**Abstract.** Numerous recent studies have tested the clumped isotope ( $\Delta_{47}$ ) thermometer on a variety of biogenic carbonates such as foraminifera and bivalves and showed that most follow a common calibration. However, there may be a difference between biogenic carbonate-based calibrations and the most recent inorganic carbonate calibrations that are assumed to have formed close to isotopic equilibrium. Biogenic calibrations such as those based on foraminifera from seafloor sediments suffer from uncertainties in the determination of the calcification temperatures. Therefore, well-constrained laboratory cultures without temperature uncertainty can help resolve these discrepancies. Although the sample size requirements for a reliable  $\Delta_{47}$  measurement have decreased over the years, the availability and preservation of many biogenic carbonates is still limited and/or require substantial time to be extracted from sediments in sufficient amounts. Coccoliths, on the other hand, are abundant and often well-preserved in sediments, and are a potential interesting target for palaeoceanography. We thus determined the  $\Delta_{47}$ -temperature relationship for coccoliths because they are relatively easy to grow in the laboratory. The carbon and oxygen isotopic compositions of coccolith calcite have limited use in palaeoenvironmental reconstructions due to physiological effects that cause variability in the carbon and oxygen isotopic fractionation during mineralisation. However, the relatively limited data available suggest that clumped isotopes may not be significantly influenced by these effects. We cultured three species of coccolithophores under controlled carbonate system conditions with  $\text{CO}_{2(\text{aq})}$  concentrations between 5 and 45  $\mu\text{M}$  and temperatures between 6°C and 27°C.

Our well-constrained results agree with a previous culture study that there are no species- or genus-specific vital effects on the  $\Delta_{47}$ -temperature relationship in coccolithophores despite significant deviations from equilibrium in the C and O isotopic composition. We find that varying environmental parameters other than temperature does not have a significant effect on  $\Delta_{47}$ , changing the parameters yields  $\Delta_{47}$ -temperature calibrations that agree within 1.2 ppm. Our well-constrained coccolith-specific  $\Delta_{47}$ -temperature calibration shows a positive offset of 2-3°C to the inorganic carbonate calibrations, which point to as yet unknown coccolith-specific disequilibrium effects. All published biogenic studies fall within within  $\pm 1^\circ\text{C}$  of our coccolith-specific calibration if the original calcification temperatures are considered, while a cold bias and offsets of 1-2°C are present using the recalculated calcification temperatures of a recent study.

30 Thus, we suggest the use of our coccolith-specific calibration for further coccolith palaeoceanographic studies and that  
calibrations derived from laboratory-grown biogenic carbonates, in particular foraminifera, are desirable to reinforce the  
confidence of clumped isotope-based temperature reconstructions in palaeoceanography.

## 1 Introduction

35 Clumped isotope thermometry is a relatively new and increasingly used methodology for the reconstruction of  
paleotemperatures, palaeohydrology, diagenetic regimes, and as an isotopic tracer (see Huntington and Petersen, 2023 for a  
recent review). In a carbonate molecule, bonds between the rare heavy isotopes  $^{13}\text{C}$  and  $^{18}\text{O}$  can be formed and their excess  
abundance relative to a stochastic distribution is denominated as “clumping”, which increases with decreasing temperature.  
To measure this clumping, the carbonate is converted to  $\text{CO}_2$  by reaction with phosphoric acid, and the excess abundance of  
 $^{13}\text{C}^{18}\text{O}^{16}\text{O}$  (cardinal mass 47) in the released  $\text{CO}_2$  relative to a stochastic distribution is measured and reported as  $\Delta_{47}$  (Schauble  
40 et al., 2006; Eiler, 2007). In early studies, before the introduction of carbonate standardisation (Bernasconi et al. 2021),  $\Delta_{47}$  in  
different calibration studies of the same carbonate material had widely variable relationships with temperature. More recent  
studies (Petersen et al., 2019; Meinicke et al., 2020; Anderson et al., 2021) have shown that most but not all of these  
discrepancies were caused by poor interlaboratory comparability caused by the lack of a robust standardisation methodology  
(Bernasconi et al. 2018, 2021).

45 Based on these recent studies,  $\Delta_{47}$  has a consistent relationship with temperature and its temperature dependence is well  
established empirically at a large range of temperatures (e.g., Anderson et al., 2021; Fiebig et al., 2021). The  $\Delta_{47}$ -temperature  
relationship is independent of the carbon and oxygen isotope composition of the fluid from which carbonates precipitate  
(Ghosh et al., 2006). Empirical calibrations between temperature and  $\Delta_{47}$  have been established for temperatures between  $0^\circ\text{C}$   
and  $1100^\circ\text{C}$  for inorganic carbonates (Kele et al., 2015; Bonifacie et al., 2017; Kelson et al., 2017; Müller et al., 2019; Swart  
50 et al. 2019; Jautzy et al. 2020; Anderson et al., 2021). Further empirical studies on biogenic carbonates, such as for  
foraminifera, coccoliths, gastropods, and bivalves, have found similar relationships between  $\Delta_{47}$  and calcification temperature  
(Katz et al., 2017; Peral et al., 2018; Leutert et al., 2019; Piasecki et al., 2019; de Winter et al., 2022; Huyghe et al., 2022),  
although specific types of biogenic carbonates such as shallow-water corals (Spooner et al., 2016; Davies et al., 2022), juvenile  
bivalves (Huyghe et al., 2022), and brachiopods (Bajnai et al., 2018; Davies et al., 2023; Letulle et al., 2023) do not. However,  
55 there are clear discrepancies between most inorganic calibrations (Swart et al. 2019; Jautzy et al. 2020; Anderson et al., 2021;  
Fiebig et al., 2021) and an often used, generalised biogenic calibration (Meinicke et al., 2020). One interpretation is that this  
discrepancy results from uncertainties in the calculation of calcification temperatures for planktonic foraminifera and is  
resolved with alternate approach to calcification temperature estimation (Daëron and Gray, 2023). With this study using  
cultured coccoliths we generate biogenic carbonate under well-constrained temperature conditions, so there is little uncertainty  
60 in the calcification temperatures.

Other methodological problems can also limit the overall use of clumped isotopes. The relative abundance of  $\Delta_{47}$  to all isotopologues of  $\text{CO}_2$  is only  $\sim 45$  ppm, which requires a sample in the range of 80 to 120  $\mu\text{g}$  with Thermo-Fischer Kiel IV devices coupled to Thermo-Fischer 253 Plus mass spectrometers (Müller et al., 2017) to 2-10 mg for a single measurement with common acid bath systems (e.g. Ghosh et al., 2006; Kelson et al., 2017; Peral et al., 2018; Fiebig et al., 2021). As the analytical error in clumped isotope measurements is large compared to the natural variability, many replicates are needed to achieve an analytical uncertainty allowing meaningful interpretations in palaeoceanography (Bernasconi et al., 2021; Fernandez et al., 2017; Daëron, 2021). Sample size requirements can be a major limiting factor for biogenic calcite. Both limited abundance and time requirements for picking single species, limits the availability of planktonic foraminifera, and the need for sampling precise seasonal increments in slow-growing molluscs can also restrict the mass of carbonate available for analysis (Leutert et al., 2019; de Winter et al., 2022; Huyghe et al., 2022). Coccoliths are a promising alternative as they are often found in greater abundance and have a better preservation potential than foraminifera (Berger, 1973; Subhas et al., 2019). The abundance of coccolith-associated-polysaccharides both around and within the coccolith aid in protecting the coccolith calcite from dissolution and overgrowth, and remain in place for millions of years (Henriksen et al., 2004; Sand et al., 2014; Lee et al., 2016). Few anion substitutions and a lack of lattice defects on the coccolith surface further aid in a better preservation relative to foraminifera (Berman et al., 1993; Stoll et al., 2001; Fröhlich et al., 2015; Walker et al., 2019). Biogenic carbonates often feature carbon and oxygen isotopic compositions that differ from those expected for abiogenic carbonates near equilibrium, offsets informally called “vital effects”. Such offsets have been described for coccolith calcite (Ziveri et al., 2003; Rickaby et al., 2010; Ziveri et al., 2012; Candelier et al., 2013; Hermoso et al., 2014; Stevenson et al., 2014; Hermoso et al., 2016, Katz et al., 2017) and the contributing processes simulated in models (Langer et al., 2012; Ziveri et al., 2012; Bolton and Stoll, 2013; Holtz et al., 2017; McClelland et al., 2017). The vital effects limit the use of stable isotope signatures of coccolith calcite in palaeoceanography. However, initial studies of clumped isotopes in coccolithophorids found that while multiple coccolithophore species display clear carbon and oxygen vital effects, they follow previous  $\Delta_{47}$ -temperature calibrations (Drury and John, 2016; Katz et al., 2017), making them potentially useful for palaeoceanography. However, because these studies and calibrations were performed before carbonate standardisation (Bernasconi et al., 2021) and have a limited number of replicate analyses, robustness and interpretation of their conclusions need to be verified with new studies. Other aspects such as the dissolved inorganic carbon chemistry in the cultures and growth conditions as possible influences on  $\Delta_{47}$  also still need to be examined.

To this end, three species of calcifying coccolithophores were cultured under controlled temperature and carbonate chemistry conditions. A temperature range of 21°C and  $\text{CO}_{2(\text{aq})}$  range of 40  $\mu\text{M}$  was covered. Coccolithophores from the *Gephyrocapsa* genus were cultured between 6°C and 27°C, using the warm-adapted *G. oceanica* and the cold-adapted *G. muelleriae*. Inter-genus vital effects were tested through comparison with *Calcidiscus leptoporus*, which features distinct carbon and oxygen isotopic vital effects compared to *Gephyrocapsa* in previous studies (Ziveri et al., 2003; Hermoso et al., 2014; Katz et al., 2017). Finally, through comparison with a previous coccolith culture (Katz et al., 2017), inorganic (Anderson et al., 2021;

Daëron and Vermeesch, 2024), biogenic (Peral et al., 2018; Meinicke et al., 2020; de Winter et al., 2022), and recalculated  
95 (Daëron and Gray, 2023)  $\Delta_{47}$ -temperature calibrations, the potential need for a coccolith-specific calibration is assessed.

