**Abstract.** Continued anthropogenic pressures on the Earth system hold the potential to disrupt established circulation patterns in the ocean and atmosphere. In this narrative review, we investigate tipping points in these systems by assessing scientific evidence for feedbacks that may drive self-sustained change beyond critical forcing thresholds, drawing on insights from expert elicitation. The literature provides multiple strands of evidence for oceanic tipping points in the Atlantic Meridional Overturning Circulation (AMOC), the North Atlantic Subpolar Gyre (SPG), and the Antarctic Overturning Circulation, which may collapse under warmer and ‘fresher’ (i.e. less salty) conditions. A slowdown or collapse of these oceanic circulations would have far-reaching consequences for the rest of the climate system and could lead to strong impacts on human societies and the biosphere. Among the atmospheric circulation systems considered, a few lines of evidence suggest the West African monsoon as a tipping system. Its abrupt changes in the past have led to vastly different vegetation states of the Sahara (e.g. “green Sahara” states). Despite multiple potential sources of destabilisation, evidence about tipping of the monsoon systems over South America and Asia is limited. Although theoretically possible, there is currently little indication for tipping points in tropical clouds or mid-latitude atmospheric circulations. Similarly, tipping towards a more extreme or persistent state of the El Niño-Southern Oscillation (ENSO) is currently not fully supported by models and observations. While the tipping thresholds for many of these systems are uncertain, tipping could have severe socio-environmental consequences. Stabilising Earth’s climate (along with minimising other environmental pressures, like aerosol pollution and ecosystem degradation) is critical for reducing the likelihood of reaching tipping points in the ocean-atmosphere system.

## 1 Introduction

### 1.1 Tipping Points in circulation systems

The Earth’s oceans and atmosphere shape both the climate and weather of the planet. Human-driven climate change is causing and will continue to cause far-reaching and long-term changes in the circulation of the oceans and atmosphere. The effect of rising greenhouse gas concentrations is to trap additional heat in the Earth system, driving atmospheric and ocean warming (with the latter accounting for more than 90 per cent of the heat trapped so far, IPCC AR6 WG1 Ch9). There is increasing evidence for changes in key circulation patterns, such as a slowing of the Atlantic Meridional Overturning Circulation (AMOC) (Dima and Lohmann 2010; Caesar et al., 2018; Rahmstorf et al. 2015; Zhu et al., 2023), and trends in mid-latitude weather patterns (Faranda et al., 2023; Horton et al., 2015; Coumou et al., 2018). A growing body of research suggests potential tipping points in some of these systems. Tipping points are defined as critical forcing thresholds (e.g. levels of global warming or deforestation), **beyond which the system switches to a qualitatively different state due to small perturbations** (Lenton et al., 2008; Wang et al., 2023; Matthews et al., 2021). **Here we focus on the large sub-class of systems where this change is driven by** positive feedbacks in a self-sustained fashion (Armstrong McKay et al. 2022; Lenton et al., 2023). Systems with these features are called *tipping systems* (or *tipping elements* in the

73 context of large-scale Earth system components), and undergo a fundamental state transition at a rate largely determined by  
74 the system itself (Armstrong McKay et al., 2022; NRC; 2002). This often occurs abruptly and/or irreversibly, with severe  
75 consequences for the Earth and human systems (IPCC AR6 WG1 Ch4). Prominent examples involve potential widespread  
76 dieback of the Amazon forest system, collapse of the ice sheets on Greenland and Antarctica, coral bleaching and permafrost  
77 melting synchronised over large spatial extents. Similarly, indications for tipping can be found across the circulations in the  
78 ocean and atmosphere: Paleoclimate proxy data suggest deep water formation in the North Atlantic has abruptly shifted to a  
79 weaker or completely ‘off’ state during previous glacial cycles, with major climatic consequences – a pattern supported by  
80 some models (Böhm et al. 2015; IPCC AR6 Ch8, 2021: Ch9 2021). Some model simulations have also shown abrupt  
81 changes in the Antarctic deep water formation (Lago and England, 2019; Li et al., 2023). It has also been suggested that the  
82 Indian Summer Monsoon could shift to an alternative state as a result of aerosol emissions, counter to the general trend of  
83 monsoon strengthening with warming (Levermann et al. 2009; IPCC AR6 WG1 Ch10), as well as potential shifts in  
84 circulations on the Southern Hemisphere to El Niño-like mean conditions (Fedorov et al, 2006). Additionally, numerical  
85 simulations point to the possibility of tipping behaviour in atmospheric blocking, in the form of a self-sustaining,  
86 feedback-driven shift (Drijfhout et al., 2013). Furthermore, there have been discussions on potential large-scale  
87 reorganisation of tropical circulation and cloud systems (Schneider et al., 2019, Caballero and Carlson, 2018).

