21 **Abstract:**

22 Nitrogen (N) fertilization has received worldwide attention due to its benefits to soil fertility and
23 productivity, but excess N application also causes an array of ecosystem dis-services, such as
24 greenhouse gas emissions. Soil microorganisms are considered to be involved in a variety of ecosystem
25 services and dis-services. However, the relationships between soil ecosystem services and microbial
26 traits under different N fertilizer application rates remain uncertain. To address this uncertainty, a
27 4-year in situ field experiment was conducted in a meadow soil on the Northeast China Plain. The
28 experiment was performed after straw return with the following treatments, which included regular
29 phosphorus (P) and potassium (K) fertilization: (i) regular N fertilizer (N+PK); (ii) 25% N fertilizer
30 reduction (0.75N+PK); (iii) 50% N fertilizer reduction (0.5N+PK); and (IV) no N fertilizer (PK).
31 Ecosystem services, dis-services and microbial traits responded distinctly to the different N fertilizer
32 rates. The 0.75N+PK treatment had overall positive effects on soil fertility, productivity, straw
33 decomposition, and microbial abundance and function and alleviated greenhouse gas emissions.
34 Specifically, no significant differences were observed in SOC, total N and P contents, straw C and N
35 release amounts, microbial biomass C and N contents, or cellulase and N-acetyl-D-glucosaminidase
36 activities relative to those of 0.5N+PK and PK. Greenhouse gas mineralization was reduced with
37 decreasing N input. Moreover, 0.75N+PK had the highest straw biomass and yield, which were
38 significantly higher than those in 0.5N+PK and PK. Furthermore, 0.75N+PK increased aboveground
39 biomass and soil C:N and increased the abundance of genes encoding cellulose-degrading enzymes,
40 which implies the potential for C and N turnover. Most of the observed changes in ecosystem services
41 and dis-services were strongly associated with specific microbial modules and keystone taxa. The
42 *Lasiosphaeriaceae*-driven module 1 community promoted straw degradation and C and N release,

43 while the *Terrimonas*-driven module 3 community enhanced production, which was conducive to soil
44 multifunctionality. Therefore, our results suggest that straw return with a 25% reduction in chemical N
45 fertilizer is optimal for providing ecosystem services. This study highlights the importance of abiotic
46 and biotic factors in soil health and supports green agricultural development by establishing the optimal
47 N fertilizer rates in meadow soil after straw return.

48 **Keywords:** Ecosystem services; Straw return; Nitrogen fertilization; Microbial community; Crop yield

49 1. Introduction

50 Multiple soil ecosystem services are indicators of soil health (Kihara et al., 2020; Lehmann et al.,
51 2021). Soil ecosystem services are related to the ability of soil to function as a vital living system to
52 sustainably increase crop productivity, improve environmental quality, mitigate climate change and
53 promote plant and animal health (de Bello et al., 2010; Tang et al., 2019). Intensive agriculture has
54 posed a wide range of threats to agroecosystem services (Robertson et al., 2014; Allen et al., 2015).
55 Chemical fertilizers, especially nitrogen (N), have been inappropriately applied around the world to
56 increase crop yields in response to population growth (Shi et al., 2019). N is considered an essential
57 macronutrient for all biota, but excessive N fertilizer input not only reduces soil fertility and
58 productivity but also imposes environmental burdens (Trost et al., 2016). Recent research has indicated
59 that an appropriate reduction in N fertilizer input can not only maintain crop yield by increasing N
60 fertilizer use efficiency but also promote soil health by regulating the soil C:N ratio (Chen et al., 2014).
61 However, an excessive reduction in N fertilizer input can lead to an “N-mining” effect, resulting in the
62 loss of soil organic matter, which reduces crop yields (Chen et al., 2014). Therefore, how to maintain
63 agroecosystem services by regulating N fertilizer application rates needs to be fully assessed.

64 Straw return is widely implemented to support soil ecosystem services (Xu et al., 2021). Plant

65 residues contain abundant N, which affects soil fertility and productivity (Pan et al., 2009; Liu et al.,
66 2014). Thus, the N released during straw degradation is an important source that could partially
67 substitute chemical N fertilizer (Wang et al., 2017; Latifmanesh et al., 2020). However, crop fields with
68 abundant organic matter usually have low reutilization efficiency (Hou et al., 2020). Generally, most of
69 the N in straw is released into the atmosphere as oxynitrides, such as nitrous oxide (N₂O) (Wang et al.,
70 2019; Sun et al., 2021). Studies have shown that straw return significantly elevates greenhouse gas
71 emissions and that less than 15% of straw-derived N is converted into soil organic matter (SOM) (Yin
72 et al., 2018; Wu et al., 2019). However, whether straw can partially replace chemical N fertilizer is still
73 unclear.

74 Soil microorganisms are the drivers of soil ecosystem services (Handa et al., 2014; Wagg et al.,
75 2014). Agronomic management strategies targeting “multifunctionality” have prompted research into
76 the impact of microbes on achieving the desired rates of multiple ecosystem processes (Gong et al.,
77 2020). Fertilization-induced changes in microbial communities and functions regulate a variety of
78 ecosystem functions, including SOM formation, greenhouse gas emissions, litter decomposition, and
79 crop production (Dominati et al., 2014). For example, Ning et al. (2020) found that long-term manure
80 application increased the abundance of specific fungi involved in yield improvement. Duan et al. (2021)
81 reported that adequate N input improved the cellulose degradation ability of bacteria. Empirical
82 evidence of the relationships among N fertilizer application, specific microbial communities or
83 functions and multiple ecosystem services is still lacking, and the diverse cropland services driven by
84 complex microbial traits under different N fertilizer rates are unclear.

85 Microorganisms contribute to ecosystem services by modulating microbial function, community
86 composition and succession, which are influenced by N fertilizer input levels (Bradford et al., 2014;

87 Chen et al., 2019a). Generally, bacteria and fungi are the main drivers of the decomposition of labile
88 and recalcitrant compounds, respectively, in straw (Frey et al., 2013; Ge et al., 2017; Hogberg et al.,
89 2007). In addition, microbial modules and keystone taxa have been used to explain ecosystem services.
90 Chen et al. (2019b) found that specific microbial modules participated in N and phosphorus (P)
91 turnover in a Cambisol. Actinobacteria have been extensively studied and can be considered the main
92 degraders of straw due to their secretion of cellulase (Bao et al., 2021). C, N and P stoichiometry has
93 profound impacts on microbial in vivo metabolism and ex vivo modification processes (Chen et al.,
94 2016). Nevertheless, the understanding of the microbial mechanisms that modulate ecosystem services
95 in response to N fertilizer input levels is still limited.

96 As an important grain-producing region, the Northeast China Plain contributes more than 20% of
97 the total grain yield in China (Li et al., 2017; Zhao et al., 2018). Here, a field experiment was
98 conducted to reveal the influences of N input levels on soil ecosystem multifunctionality and associated
99 microbial traits. In the present study, two hypotheses were tested: (i) soil ecosystem services and
100 dis-services would show distinct responses to N fertilizer input levels, and (ii) the changes in cropland
101 ecosystem services and dis-services would be linked to specific microbial traits. The purpose of this
102 study was to optimize the N fertilizer application rate to achieve soil ecosystem multifunctionality and
103 explore the potential microbial mechanism in a Mollisol.

104 **2. Materials and methods**

105 **2.1 Site description and sampling**

106 A field experiment with varying inorganic N fertilizer input levels was established in 2018 in
107 Wenchun town (44°59'61" N, 129°59'18" E), Mudanjiang city, Heilongjiang Province, Northeast China
108 Plain, which is an important grain-producing area. This region has a typical temperate continental

109 monsoon climate with an average annual temperature of 4.3 °C and a mean annual precipitation of
110 579.7 mm. The soil is classified as a meadow soil according to the US Soil Taxonomy (USST). The
111 cropping system was a continuous maize (*Zea mays* L.) monoculture. Four treatments were established
112 with different N fertilizer input levels after straw return to the field for 4 years as follows: (1) regular
113 chemical fertilization, N+PK (300 kg urea (N 46%) ha⁻¹ yr⁻¹, 250 kg diammonium phosphate (P₂O₅
114 48%) ha⁻¹ yr⁻¹, 150 kg potassium chloride (K₂O 50%) ha⁻¹ yr⁻¹); (2) 25% reduction of N fertilizer,
115 0.75N+PK (225 kg urea ha⁻¹ yr⁻¹, 250 kg diammonium phosphate ha⁻¹ yr⁻¹, 150 kg potassium chloride
116 ha⁻¹ yr⁻¹); (3) 50% reduction of N fertilizer, 0.50N+PK (150 kg urea ha⁻¹ yr⁻¹, 250 kg diammonium
117 phosphate ha⁻¹ yr⁻¹, 150 kg potassium chloride ha⁻¹ yr⁻¹); and (4) no N fertilizer, PK (250 kg
118 diammonium phosphate ha⁻¹ yr⁻¹, 150 kg potassium chloride ha⁻¹ yr⁻¹). All straw and chemical fertilizers
119 were applied with shallow tillage to 20 cm. Straw was cut into pieces less than 5 cm and returned to the
120 field after harvest in October, while the chemical fertilizers were applied during plowing in May of the
121 following year. All other normal management practices were consistent among the treatments during
122 the experiment. Before the experiment, the soil contained 18.74 g kg⁻¹ SOC, 1.03 g kg⁻¹ total N and
123 0.54 g kg⁻¹ total P with a pH of 7.37 (H₂O). The yield and selected soil chemical properties under
124 different treatments during the experiment are shown in Supplemental material Table S1.