## 2 Materials and methods

### 2.1 Batch and continuous culture setup

Three monoclonal coccolithophore strains, *Gephyrocapsa oceanica* (RCC 1303), *Gephyrocapsa muelleriae* (RCC 3370), and  
*Calcidiscus leptoporus* (RCC 1130) obtained from the Roscoff Culture Collection were cultured at ETH Zürich. *G. oceanica*  
100 is an abundant cosmopolitan coccolithophore species that has been found at temperatures between 12-27°C but favours  
temperatures above 20°C (Sett et al., 2014; von Dassow et al., 2021). *G. muelleriae* is from the same genus as *G. oceanica*,  
favours colder and less saline conditions, and can grow at 6°C (von Dassow et al., 2021). *C. leptoporus* is a large  
coccolithophore, is especially abundant in low latitude upwelling settings, is resistant to dissolution and thus a major  
contributor to coccolith carbonate, and is known to have large isotopic vital effects (Thierstein and Young, 2004; Ziveri et al.,  
105 2007; Langer et al., 2012; Hermoso, 2014). Thus, the three strains were cultured to provide a temperature range of 21°C while  
also highlighting potential isotopic vital effects. *G. oceanica* was cultured in a turbidostat or continuous culture setup as seen  
in Fig. 1a, between a  $\text{CO}_{2(\text{aq})}$  of 5 and 45  $\mu\text{M}$  for at least two temperatures (Table 1). All three strains were grown in at least  
two temperatures in batch culture setup as seen in Fig. 1b, and provide a wide range of temperatures (Table 1).

All cultures were carried out in artificial seawater, following Kester et al. (1967), as the basis of a K/2 medium (Keller et al.,  
110 1987). The final pH and DIC were adjusted through addition of HCl and  $\text{Na}_2\text{CO}_3$  and covered a range of 40  $\mu\text{M}$  of  $\text{CO}_{2(\text{aq})}$   
values. A Tris buffer was not included for all experiments as this would interfere with the carbonate chemistry control. Prior  
to inoculation, the K/2 media was sterilized through an 0.2  $\mu\text{m}$  Millipore Stericup filter.

Before starting the experiments, the strains were maintained at a constant temperature of 18°C and slowly acclimatized to the  
experimental temperature for at least 4-6 generations. Cultures were inoculated at cell densities of  $\sim 5000$  cells  $\text{mL}^{-1}$  for *G.*  
115 *oceanica* and *G. muelleriae* and  $\sim 2000$  cells  $\text{mL}^{-1}$  for *C. leptoporus*.

Batch cultures were carried out in 1 or 2 L Nalgene polycarbonate sterile flasks with 50- and 100-mL headspace respectively  
and kept in a lit incubator set to the experimental temperature ( $\pm 0.1^\circ\text{C}$ ). For the duration of the experiments, the flasks were  
rotated on a roller set at 10 rpm to reduce settling and allow for uniform light exposure, see Fig. 1b. *C. leptoporus* did not grow  
under turbulent conditions and was manually shaken every day (Houdan et al., 2006). The cultures were illuminated by LED  
120 lights on a sinusoidal 14/10-hour light/dark cycle and a maximum luminosity of 120  $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ . Harvesting took  
place in a semi-continuous manner, where 80-90% of the total volume was harvested and then refreshed when the culture  
reached a set cell density ( $100\text{-}150 \times 10^3$  cells  $\text{mL}^{-1}$ ). In general, we used a higher cell density compared to previous culturing  
studies due to the larger sample material requirement for clumped isotope measurements. Yet each strain was maintained in  
their early- to mid-exponential phase to prevent a reservoir effect and an enriching of the  $\delta^{13}\text{C}$  of the media ( $\delta^{13}\text{C}_{\text{DIC}}$ ) relative  
125 to the initial conditions (Barry et al., 2012; Hermoso, 2014). Certain batch and continuous cultures had a higher cell density

and significant drift in the DIC, pH, or CO<sub>2(aq)</sub> over the course of the experiment and serve to test the sensitivity of vital effects to a varying carbon system.

Continuous cultures were performed in 1L (FMT 150/1000) or 3L (FMT 150/3000) photobioreactor (PBR) connected to a PP600 peristaltic pump and a GMS 150 gas mixing system (Photon Systems Instruments, Drásov, Czech Republic), see Fig. 1a. For a more detailed description of the experimental setup see Zhang et al. (2022). The strains were illuminated with LEDs on a 16/8-hour light/dark cycle with a maximum luminosity of 200 μmol photons m<sup>-2</sup>s<sup>-1</sup>. The optical density (OD), which is proportional to the cell density, was calibrated to a zero point before inoculation. With continuous OD monitoring and (sub-)daily measurements of the cell density, the OD could be set to a cell density threshold between 100 and 200 x 10<sup>3</sup> cells mL<sup>-1</sup>. If the OD exceeded this threshold, the peristaltic pump pumped fresh media into the PBR equivalent to 10% of the culture volume, and media from inside the PBR was pushed into the outflow bottle. Ambient air was first scrubbed of CO<sub>2</sub> and then passed through a gas mixing system with a set amount of CO<sub>2</sub> with a constant composition (δ<sup>13</sup>C = -14.36 ± 0.06‰ VPDB; δ<sup>18</sup>O = 19.85 ± 0.14‰ VSMOW). Thus, the pCO<sub>2</sub> was controlled and maintained at a constant level, which was checked at the beginning and end of each experiment. Temperatures were continuously controlled with a pH-temperature probe in the vessel, which kept a constant temperature with <0.1°C deviation through Peltier-elements at the bottom of the vessel.

Cell density and size were measured using a Z2 Coulter Particle Counter and Size Analyzer with an aperture size of 100 μm (Beckman Coulter, Inc., Brea, California, United States), which were used to determine growth rates. Cell counts were taken systematically every 24 hours with an extra measurement taken before and after harvest.

The net growth rate for batch cultures were calculated as:

$$\mu = \frac{\ln(N_t) - \ln(N_0)}{t - t_0} \quad (1)$$

where N<sub>t</sub> is the cell count at time t (in days) and N<sub>0</sub> is the initial cell count.

For continuous cultures, the dilution rate, which equates to the volume of the output (V<sub>out</sub>) over the volume of the PBR over time t also needs to be considered:

$$\mu = \frac{\ln(N_t) - \ln(N_0) + \frac{V_{out}}{V_{PBR}}}{t - t_0} \quad (2)$$

Cells were harvested by centrifugation at 4000 rpm for 5 minutes. The pellet containing coccoliths was rinsed with deionized water to remove traces of salts by 4 cycles of centrifugation and removal of the supernatant. Subsequently, the wet pellet of organic matter and coccoliths was transferred to a 2 mL vial, which was then stored at -20°C for later analysis.

At the beginning, at each harvest, and at the end of an experiment, 12 mL of water were sampled for pH and cell density measurement. Each aliquot was centrifuged once at 4000 rpm for 5 minutes, and the supernatant was used for DIC, δ<sup>13</sup>C<sub>DIC</sub>, and δ<sup>18</sup>O<sub>SW</sub> measurements. Some batch and continuous cultures were kept until higher cell densities were reached. In these cases, pH, DIC, and δ<sup>13</sup>C<sub>DIC</sub> were measured more often to track the evolutions from initial conditions as a result of cell growth and cell density increase.

## 2.2 Sample cleaning

Contaminants from organic matter or sulphur compounds contained within carbonates are known to interfere with the clumped isotopic measurements for carbonates (Eiler and Schauble, 2004; Dennis and Schrag, 2010). In this study we used three methodologies for the removal of possible contaminants from the coccolith pellet. Initially the aliquots were dried in a 60°C oven for at least 4 hours to remove any remaining water that could dilute the cleaning reagents. Then one of three cleaning methodologies was performed.

One method used oxidation of the organic matter through reaction with a 18% H<sub>2</sub>O<sub>2</sub> solution neutralized with NaOH to pH 8-9 following the protocol of Falster et al. (2018). The second methodology used a solution of 10% H<sub>2</sub>O<sub>2</sub> neutralized with NH<sub>3</sub> to pH 8-9. For both solutions the pellets were reacted overnight at room temperature and then rinsed 4-5 times with milli-Q until a neutral pH of 7 was obtained. The third method used is Total Lipid Extraction (TLE), following Matyash et al. (2008). The pellets were first suspended in 1 mL of isopropanol and homogenized through vortexing and sonication until there were no visible clumps. 3 mL of methyl-tert-butyl ether were added and the total solution was again vortexed. 1 mL of DI water was added and the sample was centrifuged at 4000 rpm for 5 minutes. This method removes the polar and apolar organic compounds from the pellet into the upper 4 mL of the solution. This supernatant is subsequently discarded, while maintaining a 1 mL of aqueous phase with the cleaned coccolith pellet at the bottom. When abundant organic matter was still visible after one cycle of cleaning, the procedure was repeated. After all three cleaning methodologies, the samples were dried at 60°C for at least 4 hours.

In order to confirm the effectiveness of the different cleaning methodologies and their effect on the coccolith carbonate, high resolution scanning electron images were taken using a JSM-7100F JEOL Scanning electron Microscope (SEM) at ScopeM, ETH Zürich, see Fig. S1. As harvested from the cultures, all coccoliths exhibited regular morphology with no evidence of coccolith malformation. The cleaning protocol causes slight dissolution, fragmentation, and breakage of some of the coccoliths.