## 88 1.2 Assessment approach

89 In this review article, we assess the available literature on potential tipping points across the outlined wide range of  
90 circulation systems. This work contributes to recent efforts aimed to categorise the breadth of Earth system components with  
91 respect to their potential for tipping across the different domains, and has served as the corresponding chapter for the  
92 recently published Global Tipping Points Report (Lenton et al., 2023), complementary to chapters on potential tipping points  
93 in the cryosphere and biosphere. Our assessment draws on several sources of evidence: Direct observations via in-situ  
94 measurements or remote sensing allow for near-time monitoring of the systems, and can provide indications that the system  
95 is weakening or even showing early warning signs of approaching a tipping point. However, these observational time series  
96 are often (too) short to observe nonlinear behaviour in potential tipping systems. Observational and paleoclimate proxies  
97 (i.e. indirect reconstructions) greatly extend data availability to longer time scales and offer historical analogues of tipping  
98 dynamics. They are complemented by numerical models of varying complexity, which are used to study system-wide  
99 feedbacks in a consistent setup. Concerning oceanic and atmospheric circulations, the different generations of  
100 Atmosphere-Ocean General Circulation Models (AOGCMs) up to state-of-the-art coupled Earth System models have been  
101 providing great insights into the dynamics of these systems, not least via standardised assessments in the context of the  
102 Coupled Model Intercomparison Project (CMIP, Eyring et al., 2016). Eventually, however, these models are limited in  
103 resolution and can only resolve potential tipping dynamics if the model captures the respective underlying feedback.  
104 Therefore, conceptual and low-order models are indispensable to guide the understanding of potential tipping mechanisms

and, potentially, to identify modelling gaps. In summary, all the outlined lines of evidence complement one another with their respective strengths and drawbacks, and increase confidence in a system's assessment where they converge (Boers et al., 2022).

For our assessment, we therefore draw on a rating system where confidence increases with both robustness (high robustness = multiple, consistent, independent lines of high-quality evidence) and agreement of evidence, as developed and employed in the IPCC context (Mastrandrea et al., 2010). To this end, a system is **classified as tipping system** in this work with

- **high confidence (+++):** Multiple, independent lines of evidence consistently indicate the presence of feedback loops that can drive self-perpetuating change beyond a threshold, leading to a state shift in that system. E.g., there are strong paleo analogues, consistent tipping behaviour in models across the hierarchy, and, if applicable (when the tipping threshold is expected at present-day or soon-to-be-reached forcing levels), proxy and direct observations are compatible with the expected tipping dynamics.
- **medium confidence (++):** Multiple, independent lines of evidence indicate the presence of such feedback loops, however there are uncertainties in timing, magnitude or feedback strength. E.g., there are tipping dynamics in some models, and paleo records hint at dynamics compatible with tipping. Support from observations is limited or contested.
- **low confidence (+):** Singular lines of evidence indicate the presence of such feedback loops, and tipping dynamics only emerge in specific models or under constrained assumptions. E.g., tipping is in principle conceivable via conceptual models, but there are no clear or only weak paleo analogues, and limited demonstration of tipping dynamics in numerical models.

Similarly, we classify a system as **not being a tipping system** if there is evidence indicating the lack of feedback loops that can drive self-perpetuating change beyond a threshold (with low/medium/high confidence). It is **unclear** whether the system is a tipping system if there is conflicting or limited evidence about the existence of such feedback loops. Note that in this approach, irreversibility and abruptness are useful indicators for tipping dynamics, but the defining criterion is a feedback loop beyond a forcing threshold as outlined above, extending the IPCC definition of a tipping point (*“A critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly”*; Matthews et al., 2021) by a mechanistic understanding (see also Armstrong McKay et al., 2022) reflecting the notion of a catastrophic bifurcation with a vanishing stable attractor (Dijkstra, 2013). Furthermore, it is important to emphasise that our assessment reflects the confidence in determining whether a system *can* tip (**under present-day or broadly plausible future conditions**) — not the confidence that it *will* tip. The latter depends on the trajectory of external forcing and the position of the critical thresholds, both of which are subject to considerable uncertainties.