125 Soils were sampled after the maize harvest in October 2021. A randomized complete block design
126 consisting of 4 treatments with 3 replications was adopted. Each field plot was 4.5 m × 15 m. We
127 collected nine soil cores (5 cm diameter) from the top 20 cm of bulk soil in each plot. Each soil sample
128 consisted of a mixture of subsamples randomly collected at nine different positions in the same plot. In
129 total, 12 soil samples were collected from the 4 treatments. Each treatment included 3 replicates. Soils
130 were sieved through a 2 mm mesh, the mineral particles and plant roots were carefully removed, and

131 then the soils were homogenized and stored in an incubator at 4 °C in a 40% moisture environment.
132 One part of the bulk soil sample was air-dried to measure soil properties, and the other part was used
133 for microbial molecular analysis.

134 **2.2 Field straw decomposition and carbon and nitrogen release experiments**

135 The ditch-buried straw decomposition experiment was conducted using nylon litter bags. Maize
136 straw was collected after the maize harvest in 2020 and air-dried. Ten grams of maize straw was cut to
137 2 cm in length and put into nylon litter bags, which were then heat sealed. The bags were 6 cm × 10 cm
138 in size and were made of 200 mesh nylon fabric, which permitted the free transfer of microorganisms
139 between the nylon bags and soil. On May 2nd, 2021, litter bags containing straw were buried at 10 cm
140 depth in a random design to prevent bags associated with a given decomposition stage from being
141 placed together. The litter bags were collected after harvest on October 1st, 2021.

142 The straw decomposition ratio was calculated based on dry weight loss as (dry initial mass - dry
143 final mass)/dry initial mass. The straw C concentration was measured by titrimetry after oxidation with
144 a mixture of H₂SO₄ and K₂Cr₂O₇. Total N, P and K were determined using the Kjeldahl, molybdenum
145 blue colorimetry, and flame photometry methods, respectively. All methods have been described by Lu
146 (2000). The properties of the initial maize straw and collected maize straw samples are shown in
147 Supplemental material Table S2. The amounts of total straw C and N released were calculated by the
148 following equation:

149 Amount of total straw C or N released = (initial C (or N) content × dry initial mass - final C (or N)
150 content × dry final mass) × aboveground biomass

151 **2.3 Measurement of soil properties and assessment of ecosystem services**

152 Soil pH was measured at a soil:water ratio of 1:2.5 (weight/weight). Air-dried soil and 25 mL of

153 deionized water were shaken together for 1 min and left to settle for 30 min, and the soil pH was
154 determined using an electrode. Soil organic carbon (SOC) was measured by titrimetry after oxidation
155 with a mixture of H₂SO₄ and K₂Cr₂O₇. Total N and P were determined using the Kjeldahl and
156 molybdenum blue colorimetric methods, respectively. All of these methods have been described by Lu
157 (2000).

158 Microbial biomass C (MBC) and microbial biomass N (MBN) were analyzed using the
159 fumigation-extraction method. Ten grams of fresh soil was fumigated with chloroform in the dark for
160 24 h, and then the fumigated and nonfumigated soils were extracted with 0.5 M K₂SO₄ and shaken at
161 200 rpm for 0.5 h. Soil extracts were filtered through a 0.45- μ m Millipore filter, and the C and N in the
162 extracts were determined using a Multi C/N 3100 analyzer (Analytik Jena AG). The C and N contents
163 in the nonfumigated soil extracts were subtracted from those in the fumigated soil extracts to determine
164 the C and N contents in the soil microbial biomass. Values of 0.45 and 0.54 were used to calibrate the
165 contents of MBC and MBN, respectively (Vance et al., 1987; Wu et al., 1990).

166 The activities of cellulase and N-acetyl- β -glucosaminidase were measured using
167 *p*-nitrophenyl- β -D-cellobioside and *p*-nitrophenyl-N-acetyl- β -D-glucosaminide as substrates,
168 respectively. Fresh soil (1.0 g) was mixed with 2.5 mL of 0.2 M acetate buffer (pH 5.0) and 2.5 mL of
169 0.02 M substrate and then shaken at 200 rpm and 37 °C for 1 h. The reaction was stopped by adding 1
170 mL of 0.5 M CaCl₂ and 4 mL of 0.1 M Tris buffer (pH 12.0). The mixture was vortexed and filtered,
171 and the concentration of *p*-nitrophenol (PNP) was measured by colorimetry at 400 nm. The same
172 procedure was followed for the controls, with the exception that the substrate was added after
173 incubation, and CaCl₂ and Tris buffer were added (Dick, 2011; Geisseler and Horwath, 2009).

174 To estimate the greenhouse gas emission potential, we conducted a 60-day incubation experiment.

175 Briefly, 20 g of fresh soil was placed in a 250-mL flask and then sealed with a gas-tight lid with a
176 rubber stopper in the middle. Gas samples (10 mL) were taken from the headspace of each flask at 1, 3,
177 7, 15, 30, and 60 days after sealing using a plastic syringe. Each gas sample was immediately injected
178 into a preevacuated 10-mL glass vial. The concentrations of methane (CH₄), N₂O and carbon dioxide
179 (CO₂) were determined using a gas chromatograph (Agilent 7890) with a flame ionization detector for
180 CO₂ and CH₄ and a ⁶³Ni electron capture detector for N₂O. The gas standards were provided by the
181 National Research Center for Certified Reference Materials, Beijing, China. The precision for
182 greenhouse gas concentrations was ±0.5% based on repeated measurements of gas standards (Qiu et al.,
183 2019). When the maize plants matured, all plants and grains were harvested from each plot, oven-dried
184 at 60 °C for 48 h and weighed. The straw aboveground biomass and crop yield were converted into
185 weight per hectare.

186 We selected 15 soil and crop properties to represent cropland ecosystem services; these properties
187 were related to the soil fertility index (SOC, total N, total P, MBC and MBN), greenhouse gas
188 emissions (CO₂, N₂O and CH₄), straw decomposition and C and N release, soil extracellular enzymes
189 (cellulase and N-acetyl-D-glucosaminidase), and maize biomass (aboveground biomass and crop yield).
190 Generally, SOC, total N and total P are the major soil fertility factors and indicate the nutrient status in
191 cropland, which can be related to soil fertility conditions. Microbial biomass reflects ecosystem
192 productivity. Greenhouse gas emissions are related to climate change and can be regulated by
193 fertilization regimes and soil microbial activities. Soil extracellular enzymes catalyze the
194 decomposition of a range of organic polymers, resulting in C and N turnover. Maize biomass
195 parameters (such as aboveground biomass and crop yield) reflect soil productivity. All of these
196 variables contribute to cropland functions. To evaluate the functions of the cropland ecosystem under

197 different fertilization conditions, we calculated an integrated soil ecosystem multifunctionality index
198 for further analysis. Notably, the opposite numbers of greenhouse gas emissions were used to evaluate
199 their negative effects. Due to the lack of a specific definition of multifunctionality, we first calculated
200 the Z scores of the 15 measured variables and then obtained a multifunctionality value for each plot by
201 averaging these 15 Z scores (Chen et al., 2019).

202 **2.4 DNA extraction and quantification of fungal ITS sequences, bacterial 16S rRNA genes and** 203 **genes encoding cellulose-degrading enzymes**

204 Total DNA was extracted from 0.5 g of freeze-dried soil by using a Fast DNA Spin Kit for Soil
205 (MPBio, USA) according to the manufacturer's instructions and then dissolved in 50 µl of Tris-EDTA
206 buffer. The quality of the extracted DNA was characterized by electrophoresis on 1% (wt/vol) agarose
207 gel. The quantity and quality of the DNA were checked using a Nanodrop spectrophotometer
208 (Nanodrop, PeqLab, Germany). The extracted DNA samples were stored at -80 °C before molecular
209 analysis.