## 2.3 Isotope measurements

### 2.3.1 Coccolith carbon, oxygen, and clumped isotopes

Carbon, oxygen, and clumped isotopes from the cultured coccoliths were measured on two ThermoFisher Scientific mass spectrometers, a MAT253 and a 253Plus, coupled to Kiel IV preparation devices as described in Müller et al. (2017). Aliquots of 110-180 µg of sample and carbonate standards (ETH-1, 2, 3, and IAEA C2) were measured with a Kiel device at 70°C. The samples were reacted for 300 seconds with three drops of 104% phosphoric acid, and the released CO<sub>2</sub> was immediately frozen in a liquid nitrogen (LN<sub>2</sub>) trap kept at -190°C. After the sample was reacted fully, the first LN<sub>2</sub> trap is heated to -100°C, and the CO<sub>2</sub> gas was transferred through a 10 mm PorapakQ (50-80 mesh) to a second LN<sub>2</sub> trap kept at -190°C. The PorapakQ tubing was coated with Sulfinert 2000, stuffed with silver wool, and kept at -40°C to capture and eliminate possible organic contaminants. The second LN<sub>2</sub> trap was then heated to room temperature and measured using the Long Integration Dual Inlet protocol (Hu et al., 2014, Müller et al., 2017). The initial gas intensity of the sample gas is recorded and then immediately

measured for 400 seconds, 40 cycles of 10 seconds. Subsequently, the reference gas is measured for the same duration starting  
190 at the same initial gas intensity. Before measuring, background scans at different beam intensities were carried out to determine  
the pressure dependent background on all beams (Bernasconi et al., 2013; Meckler et al., 2014). Using the Easotope software  
(John and Bowen, 2016) a pressure-sensitive baseline correction was applied, and raw carbon and oxygen values were  
converted to VPDB using the Brand parameters as suggested by Daëron et al. (2016). Further, the raw vs accepted  $\Delta_{47}$  values  
for the carbonate standards and an empirical transfer function were used to convert and normalize the sample  $\Delta_{47}$  data to the  
195 Intercarb carbon dioxide equilibrium scale (I-CDES; Bernasconi et al., 2021).

Each individual reported clumped isotope value consists of at least 10 replicates, with an average of 13 replicates. Long-term  
accuracy and reproducibility of the  $\Delta_{47}$  measurements were evaluated based on monitoring of the IAEA-C2 international  
carbonate standard, which was treated as an unknown sample (MAT253:  $\Delta_{47} = 0.6385 \pm 0.034$ , MAT253 Plus:  $\Delta_{47} = 0.6411 \pm$   
 $0.026\text{‰}$ ;  $1\sigma$  n=241) and fit within the accepted values ( $0.6409\text{‰} \pm 0.003\text{‰}$ ; Bernasconi et al., 2021). Analytical errors are  
200 reported at the 95% confidence interval (Fernandez et al., 2017) without taking into account the standardisation error. However,  
as the measurements are carried out with a 50:50 standard to sample ratio, the additional uncertainty related to standardisation  
would be small (Bernasconi et al. 2021).

### 2.3.2 DIC and seawater carbon and oxygen isotopes

DIC and pCO<sub>2</sub> were measured on a Picarro G-2131-i Cavity Ringdown Spectrometer (Picarro Inc, USA) coupled to a AS-D1  
205 DIC- $\delta^{13}\text{C}$  Analyzer (Apollo Scitech, USA). For DIC measurements, 3 mL of centrifuged media were taken and reacted within  
the AS-D1 analyser with 0.9 mL of a 3% H<sub>2</sub>PO<sub>4</sub> and 7% NaCl solution. The absolute DIC concentration was found through  
quantification of the extracted CO<sub>2</sub> concentration as described in Deng et al. (2022). A threshold of  $\leq 20$  ppm pCO<sub>2</sub> for  
background synthetic air (80% N<sub>2</sub>, 20% O<sub>2</sub>; PanGas) was first defined. After at least 10 measurements of background air below  
this threshold, the stable baseline was reached and the sample is injected into the measuring chamber. As the extracted CO<sub>2</sub>  
210 flows into the measuring chamber, measurements of pCO<sub>2</sub> were taken every 3-5 seconds until all of the extracted CO<sub>2</sub> had  
passed through the measuring chamber, and the stable baseline was reached again. For the absolute DIC concentration, the  
integrated area of pCO<sub>2</sub> between the two baselines is plotted against the total DIC content. The latter is defined as the volume  
multiplied by the measured DIC. A Certified Reference Material, NOAA batch 186 with a known absolute DIC concentration  
of 2012  $\mu\text{M}$ , is used for calibration. Through variation of the Certified Reference Material volume, a range of integration areas  
215 and total DIC content was obtained and internally defined. Two secondary standards with calibrated DIC concentrations were  
also used. Each measurement was repeated twice with the same centrifuged media in quick succession to reduce CO<sub>2</sub> exchange  
with the atmosphere, which gave an average DIC and uncertainty for each measured replicate. At least three of these replicates  
were taken and measured for each experiment.

For  $\delta^{13}\text{C}_{\text{DIC}}$  measurements, 1 mL of centrifuged media was acidified with 150 $\mu\text{L}$  of 104% H<sub>2</sub>PO<sub>4</sub> in a He-flushed vial.  
220 Subsequently the  $\delta^{13}\text{C}_{\text{DIC}}$  was measured on a Gasbench II coupled to a Delta V Plus mass spectrometer (Thermo Fischer

Scientific, USA). Two in-house NaHCO<sub>3</sub> standards dissolved in deionized water with δ<sup>13</sup>C<sub>DIC</sub> values of -4.66‰ and -7.94‰ were used.

The oxygen isotopic composition of the seawater (δ<sup>18</sup>O<sub>sw</sub>) was measured on a Picarro L2130-*i* Isotope Wavelength-Scanned Cavity Ring-Down Spectrometer following Gupta et al. (2009). The water sample is first passed through a salt catchment trap, vaporized, and injected at a uniform concentration and flow rate into the Picarro spectrometer. This delivers a pulse with a constant concentration profile, during which the δ<sup>2</sup>H and δ<sup>18</sup>O are measured. Three in-house standards calibrated to three IAEA and USGS standards (SLAP2, GRESP, and VSMOW2) were run every 20 samples. Another in-house standard is run as an unknown sample. All standards fell within 1 standard deviation of their accepted value. Measurement precision was affected by the residual salt from the seawater. At least two seawater measurements were taken for each experiment. Subsequently an average δ<sup>18</sup>O<sub>sw</sub> and uncertainty (mean σ=0.32‰) for each condition was obtained, see Table S1. This uncertainty is used for the uncertainty of the oxygen isotope offset from seawater, δ<sup>18</sup>O<sub>c</sub> – δ<sup>18</sup>O<sub>sw</sub> (Δ<sup>18</sup>O<sub>c-sw</sub>) as reported in Table 1, and will be used in subsequent figures (mean σ=0.29‰).

pH measurements were made using a Mettler Toledo LE410 pH-probe (Mettler Toledo, Greifensee, Switzerland) and were calibrated with three NBS standards (pH=4.00, 7.01, 9.03 at 21°C), with a standard deviation of ±0.01. All pH measurements are given in the NBS scale. Seawater carbon chemistry was calculated through CO2SYS (Lewis and Wallace, 1998), with input of measured pH and DIC, and using the K1, K2 constants of Leuker et al. (2000), KHSO<sub>4</sub> of Dickson (1990), KHF of Perez and Fraga (1987), and [B]<sub>I</sub> value of Lee et al. (2010).

DIC and pH measurements are compared and normalized to the initial measured values to detect potential drift and stability of the carbon chemistry of each culture. These are reported as initial DIC – measured DIC (Δ<sub>DIC</sub>) and initial pH – measured pH (Δ<sub>pH</sub>) in Table S1. We report the uncertainty of the fractionation between coccolith calcite and DIC (Δ<sup>13</sup>C<sub>c-DIC</sub>) from both the standard deviation of δ<sup>13</sup>C<sub>c</sub> and the range of all measured δ<sup>13</sup>C<sub>DIC</sub> over the course of the sampled culture, to take into account the potential effect of DIC evolution and drift, and will be used in subsequent figures.

The same media was used for both batch and continuous cultures and thus the same δ<sup>13</sup>C<sub>DIC</sub> would be expected for both. However, through the continuous bubbling and gas-exchange in the continuous cultures, there is a potential for different δ<sup>13</sup>C<sub>DIC</sub> values than the batch culture setup. Indeed, there is a non-systematic enrichment of 0-1‰ for the batch culture δ<sup>13</sup>C<sub>DIC</sub>. However, the fractionation between coccolith calcite and DIC i.e. Δ<sup>13</sup>C<sub>c-DIC</sub>, is not affected by these differences.

An often-used index in coccolithophore geochemistry studies (McClelland et al., 2017; Phelps et al., 2021) for the relative usage of carbon supply and demand is the dimensionless τ:

$$\tau = \frac{r * \rho * \mu}{3 * CO_{2(aq)} * P_c} \quad (3)$$

It reflects the degree of carbon utilization by the coccolithophore as measured through growth rate (μ), defined in Eqs. 1 and 2 for batch and continuous culture setup respectively, the cell radius (r), and cellular carbon density (ρ) against the diffusive CO<sub>2</sub> supply into the cell set by (CO<sub>2(aq)</sub>) and the permeability to CO<sub>2</sub> (P<sub>c</sub>). We use a P<sub>c</sub> of 1.4 x 10<sup>-3</sup> μm day<sup>-1</sup> (Blanco-Ameijeiras et al., 2020) and ρ of 2 x 10<sup>-3</sup> μM (McClelland et al., 2017). It is assumed that there is only a diffusive supply of CO<sub>2</sub> into the

cell. Our cell size measurements assume a perfect coccusphere for each counted cell, which results in a coccusphere radius  
255 that is slightly different than the cell radius. This is taken into account, together with uncertainties in  $\mu$  and  $\text{CO}_{2(\text{aq})}$ , into the  
uncertainty of the final  $\tau$  value.