Although tipping point research is expanding, systematic model intercomparison studies dedicated to tipping dynamics remain scarce—limited so far to isolated efforts like the North Atlantic Hosing Modelling Intercomparison Project, (NAHosMIP; Jackson et al., 2023) or the Ice Sheet Model Intercomparison Project (ISMIP; Nowicki et al., 2016) targeting specific aspects of one system. As a result, current assessments like ours can offer rather qualitative confidence statements as

139 outlined above, while highlighting the need for future work to establish a more comprehensive quantitative foundation. In  
140 the future, emerging initiatives like the Tipping Points Modelling Intercomparison Project (TIPMIP; Winkelmann et al.,  
141 2025) could enable confidence ratings based on the fraction of models that exhibit abrupt shifts in setups dedicated to  
142 scrutinise tipping dynamics. For now, this review contextualises the current state of science through the lens of  
143 self-reinforcing feedbacks beyond critical forcing thresholds, with a focus on consistency and qualitative agreement across  
144 lines of evidence.

145  
146 **Figure 1: Potential tipping systems in ocean and atmosphere circulations considered in this review. +/++/+++ denotes that a system**  
147 **is classified as a tipping system with low/medium/high confidence; “?” marks conflicting or limited evidence.**

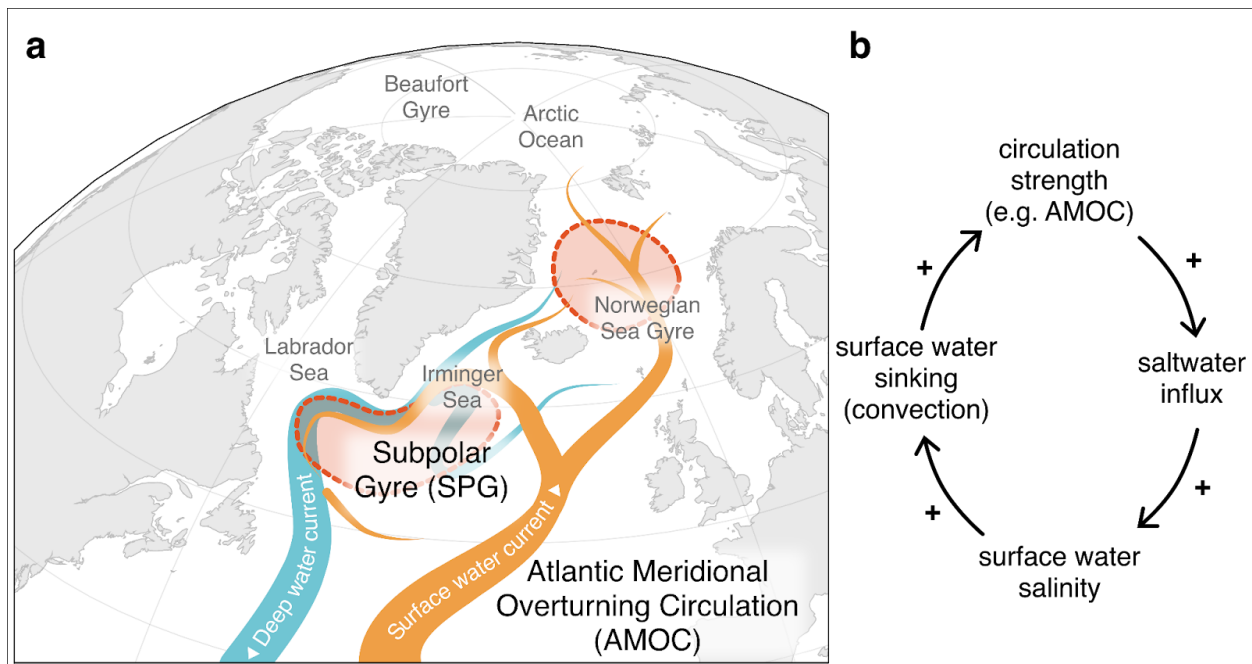

## 148 2 Ocean Circulation

### 149 2.1 Atlantic Meridional Overturning Circulation (AMOC)

150 The Atlantic Meridional Overturning Circulation (AMOC) refers to a three-dimensional circulation present in the Atlantic  
151 (Figure 2a) whereby warm upper ocean waters ('upper branch') move northward from the tip of Southern Africa to the  
152 northern North Atlantic, where they cool, sink and return southwards as cold deep waters ('lower branch'). The AMOC  
153 shapes the climate of the whole Earth, influencing, for example, the 1-2°C temperature difference between the Northern and  
154 Southern Hemispheres, and the location and strength of rainfall across all tropical regions (Buckley and Marshall, 2016,  
155 Feulner et al., 2013, Marshall et al., 2014).