210 Bacterial and fungal abundances were determined to reveal the changes in microbial community
211 composition. The abundances of bacteria and fungi were measured according to modified procedures
212 (Fierer and Jackson., 2005). We selected the primers *338F/518R* (*338F: CCTACGGGAGGCAGCAG;*
213 *518R: ATTACCGCGGCTGCTGG*) and *NSII/58A2R* (*NSII: GTAGTCATATGCTTGTCT; 58A2R:*
214 *CATTCCCCGTTACCCGTT*) for the qPCR assay. The thermal qPCR profiles for bacteria and fungi
215 were as follows: 95 °C for 2 min for DNA denaturation, 35 cycles of (95 °C for 30 s, 60 °C for 30 s,
216 72 °C for 30 s, and 80 °C for 15 s) for DNA annealing, and 81 °C for 10 s for DNA extension; and
217 95 °C for 10 min for DNA denaturation, 40 cycles of (95 °C for 15 s, 52 °C for 30 s, 72 °C for 30 s,
218 and 79 °C for 30 s) for DNA annealing, and 81 °C for 10 s for DNA extension, respectively. The initial

219 concentrations of the two plasmids used as standards for the bacterial and fungal abundance analyses
220 were 1.22×10^{10} and 9.05×10^9 , respectively.

221 The fungal *cbhl* gene and bacterial *GH48* gene were selected as functional biomarkers of
222 cellulolytic fungi and bacteria, respectively. The primers *GH48_F8/GH48_R5* (*GH48_F8*: 5 -
223 GCCADGHTBGGCG ACTACCT - 3; *GH48_R5*: 5 - CGCCCCABGMSWWGTACCA - 3) and *cbhl*
224 *F/cbhl_R* (*cbhl_F*: ACCAAYTGCTAYACIRGYAA; *cbhl_R*: GCYTCCCAIATRTCCATC) were used for
225 the qPCR assay. The abundances of bacterial *GH48* and fungal *cbhl* genes were quantified according to
226 modified procedures (Zhang et al., 2017). The qPCR thermal profiles for the target genes of *GH48* and
227 *cbhl* were as follows: 95 °C for 5 min for DNA denaturation, 40 × (94 °C for 30 s, 60 °C for 45 s, and
228 72 °C for 90 s) for DNA annealing, and 84 °C for 10 s for DNA extension; and 94 °C for 4 min for
229 DNA denaturation, 40 × (94 °C for 45 s, 50 °C for 30 s, and 72 °C for 60 s) for DNA annealing, and
230 81 °C for 10 s for DNA extension, respectively. The initial concentrations of the two plasmids used as
231 standards for bacterial *GH48* and fungal *cbhl* gene abundance analysis corresponded to 1.85×10^{11} and
232 2.65×10^{10} copies g^{-1} dry soil, respectively. qPCR was performed in triplicate, and amplification
233 efficiencies higher than 95% were obtained with r^2 values > 0.99.

234 **2.5 Bacterial 16S rRNA gene and fungal ITS amplification and sequencing**

235 High-throughput sequencing was performed with the Illumina MiSeq sequencing platform
236 (Illumina, Inc.). Both the forward and reverse primers were tagged with an adapter and linker sequence,
237 and 8-bp barcode oligonucleotides were added to distinguish the amplicons from different soil samples.

238 The primers *515F* (5'-GTGCCAGCMGCCGCGGTAA-3') and *907R*
239 (5'-CCGTCAATTCMTTTRAGTTT-3') were chosen to amplify the V4–V5 hypervariable region of the
240 16S rRNA gene. PCR was conducted in a 50- μ L reaction mixture containing 27 μ L of ddH₂O, 2 μ L (5

241 μM) of each forward/reverse primer, 2.5 μL (10 ng) of template DNA, 5 μL (2.5 mM) of
242 deoxynucleoside triphosphates, 10 μL of 5 \times Fastpfu buffer, 0.5 μL of bovine serum albumin, and 1 μL
243 of TransStart Fastpfu polymerase (TransGen, Beijing, China). The PCR conditions were 94 $^{\circ}\text{C}$ for 5
244 min; 30 cycles of 94 $^{\circ}\text{C}$ for 30 s, 52 $^{\circ}\text{C}$ for 30 s and 72 $^{\circ}\text{C}$ for 30 s of extension; and 72 $^{\circ}\text{C}$ for 10 min
245 (Caporaso et al., 2010).

246 The fungal ITS1 region was amplified using the primer pair *ITS1F*
247 (*CTGGTCATTAGAGGAAGTAA*)/*ITS2* (*GCTGCGTTCTTCATCGATGC*) (Ghannoum et al., 2010).

248 The 50- μL reaction mixture consisted of 1 μL (30 ng) of DNA, 4 μL (1 μM) of each forward/reverse
249 primer, 25 μL of PCR Master Mix, and 16 μL of ddH₂O. PCR amplification was conducted at 98 $^{\circ}\text{C}$ for
250 3 min, followed by 30 cycles (98 $^{\circ}\text{C}$ for 45 s, 55 $^{\circ}\text{C}$ for 45 s, and 72 $^{\circ}\text{C}$ for 45 s), with a final extension
251 at 72 $^{\circ}\text{C}$ for 7 min (Ghannoum et al., 2010). All amplicons were cleaned and pooled in equimolar
252 concentrations in a single tube, after which they were subjected to library preparation, cluster
253 generation, and 250-bp paired-end sequencing on the Illumina MiSeq platform (Illumina Inc., San
254 Diego, CA, USA).

255 The raw sequence data were processed using the Qualitative Insights into Microbial Ecology
256 (QIIME) pipeline (Caporaso et al., 2010). Sequences that fully matched the barcodes were selected and
257 distributed into separate files for the bacterial 16S rRNA and fungal ITS genes. Poor-quality sequences
258 with a length less than 200 bp (for fungal ITS) and 500 bp (for bacterial 16S) and a quality score less
259 than 20 were discarded, and chimeras were removed using the UCHIME algorithm (Edgar et al., 2010).
260 The remaining sequences were assigned to operational taxonomic units (OTUs) with a 97% similarity
261 threshold using UCLUST (Edgar, 2010). Alpha diversity and Bray–Curtis distances for principal
262 coordinate analysis of the soil microbial community were calculated after rarefying all samples to the

263 same sequencing depth.

264 **2.6 Statistical analysis**

265 The soil ecosystem multifunctionality index, crop yield, microbial traits and other relevant soil
266 variables among treatments were subjected to a chi-square test for independence of variance.
267 Significant differences were determined by one-way analysis of variance (ANOVA) based on the post
268 hoc Tukey test at the 5% level. Prior to ANOVA, the normality and homogeneity of variances were
269 tested by the Kolmogorov–Smirnov test and Levene’s test, respectively. If normality was not met, log
270 or square-root transformation was implemented. One-way ANOVA was performed using SPSS 21.0
271 (SPSS Inc., Chicago, IL, USA).

272 Nonmetric multidimensional scaling (NMDS) analysis was used to evaluate the microbial
273 community composition. NMDS was performed in the “Vegan” package of R (4.0.2). Analysis of
274 similarities (ANOSIM) was used to examine the significant differences in microbial community
275 structure under different fertilization treatments. To describe the complex co-occurrence patterns of
276 various organisms, we constructed co-occurrence networks. We focused on the abundant microbial
277 phylotypes (with an average relative abundance > 0.01% for bacteria and fungi) for network
278 construction. Nodes with Pearson correlations greater than 0.70 and $p < 0.05$ were retained. Network
279 visualization of microbial taxa and ecological clusters of microbial phylotypes was conducted with
280 Gephi software. To obtain the keystone species of each network, a Z_i-P_i plot series was constructed to
281 determine the role of each OTU. According to Deng et al. (2012), the plot includes (a) peripheral nodes
282 ($Z \leq 0.25, P \leq 0.62$), (b) module hubs ($Z > 0.25, P \leq 0.62$), (c) connectors ($Z \leq 0.25, P > 0.62$) and (d)
283 network hubs ($Z > 0.25, P > 0.62$). From an ecological perspective, OTUs in module hubs, connectors
284 and network hubs may be regarded as the microbial keystone taxa of the network systems (Deng et al.,

285 2015).

286 A first heatmap was constructed to reveal the associations between soil ecosystem services and
287 microbial module communities. Another heatmap was constructed to reveal the associations between
288 microbial traits and fertilizers, soil properties, greenhouse emissions and ecosystem multifunctionality.
289 The random forest algorithm was applied in the R package (4.0.2) “RandomForest” to estimate the
290 importance of the predictors of soil properties and microbial traits with respect to ecosystem
291 multifunctionality.

