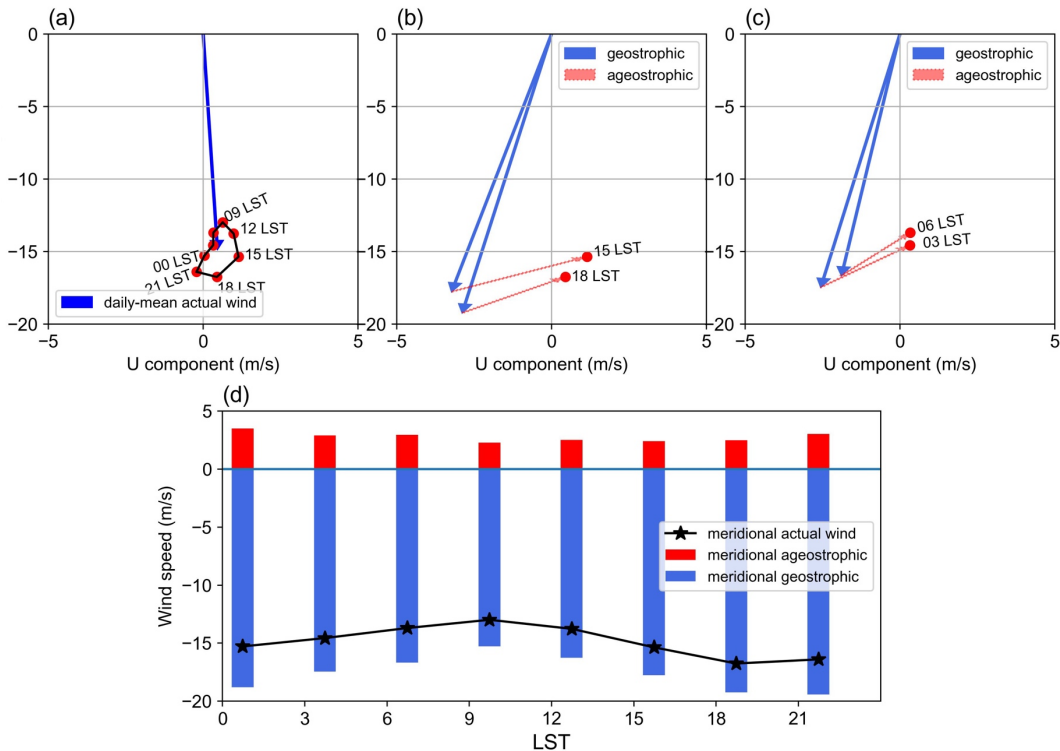

440
 441 **Figure 13. Background circulations of the California coastal N-LLJ in JJA: (a) sea-level pressure, (b) geopotential height**
 442 **of 800 hPa, (c) cross section including meridional winds (lines) and potential temperature (shading), and (d) diurnal cycle**

443 of frequency with the shaded 95% confidence intervals. The red lines and points in (a) and (b) show the position of cross-
 444 section and chosen jet core, the vertical line in (c) shows the zonal location of the chosen jet core.

445

446 The wind deviations for California's N-LLJ shown in the hodograph (Figure 14a) still have a clockwise rotation in 24
 447 hours. However, compared with the magnitude of the daily mean jet-core wind, this diurnal cycle is not quite as
 448 obvious as the cycle for Quebec and Great Plain LLJs, but it is similar to the frequency cycle shown in Figure 13d. In
 449 comparison between geostrophic and ageostrophic winds (Figure. 14b and 14c), during the afternoon (15 and 18 LST),
 450 the amplitude of geostrophic wind is the largest, and the ageostrophic flow diminishes the geostrophic wind. However,
 451 in the morning 12 hours later, the relative angle between ageostrophic and geostrophic vectors does not change,
 452 meaning that the ageostrophic wind is still weakening the geostrophic wind and that there is no rotation of the
 453 ageostrophic wind, as Blackadar inertial oscillation theory describes. Figure 14d helps to explain the change in
 454 meridional winds. Looking at the magnitudes of ageostrophic winds, one can see that all are weak and southerly and
 455 that they do not exhibit a significant diurnal signal. Furthermore, the change of geostrophic wind is highly consistent
 456 with the trend of the actual meridional wind. Thus, the N-LLJ in California can be considered mostly as geostrophic
 457 and the diurnal variation as being related to the change in geostrophic winds.