156

157

158 **Figure 2: Overview of the major oceanic circulation systems in the North Atlantic. a) The surface currents (orange pathways) are**  
159 **connected to deep ocean currents (blue) through sites where dense (cold, salty) water sinks, driving the overturning circulation**  
160 **(pink shaded areas). b) One critical feedback is the salt-advection feedback, in which a weakening of the circulation strength**  
161 **reduces the northward advection of salt, which in turn weakens the circulation.**

162 Fresh, warm water is less dense than cold, salty water. In the future, surface waters in the northern North Atlantic will  
163 become less dense, because of anthropogenic warming and freshening from ice melt and increased regional precipitation.  
164 This will weaken deep water formation in that region, which will disrupt the AMOC, causing it to weaken significantly or  
165 even collapse completely. AMOC strength has only been observed directly since 2004 (Srokosz and Bryden, 2013), with  
166 more uncertain reconstructions based on observations such as surface temperature, which extend back in time before 2004  
167 ('observational proxies'), or from paleoclimate archives such as ocean sediment cores which extend back to prehistoric times  
168 ('paleoclimate proxies') (Caesar et al. 2018, 2021, Moffa-Sánchez et al., 2019). The lack of a sufficiently long observational

record is a major hurdle for robust understanding of the AMOC, particularly since the North Atlantic is a region of high variability on interannual to decadal timescales (Boer 2000). Current observations show that it is freshening at subpolar latitudes (50-65°N), most strongly in the upper 100m, and warming, most strongly between 100-500 m water depth (IPCC AR6, 2021). Both trends act to reduce AMOC strength. Greenland Ice Sheet melt is accelerating and releasing extra fresh water into the North Atlantic (The IMBIE Team, 2020). In addition, Arctic sea ice is reducing in surface extent and thickness (Serreze and Meier, 2019) and overall Arctic river discharge is increasing (Holmes et al., 2021), adding fresh water to the Arctic which can then leak into the North Atlantic.

Limited direct observations of AMOC strength make current trends uncertain, but there are some indirect signs of ongoing weakening. Observational and paleoclimate proxies suggest the AMOC may have weakened by around 15 per cent over the past 50 years (Caesar et al. 2018) and may be at its weakest in 1,000 years (Caesar et al., 2021). However, the proxy data used in these studies have large uncertainties, and agreement amongst reconstructions is contentious (Moffa-Sanchez et al., 2019, Killbourne et al., 2022, Caesar et al., 2022, Terhaar et al., 2025). It remains therefore difficult to confidently discern potential recent trends from natural variability (Bonnet et al. 2021, Latif et al., 2022) since natural variability is still able to explain the trend over the last century. What is clear is that if the observed cooling trend in the subpolar gyre is only due to external forcing, then CMIP6 climate models do not capture correctly such a negative trend in their ensemble mean (cf. Figure 2 of Qasmi, 2022).