292 **3. Results**

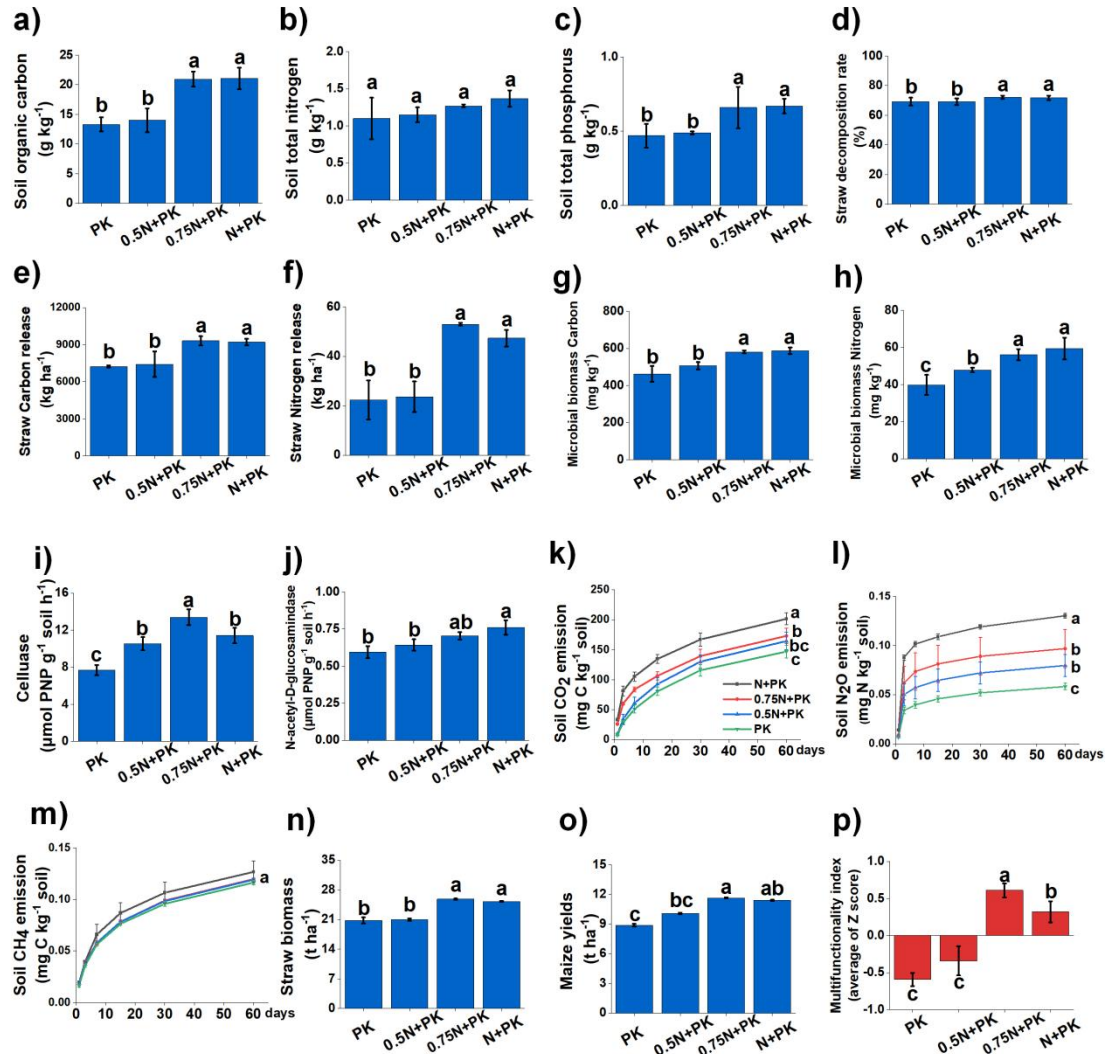

293 **3.1 Cropland ecosystem services**

294 Data collection after the continuous 4-year in situ field experiment under different N input levels
295 revealed changes in cropland ecosystem services (Fig. 1). In terms of soil fertility, compared with those
296 in the N-limited treatments (PK and 0.5N+PK), the SOC and total P contents in the N+PK and
297 0.75N+PK treatments increased significantly (Fig. 1a, c) ($P < 0.05$), while there were no significant
298 changes in total N content (Fig. 1b). After straw decomposition (Fig. 1d), the amounts of straw C (Fig.
299 1e) and N (Fig. 1f) released showed different responses to varying N fertilizer input levels. Generally,
300 the N-rich treatments (N+PK and 0.75N+PK) significantly increased the straw decomposition rate and
301 straw C and N release relative to the N-limited treatments ($P < 0.05$). However, there was no
302 significant difference between N+PK and 0.75N+PK. The MBC and MBN contents, as well as the
303 associated enzyme activities, changed after the application of different N fertilizer rates (Fig. 1g, h, i
304 and j). The MBC (Fig. 1g) and MBN (Fig. 1h) contents were significantly higher in the N-rich
305 treatments than in the other treatments. However, the highest cellulase activity was observed in the
306 0.75N+PK treatment, which was significantly higher than that in the other treatments (Fig. 1i) ($P <$

307 0.05), and the N-acetyl-D-glucosaminidase activity decreased with decreasing N application (Fig. 1j).

308 Regarding greenhouse gas emissions, with decreasing N fertilizer application levels, CO₂ and N₂O
309 emissions gradually decreased (Fig. 1k, m). No significant difference in CH₄ emissions was detected
310 among the different fertilization treatments (Fig. 1l). In addition, the N fertilizer level had a strong
311 influence on maize yield and aboveground biomass (Fig. 1n, o). As expected, the 0.75N+PK treatment
312 achieved the highest multifunctionality index (0.61), followed by the N+PK (0.32), 0.5N+PK (-0.34)
313 and PK (-0.59) treatments (Fig. 1p).

314 However, although the 0.75N+PK treatment increased the straw N release amount and may have
315 met the requirements for plant growth, the total N input was still dominated by inorganic N input (Fig.
316 S1). Therefore, the N released from the straw could not offset the deficiency of N fertilizer.
317 Additionally, different N fertilizer input levels significantly changed the stoichiometry of C, N and P
318 (Fig. S2). Notably, the 0.75N+PK treatment significantly increased the C:N ratio compared with the
319 0.5N+PK and PK treatments ($P < 0.05$). The lowest C:N ratio was obtained for the 0.5N+PK treatment
320 (Fig. S2a). The N:P and C:P ratios showed no significant difference regardless of nutrient quantity (i.e.,
321 excess or limited) (Fig. S2b and c).

322

323 **Fig. 1** Fifteen cropland variables and multifunctionality index values under different N input levels

324 after straw return. Abbreviations: N+PK, straw return plus regular inorganic N-P-K fertilizers;

325 0.75N+PK, straw return plus regular inorganic P-K with 25% N fertilizer reduction; 0.5N+PK, straw

326 return plus regular inorganic P-K with 50% N fertilizer reduction; PK, straw return plus regular

327 inorganic P-K without N fertilizer.

328 3.2 Abundances of bacteria, fungi and genes encoding cellulose-degrading enzymes

329 N fertilizer input levels had marked impacts on the abundances of fungi and bacteria (Table S3).

330 The highest fungal abundance was observed in the 0.75N+PK treatment, which was significantly

331 higher than that in the other treatments ($P < 0.05$). The N+PK treatment significantly increased

332 bacterial abundance compared with the PK treatment ($P < 0.05$), while there were no obvious
 333 differences among the N+PK, 0.75N+PK and PK treatments. The ratio of fungi to bacteria also showed
 334 contrasting responses to N fertilization (Table S3). The 0.75N+PK treatment significantly increased the
 335 ratio of fungi to bacteria compared with the other treatments ($P < 0.05$), and the lowest ratio of fungi to
 336 bacteria was found in the PK treatment.

337 **Table 1 Abundances of genes encoding cellulose-degrading enzymes**
 338 **across different N fertilizer treatments after straw return**

Treatment	<i>cbhI</i> gene abundance ($\times 10^6$ copies g^{-1} soil)	<i>GH48</i> gene abundance ($\times 10^7$ copies g^{-1} soil)	<i>cbhI</i> : <i>GH48</i> ratio
N+PK	4.75 \pm 0.16 a	1.68 \pm 0.01 a	0.28 \pm 0.01 a
0.75N+PK	4.95 \pm 0.19 a	1.60 \pm 0.04 a	0.31 \pm 0.02 a
0.5N+PK	4.01 \pm 0.12 b	1.54 \pm 0.08 a	0.26 \pm 0.03 b
PK	3.76 \pm 0.13 b	1.40 \pm 0.06 b	0.27 \pm 0.02 b

339 The results are presented as the means \pm standard deviations (n = 3). Different lowercase
 340 letters after values indicate significant differences between each treatment, $P < 0.05$. N+PK,
 341 straw return plus regular inorganic N-P-K fertilizers; 0.75N+PK, straw return plus regular
 342 inorganic P-K with 25% N fertilizer reduction; 0.5N+PK, straw return plus regular inorganic
 343 P-K with 50% N fertilizer reduction; PK, straw return plus regular inorganic P-K without N
 344 fertilizer.