458

459 **Figure 14. (a) Hodograph of jet-core winds for the California coastal N-LLJ every 3 hours over the whole JJA (red dots –**
460 **solid line) and the daily averaged actual wind velocity (blue vector); vectors of mean jet-core geostrophic winds (solid blue)**
461 **and ageostrophic winds (dashed red) at (b) 15/18 LST and (c) 03/06 LST; (d) diurnal cycles of meridional components of**
462 **actual (black line), geostrophic (blue bars), and ageostrophic winds (red bars).**

463

464 **5 Discussion and conclusion**

465 This study applied a convection-permitting WRF model to conduct the analysis of LLJs in North America. The
466 previous research for LLJs mainly focused on observation data, which have no fine coverage in temporal or spatial
467 resolution. The studies using in-situ observations may ignore some important features. Despite their better coverage,
468 reanalysis datasets usually have a coarse spatial resolution, and can introduce large inaccuracies in the identification
469 of LLJs. In addition, the application of general numerical modeling cannot avoid the uncertainty caused by
470 parameterizing small-scale physical processes. In contrast, high-resolution convection-permitting climate simulations
471 can provide relatively more comprehensive descriptions of LLJs, especially for areas with complex geographic
472 conditions or regions that lack soundings. Previous studies using high-resolution models conducted case analyses only
473 of LLJs in a specific region (Aird et al., 2022). By expanding the target domain to the whole of North America and
474 revealing the climatological characteristics of LLJs in different regions and scales, this paper provides an accurate
475 reference for future research on LLJ-related processes in North America.

476 The convection-permitting WRF model is able to recapture some LLJs that have been previously studied, such as the
477 Great Plain S-LLJ and the California coastal N-LLJ in the eastern Pacific Ocean and has obtained relatively consistent
478 results. The results indicate that the S-LLJ in the central US Plain is the most frequent and active in warm seasons and
479 that three critical high-frequency centers occur in summer: the northeast Mexico-Texas border, west-central Texas,
480 and western Oklahoma to southern Kansas. This last result is consistent with the climatology generated by Doubler et
481 al. (2015) using the NARR reanalysis data, but the patterns here are more representative of the topographic features
482 in central and southern Texas. In addition, compared with the 40-year rawinsonde climatology in the central US by
483 Walters et al. (2008), our study reveals that the S-LLJ frequency range of these three centers in the central US in
484 summer is 25%-30%, which is slightly lower than the 35% reported in the 2008 study. However, given the
485 underestimated frequencies of 15%-20% in NARR climatology, there is an advantage of using high-resolution
486 simulations in the vertical direction. Even though the simulation period does not match the time range of the literature
487 exactly, the characteristics transcend specific time frames still offer a reference.

488 The convection-permitting simulation can also capture LLJs that were poorly detected previously using coarser
489 resolution models and observational datasets. The winter N-LLJs over the eastern Rocky Mountains described in this
490 paper are generally distributed over the central US from the Dakotas to Oklahoma with a low frequency (>10%) and
491 over several sporadic small areas with a high frequency (>20%) along the boundary of the Rockies. The main
492 seasonal/diurnal variations identified in this study agree with those seen using rawinsonde data (Walters et al., 2008)
493 and NARR reanalysis (Douber et al., 2015). But the frequency of the LLJ occurrence over Nebraska-Kansas was
494 underestimated in both convection-permitting simulations (~10%) and NARR (~7%), while high-frequency hot spots
495 from Alberta to Colorado were not detected in either of the above-mentioned studies, probably because measurements
496 are lacking in these regions. The high-resolution simulation also detected LLJs on which researchers have hardly
497 focused: N-LLJs near the eastern Quebec coast and in the Appalachians Mountains, as well as an S-LLJ over the
498 British Columbia coast. In the work of Douber et al. (2015), these LLJs were shown in the climatology patterns, but
499 the 4-km WRF simulation offered more detailed descriptions of their locations. For example, this study found that the
500 Appalachian N-LLJ extends from Georgia to the northwestern Atlantic, especially on summer nights (03 UTC – 06
501 UTC), while NARR only captured LLJ occurrences over the middle coast of the Atlantic. The maximum frequency
502 (7-10%) detected in the NARR study is also less than what is illustrated here. As for the Quebec N-LLJ, the 4-km
503 WRF revealed that it mostly occurs onshore near the coast with a frequency of over 25% in winter, but NARR only
504 provided a coarse occurrence distribution over northeastern Canada.