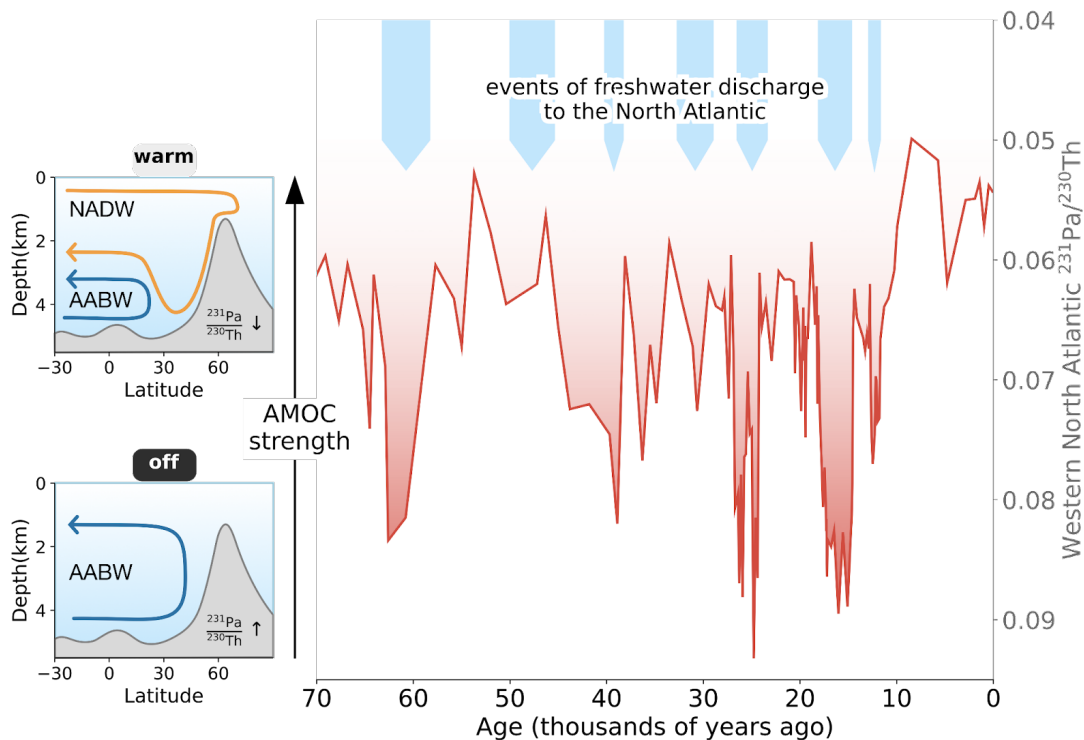

The IPCC's most recent assessment is that the AMOC has weakened relative to 1850-1900, but with low confidence due to disagreement among reconstructions (Moffa-Sanchez et al., 2019, Killbourne et al., 2022) and models forced response (IPCC AR6 Ch9, 2021). For the future, the IPCC projects that it is very likely that the AMOC will decline in the 21st century (however with low confidence on timings and magnitude) (IPCC AR6 Ch4, 2021). There is medium confidence (about 5 on a scale of 1 to 10) that a collapse would not happen before 2100, though a collapse is judged to be as likely as not by 2300. Hence the possibility of an AMOC collapse within the next century is very much left open by the latest IPCC report.

### 2.1.1 Evidence for tipping dynamics

The AMOC has been proposed as a 'global core' climate tipping system with medium confidence by Armstrong McKay et al. (2022). Paleorecords indicate it may have abruptly switched between stronger and weaker modes during recent glacial cycles (Figure 3). Most of the time (including the warm Holocene of the past 12,000 years) the AMOC is in a strong, warm mode, but during peak glacials it sometimes shifted to a weak, cold mode instead (Böhm et al., 2014). It may also occasionally have collapsed entirely to an 'off' mode during some 'Heinrich' events, in which iceberg outbursts from the North American Laurentide Ice Sheet temporarily blocked Atlantic overturning for several centuries (Alley et al., 1999; Rahmstorf et al. 2002; Weijer et al. 2019). While more evidence exists for switches between a warm and cold on-mode in the paleo records, some of these data support switches to an off-mode, possibly occurring through a two-step process from warm-on to cold-on to off (Weijer et al., 2019).

In two previous censuses of climate model projections, a shut-down of the AMOC was observed in a small minority of simulations (Drijfhout et al., 2015; Sgubin et al., 2017). This shut-down took many decades and was preceded by decreases

in subpolar surface air and ocean temperatures and increased sea ice cover. Ultimately, deep mixing ceased to occur, cutting the connection between the surface and the deep ocean. Although only a few climate models showed a shutdown of the AMOC, there are concerns that the AMOC may be too stable in CMIP-type climate models (Mecking et al., 2017, Liu et al., 2017), and hence may underestimate the likelihood of AMOC collapse (IPCC AR6 WG1 Ch9).

**Figure 3: Different AMOC modes and paleo-evidence.** The diagrams on the left show two AMOC modes as indicated by sedimentary  $^{231}\text{Pa}/^{230}\text{Th}$  in paleo records. NADW: North Atlantic Deep Water; AABW: Antarctic Bottom Water, adapted from Böhm et al., 2015. B AMOC slowdown events during the last 70,000 years as recorded by sedimentary  $^{231}\text{Pa}/^{230}\text{Th}$  data (McManus et al., 2004; Böhm et al., 2015) from the Western North Atlantic (Bermuda Rise, ca. 34°N). Sedimentary  $^{231}\text{Pa}/^{230}\text{Th}$  from the Bermuda Rise is a proxy for AMOC strength that assesses the southward flowing North Atlantic Deep Water between ca. 3,500 and 4,500m water depth. The top of the panel marks the timing of past major events of freshwater discharge to the high latitudes of the North Atlantic that decreased AMOC strength (Sarnthein et al., 2003; Carlson et al., 2013; Sanchez Goñi and Harrison, 2009). The red shading highlights past AMOC slowdown events. There is also evidence of AMOC shifts during the last interglacial period, 116,000-128,000 years ago (Galaasen et al. 2014).