Pearson correlation coefficients ( $\rho$ ) are used to determine whether two parameters are linearly correlated. If the  $\rho$  value is near  
1 or -1, there is a strong correlation and one parameter has an effect on the other. Weak correlations are here defined as  $\rho \leq$   
 $\pm 0.40$  and significance is given by a p-value  $< 0.05$ .

## 260 **3 Results**

### **3.1 Carbon chemistry**

#### **3.1.1 DIC, pH, and $\text{CO}_{2(\text{aq})}$**

The stability of the carbon chemistry was monitored with at least three DIC and pH measurements for each culture. Drift from  
the initial conditions was less than  $\pm 20\%$  and  $\pm 0.20$  for  $\Delta_{\text{DIC}}$  and  $\Delta_{\text{pH}}$  respectively for 40 culture experiments (Fig. S2 and Table  
265 S1). To ensure only well-constrained culture conditions are considered, fifteen experiments with  $\Delta_{\text{DIC}} \geq 20\%$  or  $\Delta_{\text{pH}} \geq 0.20$  are  
excluded from our main analysis in Figs. 2 through 5, but are evaluated in a subsequent comparison (see Sect. 4.3).

#### **3.1.2 Carbon isotopes**

The carbon isotope composition of the DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) varies between  $-5.10\%$  and  $0.80\%$ , with a similar large range of  $-5.52\%$   
and  $-0.07\%$  for all species' coccolith carbon isotopes ( $\delta^{13}\text{C}_c$ ; Table S1). This is mostly due to the large variability in  $\delta^{13}\text{C}_c$  for  
270 *G. oceanica*, which can be attributed to the range of different experimental conditions. The  $\delta^{13}\text{C}_c$  in *G. muelleriae* varies  
between  $-4.68\%$  and  $-3.66\%$ , while the  $\delta^{13}\text{C}_c$  in *C. leptoporus* varies between  $-5.15\%$  and  $-5.04\%$ .

The fractionation  $\Delta^{13}\text{C}_{c\text{-DIC}}$  ranges between  $-1.41\%$  and  $1.22\%$  for *G. oceanica*,  $-0.88\%$  and  $0.21\%$  for *G. muelleriae* and  $-$   
 $2.86\%$  and  $-2.22\%$  for *C. leptoporus*. No significant linear correlations were identified between *Gephyrocapsa*  $\Delta^{13}\text{C}_{c\text{-DIC}}$  and  
275 carbonate system parameters (DIC, pH,  $\text{CO}_{2(\text{aq})}$ ) or culture parameters (cell density and  $\Delta_{\text{DIC}}$ ) (Table S2). *Gephyrocapsa* culture  
data is also not significantly correlated with  $\tau$ , the index of carbon demand vs supply (Fig. 2;  $\rho = 0.06$ , p-value = 0.74).  
Including *Calcidiscus* does not improve the correlation or significance with any parameter apart from  $\Delta_{\text{DIC}}$ .

### **3.2 Oxygen isotopes**

The  $\delta^{18}\text{O}_{\text{sw}}$  are given in Table S1 for all cultures and vary by  $\sim 1.6\%$  across with no systematic differences between batch and  
continuous cultures. For a given temperature, *C. leptoporus* has systematically lower  $\delta^{18}\text{O}_c$  values by  $\sim 3\%$  while *G. oceanica*  
280 and *G. muelleriae* have similar  $\delta^{18}\text{O}_c$  values at the same temperature. The interspecies variations are independent of culture  
setup and experimental condition.

The oxygen isotope offset from seawater,  $\delta^{18}\text{O}_c - \delta^{18}\text{O}_{\text{sw}}$  ( $\Delta^{18}\text{O}_{\text{c-sw}}$ ), varies systematically for all experimental conditions as seen in Fig. 3 and Table 1. *Calcidiscus* has a systematic offset of  $\sim 3\%$  relative to *Gephyrocapsa* at the cultured growth temperatures, which agrees with previous culturing studies (Ziveri et al., 2003; Candelier et al., 2013; Stevenson et al., 2014; Hermoso et al., 2016; Katz et al., 2017). For *G. oceanica*, there is a significant negative correlation between  $\Delta^{18}\text{O}_{\text{c-sw}}$  and temperature ( $\rho = -0.94$ , p-value  $< 0.05$ ), which remains when including *G. muelleriae* ( $\rho = -0.97$ , p-value  $< 0.05$ ). The  $\Delta^{18}\text{O}_{\text{c-sw}}$ -temperature relationship is consistent between setups and experimental conditions and is not influenced by the variability in  $\delta^{18}\text{O}_{\text{sw}}$  values. The available data indicate that the range of  $\Delta^{18}\text{O}_{\text{c-sw}}$  is similar within the *Gephyrocapsa* genus.

### 3.3 Clumped isotopes

The  $\Delta_{47}$  values are shown in Table 1 and Fig. 4, and range from  $0.589\%$  –  $0.640\%$  for temperatures between  $12\text{--}27^\circ\text{C}$  for *G. oceanica*,  $0.618\%$  –  $0.659\%$  between  $6\text{--}18^\circ\text{C}$  for *G. muelleriae*, and  $0.636\%$  –  $0.652\%$  at  $12^\circ\text{C}$  for *C. leptoporus*. There is variation of  $\sim 25$  ppm at given experimental conditions, in particular at  $21^\circ\text{C}$  and  $24^\circ\text{C}$ , although all datapoints fall within the long-term standard deviation of the standards used for correction of  $0.020\%$ . There is no resolvable difference between species or genus at given temperatures; differences are within  $\pm 0.016\%$  of each other.

## 4 Discussion

For our culture experiments, in order to evaluate whether processes promoting variable stable isotope effects would systematically affect  $\Delta_{47}$ , we manipulated the media carbonate chemistry in ways that have produced variable stable isotope vital effects in coccoliths in previous cultures. We also contrasted two coccolith genera that exhibit different ranges of vital effects. Multiple physiological explanations for coccolith vital effects have been proposed (Rickaby et al., 2010; Moolna and Rickaby, 2012; Hermoso et al., 2014, 2016) and simulated previously in cellular models (Ziveri et al., 2012; Bolton and Stoll 2013; Holtz et al., 2015, 2017; McClelland et al., 2017). In our discussion, in Section 4.1 and 4.2 we briefly summarize these mechanisms, and quantify the vital effect in each experiment, so that in section 4.3 we may compare the vital effect to the  $\Delta_{47}$  variations. The focus of this study is the calibration of the temperature dependence of  $\Delta_{47}$  in coccolith calcite. Therefore, we will only briefly discuss the causes and mechanisms leading to isotopic disequilibrium in the cultures, focusing in particular on those that could also affect  $\Delta_{47}$ .

### 4.1 Oxygen isotope vital effects in coccolith calcite

At a given temperature, equilibrium oxygen isotope fractionation between calcite and water is inferred to be most closely represented by natural carbonates precipitated at extremely slow rates and independent of pH (Coplen, 2007; Daëron et al., 2019). The model of Watkins et al. (2013, 2014) approximates this equilibrium, and is shown as the ‘equilibrium limit’ in Fig. 3. This approximation is derived from their experimental setup, which is not necessarily in equilibrium, and therefore potential

small growth rate and pH effects are still present. Non-equilibrium fractionation effects between DIC and calcite that manifest at faster growth rates in experiments both with and without carbonic anhydrase (CA) include lower  $\Delta^{18}\text{O}_{\text{c-w}}$ , and a pH-dependence. This effect presumably but not necessarily occurs because calcite forms from both bicarbonate and carbonate ions in proportion to their abundance in solution. At a higher pH the proportion of calcite carbon derived from the carbonate ion increases (McConnaughey, 1989; Clark et al., 1992; Dietzel et al., 1992; Zeebe and Wolf-Gladrow, 2001; Watkins et al., 2014; Devriendt et al., 2017). Here, a pH of 8.3 at the crystallisation-site and the fastest growth rate is assumed in the model of Watkins et al. (2013, 2014) and Watkins and Devriendt (2022), with which the ‘kinetic limit’ is derived and illustrated in Fig. 3. This gives an approximate 2‰ offset and incorporates a large range of experimentally derived and modelled inorganic calcites precipitated in presence of CA. Additionally, numerous experiments and potentially many natural biogenic and abiogenic systems may precipitate calcite from a solution in which equilibrium between DIC and  $\text{H}_2\text{O}$  is not maintained due to a lack of CA or fast calcification rates (Devriendt et al., 2017; Daëron et al. 2019). Rayleigh fractionation of oxygen isotopes in the internal DIC pool occurs as a result, which is transferred to the isotopic composition of the calcite and leads to lower  $\Delta^{18}\text{O}_{\text{c-w}}$  values, thus exacerbating the disequilibrium fractionation potentially present between the DIC and calcite as described above.

Recent studies suggest that in certain systems such as synthetically precipitated calcite, oxygen isotope disequilibrium does not affect  $\Delta_{47}$ , even for systems with intermediate oxygen isotope fractionations that fall between the kinetic and equilibrium limits, as seen in Fig. 3 (Kelson et al., 2017; Levitt et al., 2018; Jautzy et al., 2020; Fiebig et al., 2021). Models also suggest little to no  $\Delta_{47}$  disequilibrium for biogenic carbonates such as foraminifera and bivalves, as the magnitude of potential  $\Delta_{47}$  disequilibrium is below the current analytical resolution for  $\Delta_{47}$  measurements although this is pH and growth rate dependent (Defliese and Lohmann, 2015; Watkins and Hunt, 2015; Watkins and Devriendt, 2022). However, this does not hold for corals, brachiopods, and speleothems, where systematic  $\delta^{18}\text{O}$  and  $\Delta_{47}$  disequilibria are present, and should be explored further in more biogenic carbonates (Watkins and Hunt, 2015; Guo and Zhou, 2019, Guo, 2020).