345
 346 N fertilizer input levels led to changes in the expression levels of genes encoding
 347 cellulose-degrading enzymes (Table 1). The N-rich treatments resulted in greater fungal *cbhI* and
 348 bacterial *GH48* gene abundance than the N-limited treatments. In contrast, the highest *cbhI* gene

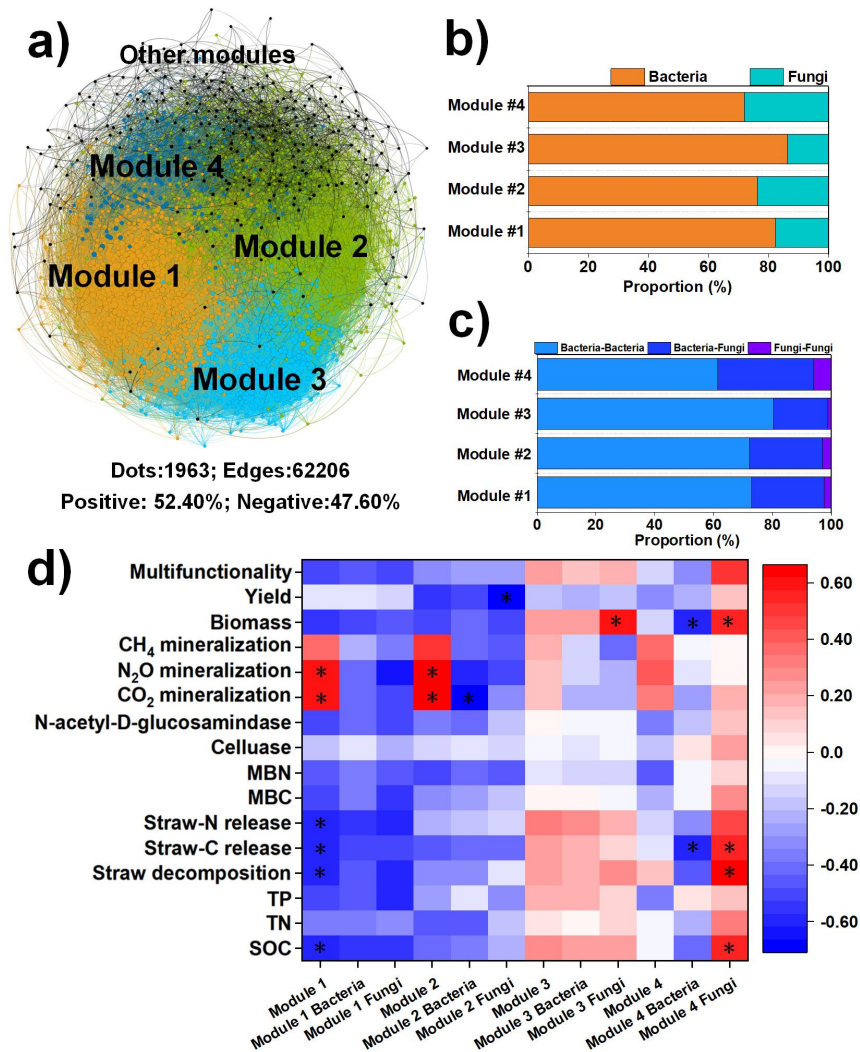

349 abundance was detected in the 0.75N+PK treatment, while the highest *GH48* gene abundance was
350 detected in the N+PK treatment. Compared with that in the PK treatment, the ratio of the fungal *cbhI*
351 gene to the bacterial *GH48* gene increased significantly in the 0.75N+PK treatment ($P < 0.05$).

352 **3.3 Co-occurrence network analysis of the microbial community**

353 Regarding fungal alpha diversity, there were no significant differences in the Chao1 index across
354 treatments. The N+PK treatment significantly increased fungal richness compared with the PK
355 treatment ($P < 0.05$) (Table S4). In addition, the PK treatment resulted in lower bacterial richness than
356 the other treatments ($P < 0.05$). No significant difference was observed in the bacterial Chao1 index
357 across treatments (Table S4). The NMDS plots showed that different N input levels significantly
358 changed the fungal (Fig. S3a) and bacterial communities (Fig. S3b) ($P < 0.05$).

359 We further conducted network analysis to identify co-occurrence patterns between specific
360 microbial taxa (Fig. 2). The cooccurrence network was aggregated into smaller coherent modules that
361 were examined to determine important module–trait relationships. The network comprised 1963 nodes
362 (composed of 1520 bacterial taxa and 443 fungal taxa) and 62206 edges with 52.49% positive
363 associations (Fig. 2a). The results showed that four dominant ecological modules (1-4) strongly
364 co-occurred within the multitrophic network and contributed 86.10% of the whole network. Among the
365 four modules, bacteria accounted for the highest proportion in each module, contributing more than
366 70% of the total (Fig. 2b). The percentage of edges linking bacteria to bacteria (B-B) was higher than
367 that of edges linking fungi to fungi (F-F) or bacteria to fungi (B-F). The highest proportion of B-B
368 (80.32%) was found in Module 3, while the highest proportions of B-F (32.66%) and F-F (6.00%) were
369 found in Module 4 (Fig. 2c).

370

372

373 **Fig. 2** Relationships of microbial module communities with soil ecosystem services and

374 dis-services. Multitrophic network including multiple ecological modules. The colors of the nodes

375 represent different ecological modules (a). OTU number proportions of bacteria and fungi (b).

376 Proportions of edges linking bacteria to bacteria (B-B), bacteria to fungi (B-F) and fungi to fungi

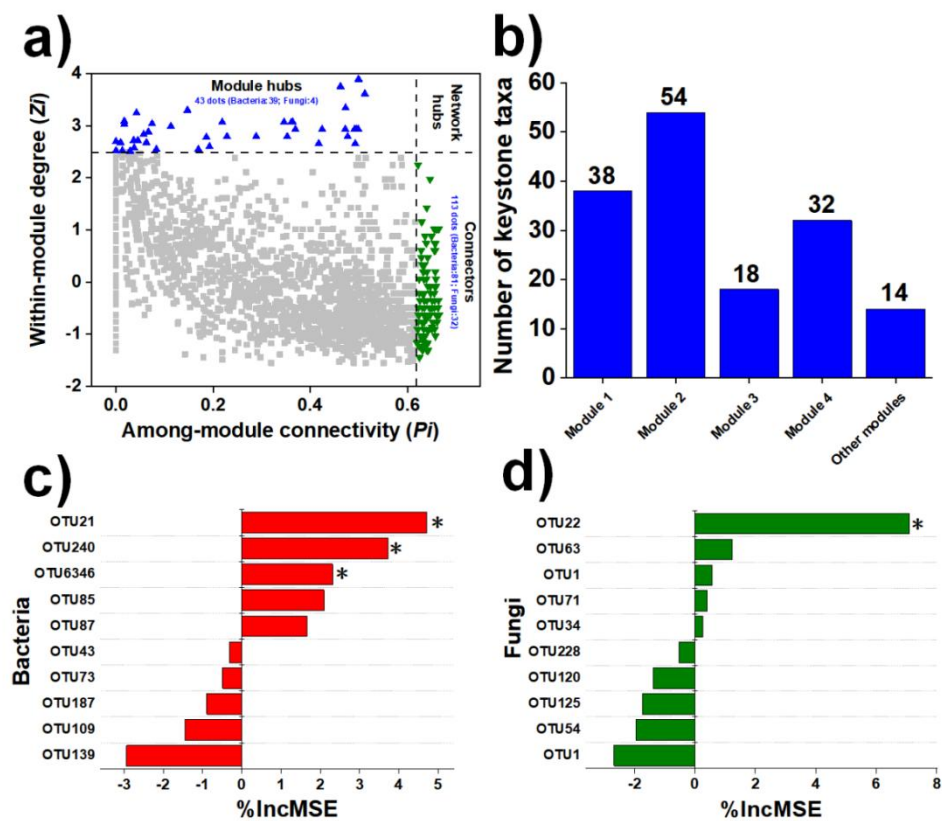

377 (F-F) in the major ecological modules (c). Links connecting specific module communities with

378 soil ecosystem services and dis-services (d). * indicates significance at $P < 0.05$. Abbreviations:

380 content to total P content.

381 Individual nodes represent different roles in the microbial network based on the intramodule
382 connectivity Z_i and the intermodule connectivity P_i . ZP plots were constructed to identify the
383 topological roles of each node in the network (Fig. 3a). As shown in Fig. 3b, 113 microbial taxa (81
384 bacterial species and 32 fungal species) were regarded as connectors, and 43 microbial taxa (39
385 bacterial species and 4 fungal species) were regarded as module hubs. Specifically, module 2 (54
386 contained the most keystone taxa, followed by module 1 (38) and module 3 (32).

387

388 **Fig. 3** Topological roles of microbial taxa and their effects on the soil multifunctionality index.