Some recent studies have suggested that early warning signals' indicating destabilisation can be detected in reconstructed 'fingerprints' of AMOC strength over the 20th Century (Boers, 2021), and if a tipping point is assumed then the collapse threshold could be reached during the 21st Century (Ditlevsen & Ditlevsen, 2023). These studies used observational proxies for temperature and salinity from the Northeastern subpolar North Atlantic, which are used as indirect AMOC fingerprints rather than direct measurements of AMOC strength. This gives long enough data to analyse for early warning signals, but using indirect proxies adds uncertainty. For instance, the models used by Boers (2021) and Ditlevsen & Ditlevsen (2023) to project collapse are highly simplified, using an indirect 1D metric for the AMOC with a double-well as its stability

landscape assumed, and do not take into account the low-frequency variability of the AMOC. After fitting the timeseries of the metric to various statistical properties of a 1D variable approaching a tipping point (switching from one well to the other in its stability landscape), there are substantial uncertainties with this methodology (see also Michel et al., 2023 highlighting potential false warnings) in particular to determine tipping times (Ben Yami et al. 2024). Despite these caveats, the results amount to a serious warning that the AMOC might be en route to tipping, supported by further potential early warning signals found from analysis of Northern Hemisphere paleoproxies (Michel et al., 2022), and as derived from a physics-based signal (van Westen et al., 2024). However, the claim that we might expect tipping within a few decades is not substantiated enough.

AMOC stability is strongly linked to the ‘salt-advection feedback’ (Stommel, 1961, and see Figure 2b). The AMOC imports salt into the Atlantic and transports it from the South Atlantic to the northern North Atlantic. If the AMOC weakens then less salt is transported to the northern North Atlantic, the surface waters freshen, which inhibits sinking, and the AMOC weakens further. The AMOC collapses seen in models (Drijfhout et al., 2015, Sgubin et al., 2017) were driven by this salt-advection feedback. However, the strength of this feedback, and the timescale over which it operates are governed by processes whose effects are quite uncertain. Although Figure 2a shows typical pathways of surface and deep water through the Atlantic, these pathways are an average picture over many decades. Individual water parcels may get caught up in basin-scale surface or deep recirculations, smaller-scale eddies and meandering currents. There is no definitive evidence though from models or observations that these small-scale processes systematically impact the salt advection feedback.

Additionally, changes in the AMOC have other impacts on salinity – for instance through affecting evaporation and precipitation patterns (Jackson 2013, Weijer et al, 2019). These other feedbacks can temporarily mask, and may even overcome, the salt-advection feedback, potentially changing the stability of the AMOC (Jackson, 2013, Gent, 2018). It is difficult to characterise these processes and feedbacks from observations alone due to insufficient data coverage both in time and space, so we are dependent on numerical models. However, many studies have used reduced complexity models, which may not capture all the potential feedbacks, and even the current generation of climate models have quite low spatial resolution and do not characterise narrow currents, eddies and processes such as horizontal and vertical mixing very well. Indeed, it has been shown recently (Swingedouw et al. 2022) that the inclusion of fine-scale processes of the order of a few kilometres can increase the spread of Greenland meltwater from coastal waters towards the centre of the Labrador Sea, which might more rapidly affect deep convection processes through reduction in surface salinity.

Armstrong McKay et al (2022) estimated with low confidence a global warming threshold for AMOC collapse of  $\sim 4^{\circ}\text{C}$  ( $1.4\text{--}8^{\circ}\text{C}$ ). In our view, the range is a better indication of the uncertainty in the different model responses rather than a relationship to global warming, as the likelihood is probably less dependent on temperature, but strongly depends on salinity changes and the strength of opposing feedbacks on the freshwater budget. Studies with climate models have found that adding freshwater can cause the AMOC to collapse and not recover in some models. Since many climate models might be biased towards stability, however, these studies use an unphysically large amount of freshwater to explore the sensitivity (Jackson et al., 2023). Although adding freshwater causes a collapse, they show the threshold is dependent on the strength of

the AMOC and deep convection, rather than on the amount of freshwater added (Jackson and Wood 2018, Jackson et al, 2023). AMOC collapse may also be more sensitive to the rate of freshwater forcing than the total magnitude (Lohmann & Ditlevsen, 2021).