Offsets from the equilibrium limit ( $\Delta\Delta^{18}\text{O}_{\text{off}}$ ) were calculated to quantify the vital effect in oxygen isotopes. Offsets may potentially arise from pH variability, growth rate, calcification rate, or disequilibrium within the DIC- $\text{H}_2\text{O}$  system. *Calcidiscus* is significantly different from equilibrium (t-test;  $t(4) = -58.68$ , p-value  $<0.05$ ) and falls outside the equilibrium and kinetic limits as seen in Fig. 3. Although for *Gephyrocapsa* the mean  $\Delta\Delta^{18}\text{O}_{\text{off}}$  value is around zero and there is no significant difference from the abiogenically defined equilibrium (t-test;  $t(72) = -0.47$ , p-value = 0.64), there is a range of  $\sim 1.5\%$  in  $\Delta\Delta^{18}\text{O}_{\text{off}}$  among different experiments. Previously published *Gephyrocapsa* data has a positive  $\Delta\Delta^{18}\text{O}_{\text{off}}$  of 0-1‰ (Fig. 5; Ziveri et al., 2003; Hermoso et al., 2016).

CA has been suggested as a potential equilibration catalyst for both oxygen isotopes and  $\Delta_{47}$  within the DIC- $\text{H}_2\text{O}$  system in calcifying organisms. Even at an elevated pH, the equilibration time is shortened considerably for abiogenic carbonates precipitated in the presence of CA (Uchikawa and Zeebe, 2012; Kelson et al., 2017). A lack or low activity of CA can potentially cause the variable  $\Delta\Delta^{18}\text{O}_{\text{off}}$  seen in our data. While the pH of the intracellular calcification site for coccoliths is not well constrained, there is experimental evidence for CA in the biomineralization pathway of *Emiliania huxleyi* (Zhang et al.,

345 2021). Although CA has not been explicitly found in *Gephyrocapsa*, it is associated with the cytosol, chloroplast, or extracellularly in other coccolithophores (Nimer et al., 1994; Elzenga et al., 2000; Herfort et al., 2002; Rost et al., 2003). Furthermore, genes have been found associated with biomineralization and CA expression in *E. huxleyi* (Quinn et al., 2006; Soto et al., 2006; Richier et al., 2011). Models show a requirement of CA activity in the calcification pathway of coccolithophores, either in the cytosol or coccolith vesicle itself, as a purely uncatalyzed exchange would have too enriched carbon isotope values in the coccolith calcite (Holtz et al., 2015; McClelland et al., 2017). Thus, it is probable that CA is present in coccolithophores. However, the activity of CA is not well constrained so it remains uncertain whether it is sufficient to ensure full equilibration of the DIC-H<sub>2</sub>O system for both oxygen isotopes and  $\Delta_{47}$ .

For *Gephyrocapsa*, the 1.5‰ range in  $\Delta\Delta^{18}\text{O}_{\text{off}}$  also did not correlate with pH, growth rate, DIC, CO<sub>2(aq)</sub>, or  $\tau$  (Figs. S4, S5; Table S2). The 1.5‰ range in  $\Delta\Delta^{18}\text{O}_{\text{off}}$  may be explained by varying degrees of isotopic equilibration between the DIC pool and intracellular water in different experiments. Non-systematic disequilibria effects could be present for our continuous culture setup as the equilibration time for oxygen isotopic exchange between our bubbled CO<sub>2</sub> gas and the seawater media is in the order of hours (Zeebe and Wolf-Gladrow, 2001; Uchikawa and Zeebe, 2012). In support of this interpretation, there is a difference of ~0.5‰ between all continuous and batch culture  $\Delta\Delta^{18}\text{O}_{\text{off}}$  (t-test; t(38) = 1.76, p-value = 0.09, Fig. 5, Table S1). Further variability in  $\Delta\Delta^{18}\text{O}_{\text{off}}$  could be a result of variable intracellular pH and/or varying calcification rates as well as the presence and activity of CA. However, these physiological variations do not exhibit systematic relationships with the individual environmental parameters such as growth rate, external pH, or carbonate system. This suggests a potential for complex co-regulation of the physiological factors and/or multiple environmental controls, which are best evaluated by cellular models and beyond the scope of this study.

#### 4.2 Carbon isotope vital effects in coccolith calcite

365 In this study (Fig. 5), all continuous (and most batch) cultures for *G. oceanica* fall within the expected range of  $0 \pm 1.5\%$  for  $\Delta^{13}\text{C}_{\text{c-DIC}}$  as found in other studies (see Fig. S3; Rickaby et al., 2010; Moolna and Rickaby, 2012; Hermoso, 2014; Katz et al., 2017). There are no comparable culture studies for *G. muelleriae*. The  $\Delta^{13}\text{C}_{\text{c-DIC}}$  values fall within the range of *G. oceanica*. Both species will be combined in any inter-genera analyses for Sect. 4. *C. leptoporus* has a  $\Delta^{13}\text{C}_{\text{c-DIC}}$  of  $-2.0 \pm 1.0\%$  comparable to previous culturing studies (Fig. 5; Ziveri et al., 2003; Hermoso et al., 2014; Katz et al., 2017).

370 Models of the vital effect in coccolith carbon simulate multiple processes affecting  $\Delta^{13}\text{C}_{\text{c-DIC}}$  (Bolton and Stoll, 2013; Holtz et al., 2017; McClelland et al., 2017). The carbon utilization (or demand) as a function of the supply, termed  $\tau$ , is an index used to describe changes in cellular carbon uptake (relative significance of diffusive CO<sub>2</sub> uptake vs active HCO<sub>3</sub><sup>-</sup> uptake), and depletion of the intracellular dissolved carbon pool that impact the carbon isotopic fractionation (Eq. 3, Fig. 2). The cellular calcification (particulate inorganic carbon; PIC) relative to photosynthesis (particulate organic carbon; POC) is described as the PIC:POC ratio. The PIC:POC intensity will modulate the  $\Delta^{13}\text{C}_{\text{c-DIC}}$  response to  $\tau$ . For moderate to heavily calcified cells with relatively high PIC:POC ratios, models simulate a decrease in  $\Delta^{13}\text{C}_{\text{c-DIC}}$  with increasing  $\tau$ , for example as might be triggered by decreasing concentrations of CO<sub>2(aq)</sub> (Eq. 3, Fig. 2). However, lightly calcified cells with PIC:POC of 0.5 exhibit

a slight increase in  $\Delta^{13}\text{C}_{\text{c-DIC}}$  with increasing  $\tau$ , while cells with PIC:POC near 1 have  $\Delta^{13}\text{C}_{\text{c-DIC}}$  nearly insensitive to  $\tau$ . The *G. oceanica* in our experiments feature a range of PIC:POC ratios from 0.4 to 1.3 (Torres-Romero et al., 2024A), which likely contributes to the absence of a single clear trend between  $\Delta^{13}\text{C}_{\text{c-DIC}}$  and  $\tau$ . We have not determined the PIC:POC in our *Calcidiscus*, but it is generally characterized by a PIC:POC of 1.2-2.3 (Langer et al., 2006, 2012; Bolton and Stoll, 2013.). The lower  $\Delta^{13}\text{C}_{\text{c-DIC}}$  of *Calcidiscus* correlate with lower  $\Delta\Delta^{18}\text{O}_{\text{off}}$  (Figure 5), as observed in size fractions from sediments (e.g. Bolton and Stoll, 2013), but the physiological mechanism of this correlation has not yet been quantitatively explored in a coupled model of carbon and oxygen isotope fractionation in coccoliths.

### 385 4.3 Calibration of coccolith clumped isotopes and temperature

Despite the significant vital effects in carbon and oxygen isotopes, our coccolith  $\Delta_{47}$  values show a consistent relationship with temperature (Fig. 6), which is similar to previous calibration studies (see Sect. 4.4, 4.5). In order to calculate a reliable coccolith  $\Delta_{47}$ -temperature regression, we used a simple least-squares fitting following Williamson (1968) and York et al. (2004), using the Excel spreadsheet by Cantrell (2008). This methodology considers the uncertainties from both the  $\Delta_{47}$  and temperature measurements. While the omni-variant generalised least squares regression would be better suited, as this incorporates the full error covariance (Daëron and Vermeesch, 2024), our data is standardised through reference materials in a moving time window and thus cannot be analysed through this method. As pointed out in a number of studies (Bonifacie et al., 2017; Fernandez et al., 2017; Katz et al., 2017; Kelson et al., 2017; de Winter et al., 2022), the bias from a low number of analytical replicates and the small temperature range can lead to significant differences in calibration slope and intercepts. In order to determine potential species- or genus-dependent effects, an unorthodox approach was initially tested. *G. oceanica* contains the most diverse and largest range of temperature datapoints, while *C. leptoporus* only contains one temperature point and three  $\Delta_{47}$  data points. Thus, the other two species' datasets will be successively included and evaluated for significance relative to the *G. oceanica* dataset. Further, each biological and technical  $\Delta_{47}$  sample and uncertainty are taken individually as to have an equal contribution of each datapoint to the final calibration. The initial uncertainty of 0.1°C for temperature is 0.018 K<sup>-2</sup> after conversion to 1/T<sup>2</sup>. The resulting slopes and intercepts of the  $\Delta_{47}$ -temperature regressions are seen in Table 2. With the successive inclusion of the two other species, there is no significant change or offset in slope or intercept relative to the initial *G. oceanica* regression. All regression lines fall within 0.0012‰ error of each other, which shows that with the available data there is no species- or genus-specific vital effect on the  $\Delta_{47}$ -temperature relationship.