389 The topological role of each OTU was determined according to the scatter plot of within-module

390 connectivity (Z) and among-module connectivity (P) (a). Distribution of keystone taxa in each

391 ecological module (b). Contributions of bacterial (c) and fungal OTUs (d) to the soil

392 multifunctionality index. *, ** and *** indicate significance at $P < 0.05$, 0.01 and 0.001,

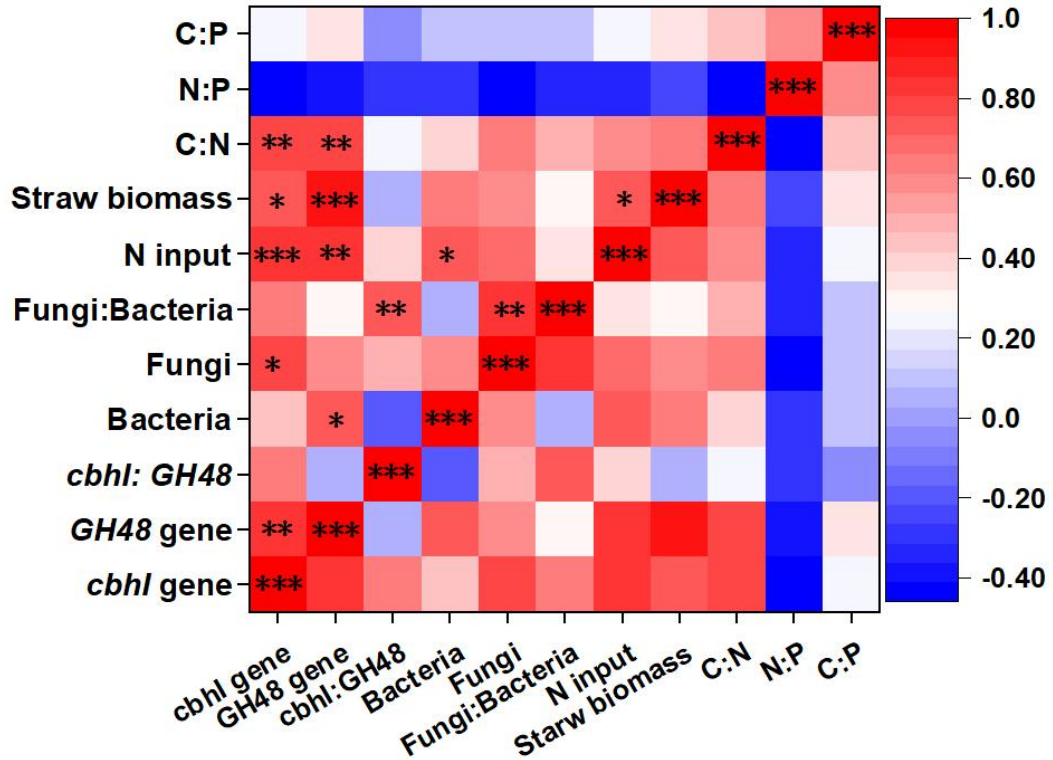

393 respectively.

394 **3.4 Relationships between microbial traits and soil ecosystem multifunctionality**

395 The heatmap showed close correlations of fertilizers (N input and straw return) with soil
396 stoichiometry and microbial traits (Fig. 4). Overall, the N input level, straw biomass and C:N ratio
397 increased the abundance of genes encoding cellulose-degrading enzymes. In addition, N input was
398 positively correlated with bacterial abundance, and a significant correlation was observed between
399 straw biomass and the N input level. The random forest model was used to identify abiotic and biotic
400 attributes correlated with soil ecosystem multifunctionality (Fig. 5). The model explained 83.89% of
401 the variance in ecosystem multifunctionality. The results indicated that the N input level, straw biomass
402 and soil C:N ratio were the predominant abiotic factors affecting the ecosystem multifunctionality
403 index; some biotic factors, such as the abundance of genes encoding cellulose-degrading enzymes,
404 significantly affected the ecosystem multifunctionality index.

405 Moreover, to clarify the potential main drivers of soil ecosystem services, the correlations between
406 microbial physiological traits and soil properties were calculated to determine the role of the microbial
407 community in soil ecosystem multifunctionality (Fig. 2d). The results indicated that the microbial
408 module community was significantly correlated with soil ecosystem services. The communities of
409 modules 1 and 2 and the fungal community in module 4 showed potential contributions to soil
410 ecosystem services (Fig. 2d). Specifically, significant correlations were observed between SOC content,
411 straw decomposition, straw C/N release, CO₂/N₂O mineralization and the module 1 community; the
412 module 2 community was positively correlated with greenhouse gas (except for CH₄) emissions; and
413 the fungal community in module 4 was positively correlated with SOC content, straw decomposition,
414 straw C/N release and straw biomass. Furthermore, the bacterial and fungal communities belonging to

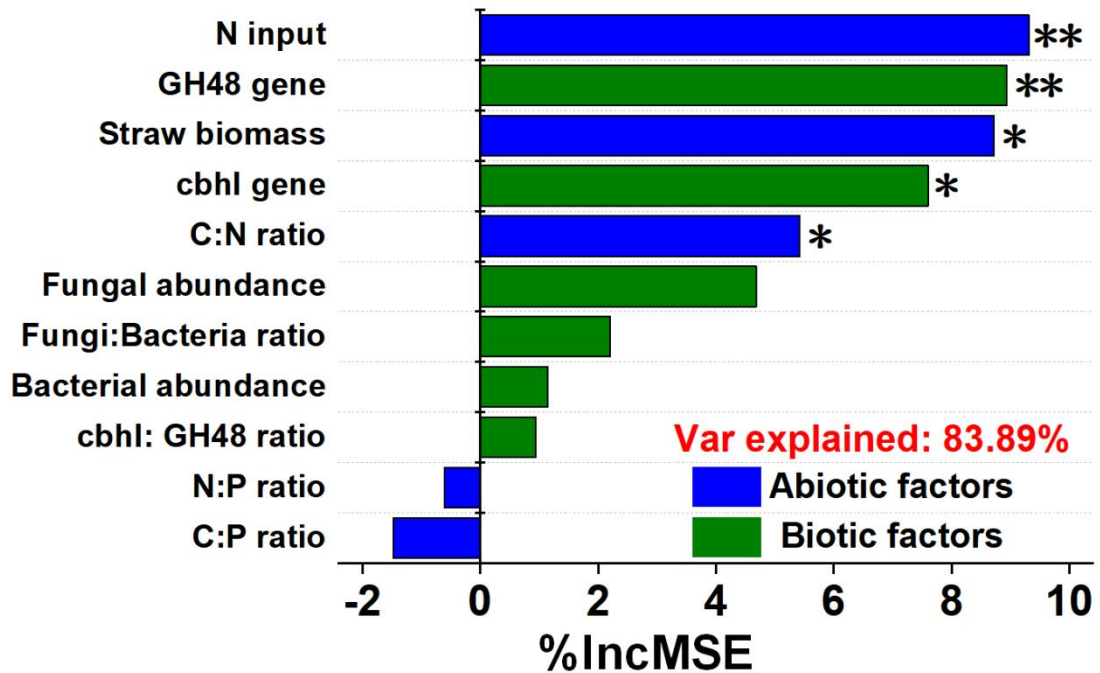

415 module 2 and the fungal community belonging to module 3 were significantly correlated with CO₂
 416 emission, maize yield and straw biomass.

417
 418 **Fig. 4** Heatmap showing the close correlations of fertilizer (N input and straw return) and soil
 419 stoichiometry with microbial traits. *, ** and *** indicate significance at $P < 0.05$, 0.01 and 0.001,
 420 respectively. Abbreviations: C:N, ratio of SOC content to total N content; N:P, ratio of total N
 421 content to total P content.

422 We selected the 20 keystone taxa at the species level (10 bacterial and 10 fungal taxa) with the
 423 highest relative abundance for further analysis. The random forest model results indicated that specific
 424 keystone taxa strongly influenced soil ecosystem multifunctionality (Fig. 3c and d). Bacterial OTU21
 425 (in module 1), OTU240 (in module 2) and OTU6346 (in module 3) were highlighted as essential
 426 predictors of soil ecosystem multifunctionality, and fungal OTU22 (module 3) was also found to be an
 427 important predictor. The relative abundances of selected keystone taxa differed among the different N

428 fertilizer treatments after straw return (Table S5). The relative abundances of fungal OTU22 and
 429 bacterial OTU21 were higher in the N-rich treatments than in the N-limited treatments. Moreover,
 430 compared with the N+PK treatment, the 0.75N+PK treatment increased the relative abundance of
 431 fungal OTU22 by 38.20% and that of bacterial OTU21 by 40.63%.

432
 433 **Fig. 5** Contribution of abiotic and biotic variables to the soil multifunctionality index. *, ** and
 434 *** indicate significance at $P < 0.05$, 0.01 and 0.001, respectively. Abbreviations: C:N, ratio of
 435 SOC content to total N content; N:P, ratio of total N content to total P content.