**Figure 4: AMOC hysteresis in a CMIP model, adapted from Heinze et al. (2023). CMIP6 overshoot experiments (using UKESM; Jones et al. 2020) showing hysteresis - different states of the AMOC (vertical axis) for the same atmospheric CO2 concentration (horizontal axis). Possible causes are delayed or non-linear response to forcing or possibly bistability of AMOC. The AMOC strength is measured in ‘Sverdrups’ (Sv; i.e. a flow of 1 million cubic metres per second); colours from yellow to blue show model years from 2015 to 2100 respectively.**

Hysteresis and bistability both refer to systems which can adopt one of two or more statistically stationary states for the same external forcing, such as CO2 concentration (see Figure 4 and Boucher et al., 2012). Commonly, this is explored by approaching the same external conditions with different trajectories in model simulations, e.g. increasing and reversing the forcing to study reversibility. Bistability involving a full collapse of the AMOC by artificially flooding the North Atlantic with freshwater has been demonstrated (or strongly implied) in theoretical models (Stommel, 1961) and climate models of reduced complexity (Rahmstorf et al., 2005; Hawkins et al., 2011). These types of numerical experiments study bistability through forcings that change slowly enough for the system to equilibrate, typically requiring long simulations and thus coarse model resolution for reasonable computational performance. Alternatively shorter experiments, where forcing is applied temporarily, have been conducted with more complex models. These have demonstrated weak AMOC states which persist for at least 100 years in about half of a test group of CMIP6-type models (Jackson et al., 2023) and in a

276 high-resolution ocean-atmosphere coupled climate model (Mecking et al., 2016). In simpler (coarser resolution models) full  
 277 hysteresis experiments have been carried out and those unequivocally support the existence of bi-stability (Weijer et al  
 278 2019). Only recently has AMOC tipping (Van Westen et al., 2025) and a bistable regime (Van Westen et al., 2023) been  
 279 found in a CMIP-type model in response to gradually changing increasing freshwater release in the North Atlantic. Hence,  
 280 AMOC tipping has been found over a whole hierarchy of ocean-climate models, still only excluding very high-resolution  
 281 (strongly eddying) climate models, for which appropriate experiments have not yet been conducted.

282 Besides a bi-stable regime bounded by two bifurcation points, a mono-stable off- and on-mode exist on each side of the two  
 283 bifurcation points. In present-day climate models through tuning the AMOC always is characterised by the warm on-mode  
 284 and either resides in the monostable or bistable regime. Whether or not the AMOC is stable under pre-industrial and  
 285 present-day conditions must be model-dependent, depending on details of the background state, probably to a large extent  
 286 determined by the freshwater balance in the Atlantic and how northward salinity or freshwater transport by the ocean  
 287 circulation balanced by the surface forcing. It is not yet understood why transitions to an off-state or much weakened AMOC  
 288 state forced by the same freshwater hosing occurs in some models and not in others (Jackson et al., 2023). However, as  
 289 previously mentioned, there is evidence that the present generation of climate models is too stable due to model biases in the  
 290 distribution of ocean salinity (Liu et al., 2017, Mecking et al 2017). Not only is it difficult to prove system bistability, the  
 291 complexity of the system and interaction with multiple drivers make it hard to assess collapse thresholds. It may be that  
 292 realistic freshwater input is not sufficient to cause the transition, or that changing CO<sub>2</sub> alters the underlying system stability,  
 293 thus increasing the critical freshwater threshold (Wood et al., 2019). Nevertheless, overshoot scenarios, where the CO<sub>2</sub> trend  
 294 is assumed to reverse at some point in the future, provide some useful information about reversibility of the AMOC on  
 295 human timescales (e.g. decades to centuries). Figure 4 shows how the AMOC changes in the UKESM climate model under  
 296 an overshoot emission scenario exceeding and returning to 500ppm. Even if CO<sub>2</sub> concentrations return to 500ppm by 2100  
 297 the AMOC is still only 77 per cent of the strength it was in 2050 also at 500ppm, exhibiting irreversible weakening on these  
 298 timescales.