Secondly, we tested the potential influence of variable carbonate chemistry and the carbon and oxygen “vital effects” on the  $\Delta_{47}$ -temperature relationship. To this end, we normalized our  $\Delta_{47}$  data against the Meinicke et al. (2020)  $\Delta_{47}$ -temperature calibration at each temperature to generate residual values ( $\Delta\Delta_{47,\text{off}}$ ). Pearson correlation tests were then performed for the normalized  $\Delta\Delta_{47,\text{off}}$  residual values against the different carbonate chemistry parameters. The resulting Pearson correlation coefficients are shown in Table 3. Apart from a weak non-significant, positive and negative correlation for the batch and continuous culture setup  $\Delta\Delta_{47,\text{off}}$  and pH respectively and a moderate but significant positive correlation between the continuous culture setup  $\Delta\Delta_{47,\text{off}}$  and  $\Delta\Delta^{18}\text{O}_{\text{off}}$ , there are no conclusive or significant correlations for all measurements and

experimental setups. There is no significant difference in the normalized  $\Delta\Delta_{47,off}$  values between batch and continuous culture setups (t-test;  $t(38) = 0.35$ , p-value = 0.73), further indicating that carbonate chemistry does not have an effect on the measured  $\Delta_{47}$  value. The non-significant correlation in  $\Delta^{13}C_{c-DIC}$  and  $\Delta\Delta_{47,off}$  for all setups, shows that there is no carbon isotope vital effect affecting the coccolith  $\Delta_{47}$ -values (Fig. S6). While there is a moderate, significant positive correlation between  $\Delta\Delta^{18}O_{off-}$   
415  $\Delta\Delta_{47,off}$ , it is only present for the continuous culture setup and has an  $r^2$  of 0.20. Thus, there is no evidence of an important impact of the oxygen isotope vital effect on coccolith  $\Delta_{47}$ -values.

Thirdly, average  $\Delta_{47}$  values were calculated for each species at every growth temperature. These temperature-weighted averages can highlight bias from a low number of measurement replicates at certain growth temperatures, such as at 6°C and 27°C. The resulting  $\Delta_{47}$ -temperature regression is indistinguishable from regressions using individual  $\Delta_{47}$  sample datapoints  
420 ( $\pm 6.1$  ppm; Table 2).

Lastly, if there are no species-specific nor carbonate chemistry related vital effects in the  $\Delta_{47}$ -temperature relationship, the data that were initially excluded due to the poorly characterized carbonate system (see Sect. 3.1.1) and poor constraining of the stable carbon and oxygen isotope fractionations (i.e. datapoints with  $\Delta_{DIC} \geq 20\%$  or  $\Delta_{pH} \geq 0.20$ ) can also be included. If the  $\Delta_{47}$ -temperature relationship in coccoliths is purely related to temperature, this will not interfere with the resulting calibration.  
425 Indeed, the slope and intercept fall within error of the other regressions, albeit with a slightly higher slope and lower intercept, seen in Table 2 and Fig. 6.

Based on the above analysis we conclude that all 55 datapoints can be considered for a coccolith  $\Delta_{47}$ -temperature calibration (T in K,  $\pm 1\sigma$ ):

$$\Delta_{47}(I - CDES) = 0.0375 \pm 0.004 * \frac{10^6}{T^2} + 0.181 \pm 0.048 \quad (4)$$

#### 430 **4.4 A unified coccolith $\Delta_{47}$ -temperature calibration?**

The similar culturing study of three coccolithophore species by Katz et al. (2017) also found no species-specific vital effects affecting the  $\Delta_{47}$  values and a consistent  $\Delta_{47}$ -temperature correlation. However, the study was conducted before the introduction of the I-CDES standardisation methodology using carbonates and used gas-based standardization, consequently the data could have a systematic difference that cannot be resolved with certainty. Thus, when comparing to other calibration studies we will  
435 not include Katz et al. (2017) in the dataset and use Eq. 4 as a coccolith  $\Delta_{47}$ -temperature calibration, which is only based on our culture data in the I-CDES frame.

#### **4.5 A coccolith or biogenic specific calibration?**

In Fig. 7 and 8 we compare our data with previous biogenic  $\Delta_{47}$ -temperature studies. The slopes and the intercepts of the equations with a limited number of replicates and a limited range of temperatures have larger uncertainties (Bonifacie et al.,  
440 2017; Fernandez et al., 2017; Kelson et al., 2017) and all datasets have a significant scatter due to their small variability. We focus on five biogenic (Peral et al., 2018; Meinicke et al., 2020; Caldarescu et al., 2021; de Winter et al., 2022; Huyghe et al.,

2022) and one inorganic (“MIT calibration”; Anderson et al., 2021; Daëron and Gray, 2023) carbonate studies. All datasets are converted to I-CDES using the methodology described in Bernasconi et al. (2021). The biogenic data sets are combined into a general ‘biogenic’ calibration, excluding this study. The dataset of Caldarescu et al. (2021) is included in the de Winter et al. (2022) calibration, using their equation 3. As suggested by Huyghe et al. (2022), the juvenile specimen that shows  $\Delta_{47}$  disequilibrium effects related to growth rate is not included. The planktic foraminifera data recalculated to I-CDES of Meinicke et al. (2020) and Peral et al. (2018) are combined. Both the original studies’ and recalculated calcification temperatures by Daëron and Gray (2023) are used, and named ‘Daëron & Gray 2023 orig’ and ‘Daëron & Gray 2023 recal’ respectively.

While overall the individual  $\Delta_{47}$  values for coccolith calcite fall within the scatter of the previous calibrations, our coccolith  $\Delta_{47}$ -temperature regression plots systematically above. To identify and evaluate how this would impact temperature reconstructions, a similar exercise to Sect. 4.3 was performed. At all growth temperatures, a  $\Delta_{47}$  value was calculated from each calibration.  $\Delta\Delta_{47,off}$  residuals were then generated through comparison with our study’s calibration at each temperature. All non-coccolith calibrations yield negative residuals ( $\Delta\Delta_{47,off}$ ) relative to our coccolith  $\Delta_{47}$ -temperature calibration. This results in lower calculated  $\Delta_{47}$  temperatures compared to our calibration (Fig. 8). Positive offsets were found for aragonite (de Winter et al., 2022) and brachiopods (Bajnai et al., 2018; Davies et al., 2023; Letulle et al. 2023), when compared to the Anderson et al. (2021) inorganic carbonate calibration. However, brachiopods show a complex system of kinetic disequilibrium effects in both  $\Delta_{47}$  and  $\Delta_{48}$  associated with early-stage  $\text{CO}_2$  absorption in the DIC, and do not have the CA enzyme. de Winter et al. (2022), in addition, argued that the  $\Delta_{47}$ -temperature relationship is non-linear at temperatures  $>100^\circ\text{C}$  and calibrations are substantially biased by data with a large temperature range such as Anderson et al. (2021) when used at temperatures  $<30^\circ\text{C}$ . The ‘MIT’ calibration uses only the inorganic carbonates from the Anderson et al. (2021) dataset and indeed yields lower and non-overlapping  $\Delta\Delta_{47,off}$  residuals relative to our calibration (Fig. 8). Using only the data  $<30^\circ\text{C}$  from Anderson et al. (2021) to calculate a temperature regression does yield overlapping  $\Delta\Delta_{47,off}$  residuals relative to our calibration, however due to the steeper slope of the calibration, the  $\Delta\Delta_{47,off}$  residuals are strongly temperature dependent. The non-linearity of the  $\Delta_{47}$ -temperature relationship is thus most likely not a major cause for the consistent offset of our coccolith calibration (see Table S3).

To a certain degree, offsets are also likely due to the uncertainty related to the determination of calcification temperatures in previous calibrations based on foraminifera collected from core tops. Often indirectly inferred or estimated from other proxies, these uncertainties in the calcification temperatures can result in large variabilities, obscure potential effects related to temperature, and can result in differences between calibrations. Meinicke et al. (2020) compared and discussed three different methods of determining the calcification temperature of the foraminifera used in their study, and concluded that using their oxygen isotope composition and the temperature calibration of Shackleton et al. (1974) provides the most robust estimate of the true calcification temperatures. In an extensive study, Daëron and Gray (2023) re-determined the oxygen isotope fractionation in the foraminifera species that were used by Meinicke et al. (2020) and Peral et al. (2018) for their clumped isotope calibrations using samples from laboratory cultures and plankton tows. They concluded that foraminifera calcification temperatures are best approximated by using the Kim and O’Neil (1997) calibration with species-specific offsets. They tested

this concept by comparing the calcification temperatures determined for the Meinicke et al. (2020) and Peral et al. (2018) datasets, with reconstructed water column temperatures at the sites of the core tops (Fig. 7 in Daeron and Gray, 2023), and concluded that this is a better estimate of calcification temperatures than previously published. The applications of these revised species-specific oxygen isotope fractionation curves result in a non-systematic 1-2°C offset to colder temperatures from the original studies of Peral et al. (2018) and Meinicke et al. (2020; Fig. 8), especially at temperatures below 15°C and leads to a match between these two foraminifera-based calibrations and the inorganic calibration of Anderson et al. (2021). A close examination of Fig 7 in Daeron and Grey (2023) however, shows that the majority of their discordant samples (i.e. those that record temperatures outside the measured water column temperatures at the living depth of the specific species) are on the cold part of the calibration, 12 are below 13°C. Moreover, at least 7 of the ones that are considered concordant as the error bars overlap with the measured temperatures, have an average that is 1-2°C below the lowest measured temperature. About 27 of the 37 datapoints below 15 °C are either colder than the lowest temperature or only overlap with the coldest temperatures of the observed water column temperature range. We suggest that this would impart a cold bias on those samples. Further, the proposed extension of the calcification depths to 500 m would also give a cold bias and is not supported by foraminifera living depths (Schiebel and Hembleben, 2017). Based on these considerations, we suggest that the use of calcification temperatures from oxygen isotopes need further testing, ideally on laboratory cultured specimens and warrants caution.

Both the variability and absolute  $\Delta\Delta_{47,off}$  residuals differ for all compared calibrations. The Daëron and Gray (2023) and MIT calibrations yield  $\Delta\Delta_{47,off}$  residuals that do not overlap with our dataset between 2-28°C. The original Peral et al. (2018), Meinicke et al. (2020), de Winter et al. (2022), and Huyghe et al. (2022) calibrations do yield  $\Delta\Delta_{47,off}$  residuals within the uncertainty of our dataset. Temperature offsets at the average growth temperature of our dataset, 18.7°C, are between 0°C and 4°C for the different calibrations, but vary in magnitude at different temperatures, see Table 4.