436 4. Discussion

437 4.1 Effect of N fertilizer reduction on cropland ecosystem services after straw return

438 Soil fertility, straw decomposition, C and N release amounts, and crop productivity were mostly
 439 higher under 0.75N+PK and N+PK than under the other treatments, implying that better soil
 440 multifunctionality was achieved. Moreover, N+PK increased greenhouse gas emissions (Fig. 1). Higher
 441 MBC and MBN values, as well as relevant enzyme activities, were also observed under the N-rich

442 treatments, indicating the strong positive impact of abundant N fertilizer application (Fig. 1g, h, i, j). It
443 has been reported that straw return with N fertilizer application can stimulate microbial activity and
444 promote biomass accumulation (Treseder, 2008). The substantial increases in straw decomposition and
445 straw C and N release under the N-rich treatments may be primarily attributed to microbial activity
446 (Fig. 1d, e, f), which is consistent with previous research (Ramirez et al., 2012). Our results indicated
447 that 0.75N+PK maintained parameters related to the soil fertility index and net primary production
448 compared to N+PK. The results demonstrate that the effects of 0.75N+PK on soil ecosystem services
449 are similar to those of N+PK. Therefore, it can be concluded that 0.75N+PK is a more efficient and
450 effective option for improving soil ecosystem services. Moreover, 0.75N+PK may enhance N fertilizer
451 use efficiency and stimulate microbial functioning by altering the stoichiometry of C, N and P in the
452 soil, ultimately promoting soil fertility and crop yield (Liu et al., 2010). Reducing the amount of N
453 fertilizer by more than 50% led to insufficient N input to meet the needs of both crops and microbes,
454 resulting in a decline in soil health (Williams et al., 2013). Recent studies have also proven that rational
455 N input can stimulate microbial ex vivo production of extracellular enzymes to accelerate straw
456 decomposition and nutrient transformation (Chen et al., 2016). Moreover, fungi have high nutrient
457 utilization efficiency; thus, more straw-derived C and N are stored in soil under N-rich treatments than
458 under N-limited treatments (Hou et al., 2020). Sufficient available N is a prerequisite for straw
459 decomposition and SOM formation according to the microbial “stoichiometric decomposition” theory,
460 while the “N-mining” theory, which applies to N-limited treatments, proposes that oligotrophic species
461 (such as *K*-strategists) degrade native SOM because of insufficient N input (Chen et al., 2014). In this
462 study, a 25% reduction in N fertilizer application may be the threshold value between N mining and
463 stoichiometric decomposition regimes. Finally, increases in SOC, total N and P contents and straw C

464 and N release, as well as microbial biomass and function, are commonly implicated in high
465 aboveground biomass and maize yields (Fig. 1n, o), which are favorable from the viewpoint of
466 ecosystem services.

467 However, excess N input also causes increased greenhouse gas emissions (Tang et al., 2019). In
468 the present study, greenhouse gas emissions were quantified to evaluate the ecosystem dis-services
469 under different N fertilizer input levels: the greater the emissions were, the lower the soil ecosystem
470 multifunctionality was (Fig. 1k, l, m). Straw return with N fertilizer addition might be a crucial driver
471 of CO₂ and N₂O emissions from agroecosystems and has been widely studied in the literature
472 (Gregorich et al., 2005). CO₂ and N₂O emissions increased significantly compared with those under the
473 PK treatment, likely due to stimulation of the activity of copiotrophs when sufficient C and N
474 substrates were provided. For example, on the basis of meta-analysis and field experiments, Dieleman
475 et al. (2010) found that CO₂ and N₂O increase as N input increases. Qiu et al. (2019) reported that CO₂
476 emissions enhanced root and mycorrhizal N uptake and increased N₂O emissions, which was related to
477 changes in soil denitrifier community composition favoring N₂O-producing taxa (nirK- or nirS-type).
478 In addition, there was no difference in CH₄ emissions among treatments, although contradictory results
479 have been widely reported in the literature (Tang et al., 2019). Mapanda et al. (2011) and Liu et al.
480 (2012) indicated that CH₄ emissions depend strongly on the soil water content in maize cropland,
481 which is consistent with our results. In summary, previous studies clearly demonstrated a positive
482 correlation between CO₂ emissions, N₂O emissions and N input. Accordingly, this study unequivocally
483 showed that N+PK emits more greenhouse gases than 0.75N+PK.

484 Overall, compared with the N+PK treatment, the 0.75N+PK treatment supported multiple
485 ecosystem services, including promotion of soil fertility, straw nutrient release and microbial activity

486 and mitigation of greenhouse gas emissions (Fig. 1p). Therefore, a 25% reduction in chemical N
487 fertilizer input with straw return may be an appropriate regime for promoting ecosystem services in
488 meadow soils on the Northeast China Plain.

489 **4.2 Responses of microbial abundance and function to straw return with N fertilizer reduction**

490 Fungal and bacterial abundances, as well as the ratio of fungi to bacteria, were sensitive to
491 changes in the N fertilizer input levels (Table S3 and Fig. 2). Straw addition with N fertilizer input
492 supplied enough C and N for microbial metabolism, thus promoting microbial proliferation (Chen et al.,
493 2016). Generally, bacterial abundance decreased with reduced N fertilizer input. This is mainly because
494 bacteria are more sensitive than fungi to N availability, which is consistent with the findings of a
495 previous study (Ramirez et al., 2020). Notably, compared with regular N input, a 25% reduction in N
496 fertilizer significantly increased fungal abundance. This result might be attributed to the negative effect
497 of excess N fertilizer (Wan et al., 2015). Moreover, Ning et al. (2020) performed 7 long-term field
498 experiments under different fertilization conditions across China and demonstrated that the C:N ratio
499 was a pivotal factor in fungal community composition; they also reported a significant positive
500 correlation between C:N ratio and fungal community composition. Gao et al. (2015) indicated that the
501 optimal ratio of C to N inputs was 20:1, which may meet the demands of maize growth and microbial
502 proliferation. It is well known that fungi have a stronger C utilization efficiency than bacteria (Duan et
503 al., 2021). Therefore, increasing fungal abundance and lowering the ratio of bacteria to fungi are
504 crucial for straw degradation and SOC accumulation. Previous studies have shown that the C:N ratio of
505 fungi is greater than 20; however, the C:N ratio of bacteria is less than 10. Excessive N fertilizer input
506 may reduce the soil C:N ratio, while low N fertilizer input cannot meet the growth requirements of
507 crops and microorganisms (Ning et al., 2020). Therefore, appropriate enhancement of the soil C:N ratio

508 can increase the ratio of fungi to bacteria, stimulate fungal function, and promote straw degradation and
509 SOC accumulation. Therefore, the 0.75N+PK treatment with a higher C:N ratio (16.47) may facilitate
510 the proliferation of microorganisms and promote an increase in microbial abundance.

511 Our results showed that the N-rich treatments resulted in higher microbial cellulose-degrading
512 gene abundances than the PK treatment (Table 1), which demonstrated the crucial role of N input in
513 straw degradation (Zhang et al., 2017). Additionally, the increase in fungal *cbhI* gene abundance
514 compared with bacterial *GH48* gene abundance required adequate N fertilizer input and was regulated
515 by the soil C:N ratio, which suggests that rational N fertilizer input could promote fungal degradation
516 of recalcitrant straw components (Hou et al., 2020). Therefore, the ratio of *cbhI* gene abundance to
517 *GH48* gene abundance was higher under the 0.75N+PK treatment than under the N-limited treatments
518 since the increased expression of a fungal cellulose-degrading gene implies increased straw C and N
519 release.

520 Our results indicated that 75%-100% N fertilizer could upregulate fungal and *cbhI* gene
521 abundances, which may lead to straw decomposition and SOC accumulation. It is therefore necessary
522 to further explore the potential associations between microbial traits and ecosystem services under
523 varying N fertilizer input levels.

524 **4.3 Relationships of cropland ecosystem services with microbial traits**

525 To clarify the effects of abiotic and biotic factors on soil ecosystem services, we quantified the
526 contributions of abiotic and biotic factors to the ecosystem multifunctionality index across the different
527 N input treatments (Figs. 4 and 5). Biotic factors, such as *cbhI* and *GH48* gene abundances, as well as
528 abiotic factors, including the C:N ratio, straw biomass and N input level, are also key regulators of
529 ecosystem multifunctionality (Fig. 5). In general, rapid straw degradation is an important way to

530 convert straw-C into SOM, thus improving soil fertility, aboveground biomass and crop yield. In
531 addition, fungi have a higher C utilization efficiency than bacteria; thus, a high fungal *cbhl* gene
532 abundance may correspond to better soil multifunctionality (Hou et al., 2020). Among abiotic factors,
533 the soil C:N ratio, straw biomass and N fertilizer input are regarded as the main indicators of soil
534 fertility and health, likely because they provide available nutrients and influence microbial community
535 composition (Ning et al., 2020).