505 Based on the inertial oscillation theory (Blackadar, 1957) and the baroclinic theory near complex terrain (Holton,
506 1967), this paper also analyzed the background and formation mechanisms of three LLJs: the Great Plain S-LLJ,
507 Quebec N-LLJ, and California coastal N-LLJ. Generally, all these LLJs are impacted by the thermodynamic
508 circulations generated near their topography. The Great Plain S-LLJ is affected by slope heating, and the LLJs over
509 Quebec and California are associated with the sea-land contrast. When the geostrophic and ageostrophic components
510 of the LLJs are compared, results show that the inertial oscillation better explains the night enhancement of the Great
511 Plains S-LLJ and that the diurnal feature of the Quebec N-LLJ is influenced by the combination of the Holton and
512 Blackadar theories. As for the California coastal N-LLJ, no supergeostrophic state is found, making coastal
513 baroclinicity variation a dominant factor for this LLJ's evolution the geostrophic wind changes.

514 This research adds to the existing knowledge of characteristics of the low-level wind maxima in North America, thus
515 helping researchers obtain more reliable references about LLJs in this domain. Meanwhile, with the high-resolution
516 features, it can provide more robust explanations for other interdisciplinary fields. The research also advances
517 knowledge about the formation of three dominant LLJs. Although the 13-year simulation is likely too short to provide
518 an ideal long-term climatic analysis, it is a less expensive option for finer numerical modelling in large domains.
519 Additionally, we acknowledge certain limitations in the convection-permitting WRF simulation. While the vertical
520 resolution in the boundary layer of this simulation is enhanced compared to other RCMs or reanalysis datasets, it
521 remains inferior to the observation density of radiosonde soundings. Consequently, the underestimation of LLJ events
522 in this paper is expected, as noted in previous comparative analyses. Furthermore, numerical models inherently possess
523 biases and uncertainties. Although employing the convection-permitting scale mitigates some uncertainties, it is
524 important to recognize the limitations of these results. Additionally, the version of the input dataset used in this
525 research is obsolete. However, with future advancements in technology, it is expected that longer and more accurate
526 high-resolution simulations, as well as newer input data like ERA5, will become available. Future work will address
527 the features and formation mechanisms of the small-scale low-level wind maxima, which have yet to be investigated.

546 **Appendix**

547 **Winter LLJs captured by ERA5 Dataset**

548 The convection-permitting WRF simulation exhibited excellent performance in investigating well-known LLJ systems,
549 such as the California coastal N-LLJ and the Great Plains S-LLJ. Moreover, this appendix validates WRF-simulated
550 significant winter jet systems over North America using the ERA5 reanalysis dataset. ERA5 is a global atmospheric
551 reanalysis dataset produced by the European Centre for Medium-Range Weather Forecasts (ECMWF). It provides
552 hourly data on a horizontal grid space of approximately 31 km, and the time range covers from 1979 till the present.
553 ERA5 data is widely used in climate research, weather forecasting, and various applications that require high-quality
554 atmospheric data.

555 The validation period is the same as the WRF simulation (2000-2013). From the Figure A1 below, it is evident that
556 during winter, a greater number of significant N-LLJ systems in the North American continent are mostly concentrated
557 in eastern Canada. In most parts of Newfoundland and southeastern Quebec, the occurrence frequency of N-LLJs
558 exceeds 15%, and the maximum can even surpass 25%. However, in the WRF simulation (Figure 3d), the model can
559 only capture N-LLJs on the north bank of the St. Lawrence River due to the northern boundary of the study domain
560 overlapping with the Quebec border. In comparison, the WRF-simulated frequency of N-LLJs in southeastern Quebec
561 essentially exceeds 25%, overestimated by about 5% compared to the ERA5 reanalysis. Additionally, it is worth noting
562 that the N-LLJs along the downstream of Rockies are also identified in the ERA5 dataset. The areas where the
563 frequency exceeds 5% are mainly distributed from Alberta to northern Texas, consistent with the findings in Section
564 3.2.1. Moreover, the high-value center (>10%) is located in central Kansas. In terms of the differences between the
565 two datasets, the results of the WRF simulation match more geographical features and reveal scattered high-value
566 spots (>15%) in some regions with special terrains (see Figure 3d). Furthermore, the winter Great Plains S-LLJs in
567 ERA5 reanalysis exhibit similar features, with frequencies ranging from around 15% to 20% in southern Texas. In
568 summary, the WRF model can accurately capture the features of winter LLJ systems, which are validated by the ERA5
569 reanalysis dataset over northern America. Even though the frequency of LLJs occurrence is overestimated, the
570 convection-permitting WRF simulation can provide detailed descriptions of LLJs near complex terrains.