The high variability of the temperature offsets over the given temperature range for certain biogenic carbonate studies such as de Winter et al. (2022), suggest non-uniform disequilibrium effects are present. Thus, a pooled calibration including all biogenic studies mentioned, except this study, and using either the original and recalculated calcification temperatures were performed to identify whether there is potential for a general biogenic-specific calibration (Fig. 8). Our dataset still has a positive  $\Delta\Delta_{47,off}$  relative to the biogenic calibrations, for the original calcification temperatures from 2°C to 1.5°C for 27°C to 6°C respectively and from 3°C to 2°C for the recalculated dataset. From this, two potential conclusions can be argued; there is a coccolith specific-calibration or the calcification temperatures for previous studies are underestimated. Our well-constrained coccolith cultures allow for the exclusion of effects from environmental variabilities, such as pCO<sub>2</sub>, pH, coccolithophore growth rate, and vital effects on  $\Delta_{47}$  values as discussed in Sect. 4.3. The vital effects observed in the coccolith carbon and oxygen isotopes do not have an impact on the  $\Delta_{47}$ , where  $\Delta\Delta_{47,off}$  are within 0.0012‰ despite up to ~3‰ variability for carbon and oxygen isotopes for our experimental conditions. This is below our analytical uncertainty for  $\Delta_{47}$ , thus while we can't fully rule out that vital effects are present on  $\Delta_{47}$ , the offset from the inorganic equilibrium calibration must be similar at all temperatures, systematic and unrelated to vital effects. Indeed, for the available dataset no species- or genus-related effects are present, although this must be further examined in future studies with in situ temperatures such as sediment traps

510 or cultures. Foraminifera also show variable oxygen and carbon isotope vital effects, although less extreme than coccolithophores, but follow the same  $\Delta_{47}$  relationship.

The tightly-controlled growth temperatures of our cultures eliminate the problem of uncertain calcification temperatures as in the case of foraminifera calibrations (Meinicke et al., 2020; Daëron and Gray, 2023). Indeed, the offsets of our coccolith calibration relative to the inorganic MIT calibration are consistent and suggest a uniform disequilibrium mechanism ( $\Delta\Delta_{47,off} = -0.0079 \pm 0.0005\%$ ). The purely foraminifera-based calibrations, both the original and recalculated calcification temperatures of Peral et al. (2018) and Meinicke et al. (2020), show more variability relative to the MIT calibration ( $\Delta\Delta_{47,off} = 0.0023 \pm 0.0012\%$  and  $\Delta\Delta_{47,off} = -0.0013 \pm 0.0015\%$  respectively), and suggests variable disequilibrium effects. However, at this stage it is difficult to state whether this is due to general foraminifera, species-specific disequilibria, or due to uncertainties related to the calcification temperature. This highlights the importance and uncertainties related to the calcification temperature and their implications. Modelling studies for inorganic calcite, grown in the presence of CA and at growth rates and pH ranges relevant for coccolithophores, show offsets for carbon and oxygen and find kinetic disequilibrium effects that are pH and crystal-growth rate dependent (Hill et al., 2014; Watkins and Hunt, 2015; Uchikawa et al., 2021; Watkins and Devriendt, 2022). Between our cultured temperatures of 6-27°C and in saline conditions, a shift from pH 8 to 8.5 can give an offset of  $\sim 3\%$  for  $\delta^{18}\text{O}$  and  $\sim 90$  ppm for  $\Delta_{47}$  at very fast crystal growth rates ( $10^{-5} \text{ molm}^{-2}\text{s}^{-1}$ ) and offsets of  $\sim 1\%$  for  $\delta^{18}\text{O}$  and  $\sim 1$  ppm for  $\Delta_{47}$  for 1000x slower crystal growth rates ( $10^{-7} \text{ molm}^{-2}\text{s}^{-1}$ ; Fig. 6 in Watkins and Devriendt, 2022). The latter is comparable to estimated coccolith calcification rates of  $10^{-7}$ - $10^{-8} \text{ molm}^{-2}\text{s}^{-1}$  (Langer et al., 2006, 2012; Sett et al., 2014). Also, the modelled difference of  $\Delta_{47}$  between  $\text{HCO}_3^-$  relative to  $\text{CO}_3^{2-}$  at 25°C, with a difference of  $\sim 5$  pH units, and saline conditions is  $\sim 0.034\%$ , and  $\sim 7\%$  for  $\delta^{18}\text{O}$  (Hill et al., 2014; Watkins and Devriendt, 2022). Thus, the difference due to calcification mechanisms by regulating internal pH and thus the  $\text{HCO}_3^-/\text{CO}_3^{2-}$  ratio that has been postulated to drive the carbon and oxygen vital effect differences between different coccolithophore and foraminifera species cannot be applied on its own to explain the  $\Delta_{47}$  offset from equilibrium (Spero et al., 1997; Rickaby et al., 2010; Ziveri et al., 2012; Devriendt et al., 2017; Holtz et al., 2017). Rather, a crystal growth rate variability between species is likely the cause of the 3% offset in  $\Delta\Delta^{18}\text{O}_{off}$  between *C. leptoporus* and *G. oceanica* and only  $\pm 1.2$  ppm difference in  $\Delta_{47}$ . Perhaps, a difference due to species-specific coccolith-associated-proteins that can influence different calcite saturation states within the coccolith vesicle and lead to more crystal-growth rate variability, can also have an effect (Lee et al., 2016). However, as the offset from the equilibrium inorganic calcite is systematic across the three coccolithophore species cultured here, there is more work needed to identify the disequilibrium processes for other coccolithophore species as well as for foraminifera. Future studies with constrained and in situ temperature measurements such as in sediment traps (Clark et al., 2024) or cultures are recommended to disentangle and validate our findings of this biogenic disequilibrium.

## 540 5 Conclusions

In this study we cultured three species of coccolithophores (*Gephyrocapsa oceanica*, *G. muelleriae*, and *Calcidiscus leptoporus*) in continuous and batch culture setups for temperatures between 6 and 27°C and CO<sub>2(aq)</sub> between 5 and 45 μM. Vital effects in carbon and oxygen isotopes in coccoliths were observed and their magnitude is consistent with previous culturing studies. We show that for our well-constrained continuous culture setup there are no systematic external environmental influences from pH, DIC, or CO<sub>2(aq)</sub> on the carbon and oxygen isotopic values for both *G. oceanica* and *G. muelleriae*. Both species precipitate coccolith calcite close to isotopic equilibrium with the water ( $\Delta^{13}\text{C}_{\text{c-DIC}} = \pm 1.5\text{‰}$ ;  $\Delta\Delta^{18}\text{O}_{\text{off}} = \pm 1\text{‰}$ ). *C. leptoporus* shows pronounced vital effects in both carbon and oxygen isotopes, although no clear physiological conclusions can be drawn on the source of these vital effects. A calcification model would aid in describing the sources of the vital effects.

550 We establish a coccolith-specific  $\Delta_{47}$ -temperature calibration and observe a consistent offset from previous inorganic calibrations ( $\Delta\Delta_{47,\text{off}} = -0.0079 \pm 0.0005\text{‰}$ ), which suggests disequilibrium effects in coccolith  $\Delta_{47}$  for all three coccolithophore species. There are however, no effects on the calibration are due to differences in environmental parameters or species. Our coccolith  $\Delta_{47}$  data is largely consistent with a previous coccolith culture study (Katz et al., 2017), and indicates that coccolithophores precipitate coccolith calcite in clumped isotope disequilibrium with their environment. Our well-constrained coccolith  $\Delta_{47}$ -temperature calibration (Eq. 4) also shows offsets from previous biogenic calibration studies, dependent on the choice of calcification temperature. The discrepancies derived from the differences in calcification temperature render it difficult to conclusively state whether a general biogenic calibration should be used. Thus, we suggest the use of our well-constrained  $\Delta_{47}$ -temperature calibration to reconstruct temperatures from well screened/preserved coccolith calcite, regardless of species.

865 **Table 1. Overview table for all included data points for Sect. 3, 4.1, 4.2. including temperature (°C), culture setup type, CO<sub>2(aq)</sub> (μM), Δ<sup>13</sup>C<sub>C-DIC</sub> (‰; VPDB), Δ<sup>18</sup>O<sub>C-sw</sub> (‰; VSMOW), and Δ<sub>47</sub> values (‰; I-CDES). 1 standard deviation (σ) is included for the Δ<sup>13</sup>C<sub>C-DIC</sub> and Δ<sup>18</sup>O<sub>C-sw</sub>, which take the evolution of the media over time into account, and 1 standard error (SE) for Δ<sub>47</sub>.**

Data type	Slope	Intercept
<i>G. oceanica</i>	0.0377 ± 0.009	0.179 ± 0.104
<i>G. oceanica</i> + <i>G. muellerae</i>	0.0360 ± 0.005	0.198 ± 0.063
<i>G. oceanica</i> + <i>C. leptoporus</i>	0.0387 ± 0.007	0.168 ± 0.083
Temperature-weighted averages	0.0358 ± 0.006	0.202 ± 0.073
All species	0.0367 ± 0.005	0.190 ± 0.059
Including excluded data	0.0375 ± 0.004	0.181 ± 0.048

**Table 2. Slope and intercepts with 1σ for the Δ<sub>47</sub>-temperature regression using the Williamson-York bivariate least-squares method.**

870

	pH	DIC	CO <sub>2(aq)</sub>	Δ <sup>13</sup> C <sub>C-DIC</sub>	ΔΔ <sup>18</sup> O <sub>off</sub>
All measured ΔΔ <sub>47,off</sub>	0.17	-0.01	-0.09	0.04	0.08
Continuous setup ΔΔ <sub>47,off</sub>	0.27	-0.04	-0.13	0.09	0.45*
Batch setup ΔΔ <sub>47,off</sub>	-0.32	0.20	0.11	0.13	-0.19