536 Numerous studies have shown that core microbiota play a vital role in maintaining the stability of
537 soil microbial function and the complexity of microbial networks and in promoting ecosystem services
538 related to soil nutrient cycling (Ghannoum et al., 2015); moreover, keystone species may show great
539 explanatory power in terms of the structure and function of specific networks (or modules) (Chen et al.,
540 2019b). In the present study, *Terrimonas* (a bacterial species in module 1) and *Lasiosphaeriaceae* (a
541 fungal species in module 3) were identified as the keystone taxa influencing soil multifunctionality in
542 the co-occurrence network (Table S5). A previous study demonstrated that straw addition significantly
543 increased the relative abundance of *Lasiosphaeriaceae*, which implied the potential for straw
544 decomposition (Song et al., 2020). Later, *Lasiosphaeriaceae* was proven to promote straw-derived C
545 and N accumulation by secreting multiple extracellular enzymes (Guo et al., 2022). Moreover, Sun et al.
546 (2023) revealed that *Lasiosphaeriaceae* abundance was regulated by the soil C:N ratio and was
547 especially affected by changes in mineral N. Therefore, *Lasiosphaeriaceae* can effectively promote
548 straw degradation and straw C and N release while driving the function and community of module 1,
549 which is consistent with our results (Fig. 2d). However, relatively few studies have focused on the
550 function of *Terrimonas*, so this study focused on *Chitinophagaceae*. In the literature, straw return was
551 the main contributor to increases in *Chitinophagaceae* abundance (Li et al., 2021). Furthermore,

552 *Chitinophagaceae* was indicated to have a strong ability to accumulate soil C and N and degrade
553 cellulose (Zhong et al., 2022), thus promoting production by regulating the module 3 community and
554 function, which is in line with our results (Fig. 2d).

555 Overall, straw return with sufficient N fertilizer application can increase the C:N ratio and
556 stimulate microbial traits, which ultimately promote soil ecosystem multifunctionality (Fig. 6). Straw
557 return without a sufficient N supply cannot support ecosystem services due to the decomposition of
558 native SOM and the imbalanced microbial community composition, according to the N-mining theory
559 (Chen et al., 2014); straw return with sufficient N application (N+PK and 0.75N+PK) can promote soil
560 fertility, straw release, microbial activity and crop productivity, which can be explained by the
561 stoichiometric decomposition theory (Chen et al., 2014). Additionally, N+PK caused more severe
562 ecosystem dis-services, such as greenhouse gas emissions, than the 0.75N+PK treatment. Moreover,
563 compared with the N+PK treatment, the 0.75N+PK treatment increased the soil C:N ratio and
564 stimulated the microbial community functions of modules 1 and 3, *cbhI* gene abundance, and the
565 abundances of keystone taxa, which were significantly positively correlated with soil ecosystem
566 multifunctionality. The *Lasiophaeriaceae*-driven module 1 and *Terrimonas*-driven module 3
567 communities may be involved in maintaining soil ecosystem multifunctionality. Our study suggests that
568 a 25% reduction in chemical N fertilizer after straw return is the optimal agronomic measure for
569 promoting ecosystem services in meadow soil on the Northeast China Plain.

570

571 **Fig. 6** Graphical sketch of the changes in ecosystem services and potential microbial mechanisms in
 572 response to different chemical N fertilizer application rates after straw return. N, nitrogen; SOM, soil
 573 organic matter.

574 **5. Conclusion**

575 Straw return combined with different chemical N fertilizer application rates significantly changed
 576 ecosystem services and dis-services. Collectively, our work indicates that compared with the N+PK
 577 treatment, straw return with a 25% reduction in chemical N fertilizer has the potential to improve
 578 ecosystem services by maintaining soil fertility, productivity, microbial biomass and function;
 579 promoting straw decomposition and C and N release; and mitigating greenhouse gas emissions. The
 580 0.75N+PK treatment achieved higher soil ecosystem multifunctionality than all the other treatments. In
 581 addition, the N input level, straw biomass and soil C:N ratio can increase the abundance of the *cbhI* and
 582 *GH48* genes, which may contribute to soil ecosystem multifunctionality.

583 Furthermore, changes in multiple soil ecosystem services were strongly associated with microbial
 584 module communities and keystone taxa. The relationships between ecosystem services and microbial
 585 traits confirmed that *Lasio-sphaeriaceae*, which drives the function and structure of the module 1

586 community, promoted straw degradation and straw C and N release, while *Terrimonas*, which drives
587 the function and structure of the module 3 community, likely contributed to improved production under
588 the 0.75N+PK treatment. Therefore, a 25% reduction in chemical N fertilizer with straw return might
589 be a win–win strategy that not only produces considerable ecological benefits for the pedosphere and
590 atmosphere but also reduces fertilizer costs in meadow soil on the Northeast China Plain.

Author contributions

YD, LFW, and XHM designed the experiment; YD, HMC, ZN, WLZ, and YMW performed the measurements; YD, YMC, MXZ, and JYL analyzed the data; YD and MHC wrote the manuscript draft; YML, JYL and LFW reviewed and edited the manuscript.

Declaration of competing interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgments

We thank all our laboratory colleagues for their assistance with soil sampling and analyses. This work was jointly supported by the Anhui Postdoctoral Science Foundation (2022B638); the Special Project of Zhongke Bengbu Technology Transfer Center (ZKBB202103); the China Postdoctoral Science Foundation (2023M733542); the Special Research Assistant Project of the Chinese Academy of Sciences (2023000140); and the Chinese Academy of Sciences (CASHIPS) Director's Fund (YZJJ2023QN37).

Figure captions

Fig. 1 Fifteen cropland variables and multifunctionality index values under different N input levels after straw return. Abbreviations: N+PK, straw return plus regular inorganic N-P-K fertilizers; 0.75N+PK, straw return plus regular inorganic P-K with 25% N fertilizer reduction; 0.5N+PK, straw return plus regular inorganic P-K with 50% N fertilizer reduction; PK, straw return plus regular inorganic P-K without N fertilizer.

Fig. 2 Relationships of microbial module communities with soil ecosystem services and dis-services. Multitrophic network including multiple ecological modules. The colors of the nodes represent different ecological modules (a). OTU number proportions of bacteria and fungi (b). Proportions of edges linking bacteria to bacteria (B-B), bacteria to fungi (B-F) and fungi to fungi (F-F) in the major ecological modules (c). Links connecting specific module communities with soil ecosystem services and dis-services (d). * indicates significance at $P < 0.05$. Abbreviations: SOC, soil organic carbon; C:N, ratio of SOC content to total N content; N:P, ratio of total N content to total P content.

Fig. 3 Topological roles of microbial taxa and their effects on the soil multifunctionality index. The topological role of each OTU was determined according to the scatter plot of within-module connectivity (Z) and among-module connectivity (P) (a). Distribution of keystone taxa in each ecological module (b). Contributions of bacterial (c) and fungal OTUs (d) to the soil multifunctionality index. *, ** and *** indicate significance at $P < 0.05$, 0.01 and 0.001, respectively.

Fig. 4 Heatmap showing the close correlations of fertilizer (N input and straw return) and soil stoichiometry with microbial traits. *, ** and *** indicate significance at $P < 0.05$, 0.01 and 0.001,

respectively. Abbreviations: C:N, ratio of SOC content to total N content; N:P, ratio of total N content to total P content.

Fig. 5 Contribution of abiotic and biotic variables to the soil multifunctionality index. *, ** and *** indicate significance at $P < 0.05$, 0.01 and 0.001, respectively. Abbreviations: C:N, ratio of SOC content to total N content; N:P, ratio of total N content to total P content.

Fig. 6 Graphical sketch of the changes in ecosystem services and potential microbial mechanisms in response to different chemical N fertilizer application rates after straw return. N, nitrogen; SOM, soil organic matter.

Table 1 Abundances of genes encoding cellulose-degrading enzymes across different N fertilizer treatments after straw return

Treatment	<i>cbhI</i> gene abundance ($\times 10^6$ copies g^{-1} soil)	<i>GH48</i> gene abundance ($\times 10^7$ copies g^{-1} soil)	<i>cbhI</i>: <i>GH48</i> ratio
N+PK	4.75\pm0.16 a	1.68\pm0.01 a	0.28\pm0.01 a
0.75N+PK	4.95\pm0.19 a	1.60\pm0.04 a	0.31\pm0.02 a
0.5N+PK	4.01\pm0.12 b	1.54\pm0.08 a	0.26\pm0.03 b
PK	3.76\pm0.13 b	1.40\pm0.06 b	0.27\pm0.02 b

The results are presented as the means \pm standard deviations (n = 3). Different lowercase letters after values indicate significant differences between each treatment, $P < 0.05$. N+PK, straw return plus regular inorganic N-P-K fertilizers; 0.75N+PK, straw return plus regular inorganic P-K with 25% N fertilizer reduction; 0.5N+PK, straw return plus regular inorganic P-K with 50% N fertilizer reduction; PK, straw return plus regular inorganic P-K without N fertilizer.