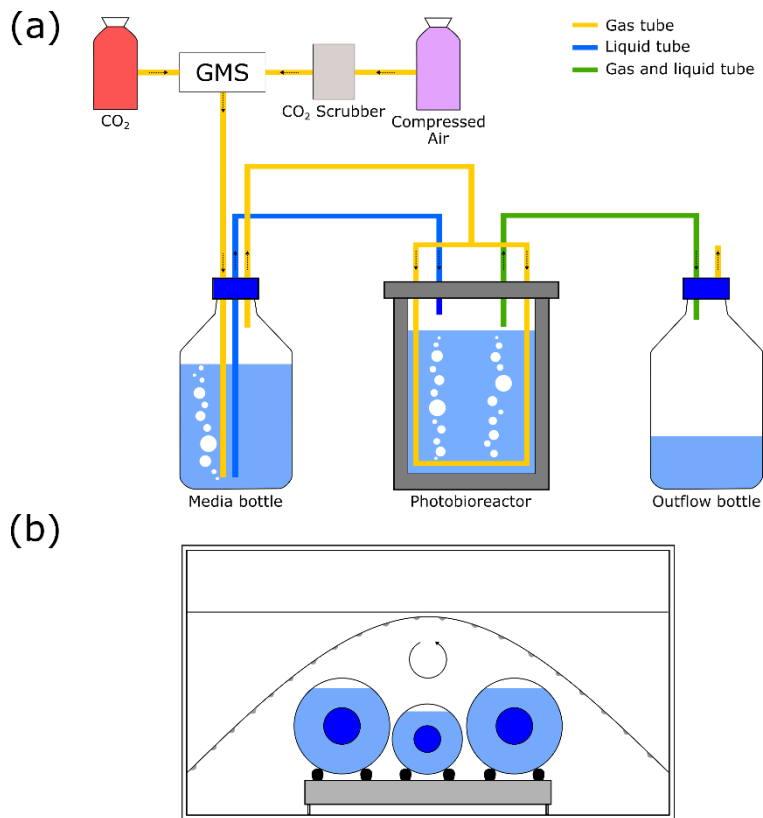

**Table 3. Pearson correlation coefficients (ρ) between ΔΔ<sub>47,off</sub> and pH, DIC, and CO<sub>2(aq)</sub> for all measurements, continuous culture, and batch culture setup. Asterisk indicates where p-value is < 0.05.**

	Measured Δ <sub>47</sub>	Peral et al. (2018)	Meinicke et al. (2020)	Daëron and Vermeesch (2024) MIT	Daëron and Gray (2023) orig	Daëron and Gray (2023) recal
ΔΔ <sub>47,off</sub> residuals (ppm ± 1σ)	-0.6 ± 3.4	-3.2 ± 0.2	-3.1 ± 1.3	-7.9 ± 0.5	-5.7 ± 0.7	-8.5 ± 0.6
Temperature offset (°C ± 1σ)	0.19 ± 1.12	-1.03 ± 0.02	-0.99 ± 0.36	-2.56 ± 0.05	-1.86 ± 0.35	-2.77 ± 0.39

875 **Table 4. Average ΔΔ<sub>47,off</sub> residuals relative to our dataset comparing our coccolith calibration equations and those from the Peral et al. (2018), Meinicke et al. (2020), Daëron and Vermeesch (2024) MIT, Daëron and Gray (2023) original temperatures, and Daëron**

and Gray (2023) recalculated temperatures. Equivalent temperature offset is based on the equivalent  $\Delta_{47}$  value at the average growth temperature (18.7°C) using Equation 4.

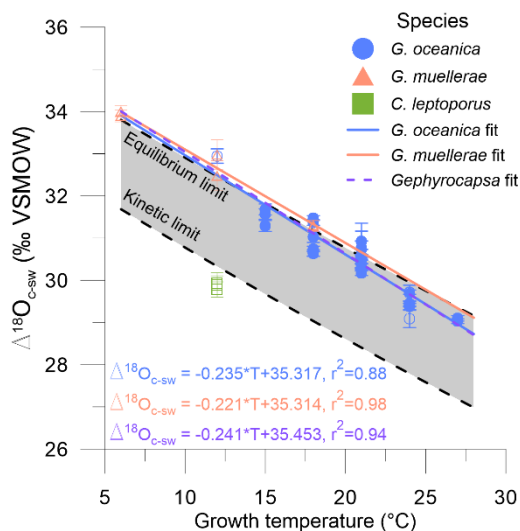

## Figures

880 Figure 1. Photobioreactor and incubator systems. (a) Photobioreactor with controlled CO<sub>2</sub> gas input, adjusted from Zhang et al. (2022), (b) Incubator with roller containing 2 2L and 1 1L bottle and LED strip for batch cultures.

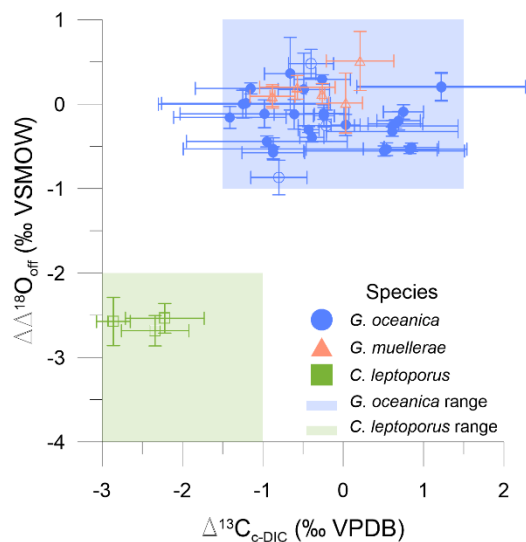

885 **Figure 2.** Coccolith carbon isotope fractionation relative to external DIC ( $\Delta^{13}\text{C}_{\text{c-DIC}}$ ) against the carbon demand vs supply ( $\tau$ ). Blue circles are *G. oceanica*, orange triangles are *G. muelleriae*, and green squares are *C. leptoporus*. Open and filled symbols are batch and continuous cultures respectively. Error bars are as described in methods. Lines represent the model simulations of McClelland et al. (2017) at different PIC:POC ratios; purple = 0.6, pink = 1.5, orange = 1.8, grey = 2.4.

890 **Figure 3.** The fractionation of oxygen isotopes in coccolith calcite from seawater ( $\Delta^{18}\text{O}_{\text{c-sw}}$ ), both in VSMOW, in relation to the growth temperature in  $^{\circ}\text{C}$ . Blue circles are *G. oceanica*, orange triangles are *G. muelleriae*, and green squares are *C. leptoporus*. Open and filled symbols are batch and continuous cultures respectively. Linear regression fits are calculated for *G. oceanica* and *G. muelleriae* separately, as well as for the whole *Gephyrocapsa* genus, with equivalent formulae. Error bars are as described in methods, temperature error bars are smaller than symbols. The kinetic and equilibrium limits are from Watkins et al. (2014) and defined as  
 895  $\left(\frac{17747}{T+273.15}\right) - 29.77$  and  $\left(\frac{17965}{T+273.15}\right) - 32.67$  respectively.

900 **Figure 4.**  $\Delta_{47}$  values from coccolith calcite versus  $10^6/T^2$  for all data points and averages. Averages are full symbols, while individual datapoints are empty symbols. Blue circles are *G. oceanica*, orange triangles are *G. muelleriae*, and green squares are *C. leptoporus* data. Error bars are as described in methods, temperature error bars are smaller than symbols.

905 **Figure 5.** The oxygen isotope offset from the equilibrium limit in Watkins et al., (2014) ( $\Delta\Delta^{18}O_{off}$ ) against the coccolith carbon isotope fractionation relative to external DIC ( $\Delta^{13}C_{c-DIC}$ ). Blue circles are *G. oceanica*, orange triangles are *G. muelleriae*, and green squares are *C. leptoporus* data. Open and filled symbols are batch and continuous cultures respectively. The  $\Delta^{13}C_{c-DIC}$  and  $\Delta\Delta^{18}O_{off}$  range of previous *G. oceanica* and *C. leptoporus* studies are given as a blue and green background respectively. Error bars are as described in methods.

910 **Figure 6.**  $\Delta_{47}$  values compared to temperature (in K) for cultured coccoliths. York regression and its 95% confidence interval are shown as a blue line and light grey envelope. The species are colour and symbol coded following Fig. 2. Blue circles are *G. oceanica*, orange triangles are *G. muelleriae*, and green triangles are *C. leptoporus*. Empty symbols are excluded data but still included for illustration and the coccolith  $\Delta_{47}$ -temperature calibration.

915 **Figure 7.**  $\Delta_{47}$  versus temperature for coccolith calcite and previous biogenic and inorganic calibrations. The York linear fit and 95% confidence interval for the unified coccolith calcite  $\Delta_{47}$ -temperature is shown as a blue line with grey shading. Daëron and Gray (2023 orig; brown dash-dot dot-dash line), Daëron and Gray (2023 recal; grey dash-dot dot-dash line), Daëron and Vermeesch (2024 'MIT'; orange dashed line), biogenic calibration without this study using original published temperatures (pink dashed line), and biogenic calibration without this study using recalculated temperatures (green dashed line).

920

**Figure 8. Temperature offset of different  $\Delta_{47}$ -temperature calibrations relative to our study's equivalent temperature. The other studies' calibration data are colour coded following Fig. 7, with additional studies of Peral et al. (2018; light blue dash-dot-dash line) and Meinicke et al. (2020; red dashed line), de Winter et al. (2022; purple dash-dot-dash line), and Huyghe et al. (2022; blue dashed line) using original published temperatures. The 95% confidence interval for our study is given as light grey shading.**