299 The timescale of AMOC tipping was estimated by Armstrong McKay et al (2022) to be 15-300 years, however this range is  
 300 very dependent on the strength of the freshwater forcing applied in experiments, which in many cases is unrealistically large  
 301 as compared to projected melting of the Greenland Ice Sheet and increase in precipitation and river runoff. Moreover, the  
 302 assessment is also potentially impacted by the models being unrealistically stable. With a realistic forcing scenario, the  
 303 timescale will depend on the feedbacks. A basin-wide salt advection feedback may have a century timescale, while the same  
 304 salt feedback acting on a regional scale (between North Atlantic subtropical and subpolar gyre) is only a few decades. The  
 305 latter feedback then may induce fast tipping to a (probably) metastable state that on the longer term is stabilised or  
 306 destabilised by the basin-wide Atlantic salt feedback. Even faster timescales associated with tipping to such a hypothetical  
 307 metastable state are possible when deep mixing is capped off by sudden increases in sea ice cover, or freshwater halocline.  
 308 This fast tipping is then induced by convective feedbacks after which the advective salt feedbacks may further stabilise or  
 309 destabilise the convection collapse (Rahmstorf et al., 2001; Kuhlbrodt et al., 2001).

AMOC collapse would lead to cooling over most of the Northern Hemisphere, particularly strong (up to 10°C relative to preindustrial) over Western and Northern Europe. In addition, a southward shift of the intertropical convergence zone would occur, impacting monsoon systems globally and causing large changes in storminess and rainfall patterns (Jackson et al, 2015). A collapse of the AMOC would influence sea level rise along the boundaries of the North Atlantic, modify Arctic sea ice and permafrost distribution (Schwinger et al., 2022; Bulgin et al, 2023), reduce oceanic carbon uptake (Rhein et al., 2016) and potentially lead to ocean deoxygenation (Kwiatkowski et al., 2020) and severe disruption of marine ecosystems (including changes in the North Atlantic Subpolar Gyre, see below), impacting North Atlantic fish stocks (e.g. Heinze et al., 2021).

### 2.1.2 Assessment and knowledge gaps

Although the AMOC does not always behave like a tipping system in many ocean/climate models, paleoceanographic evidence strongly points to its capability for tipping or at least to shift to another state that can be quasi-stable for many centuries (Figure 3). Tipping is also suggested in a recent study of several CMIP6 models (Jackson et al, 2023) and in another study which found that removing model salinity biases strongly increased the likelihood of tipping (Liu et al., 2017). This does not necessarily mean that tipping is likely in a future climate, since some of these scenarios specified unrealistic inputs of freshwater or GHG emissions. Nonetheless, although the likelihood for collapse is considered small compared to the likelihood of AMOC decline, the potential impacts of AMOC tipping make it an important risk to consider in framing mitigation targets, for instance.

The latest AR6 assessment states that we have only medium confidence that an AMOC collapse will not happen before 2100 (IPCC AR6 WG1 Ch9). This uncertainty is due to models having strong ocean salinity biases, absence of meltwater release from the Greenland Ice Sheet in climate change scenarios, and the possible impact of eddies and other unresolved ocean processes on freshwater pathways. However, a recent study with the PAGES2K database of climate reconstructions of the past 2,000 years suggests, using statistical methods based on dynamical systems theory, that the AMOC variability might be slowing down (Michel et al., 2022), as do the studies of Boers (2021) and Ditlevsen and Ditlevsen (2023). If an AMOC tipping does exist, as suggested in a number of models (e.g. Boulton et al. 2014), this might mean that the AMOC system might be approaching this tipping point. AR6 also concluded that reported recent weakening in both historical model simulations and observation-based reconstructions of the AMOC have low confidence. Direct AMOC observations have not been made for long enough to separate a long-term weakening from short-term variability. Another recent study suggests that we will need to wait until at least 2028 to obtain a robust statistical signal of AMOC weakening (Lobelle et al. 2020). Thus, the coming years will be crucial for detection of an AMOC weakening potentially leading to longer-term instability. There are substantial uncertainties around how the AMOC evolves over long timescales, because of a lack of direct observations. More paleo-reconstructions of AMOC strength, ocean surface temperature, and other AMOC-related properties with high temporal resolution, using appropriate proxies and careful chronological control performed for key past periods (e.g. last millennium, millennial-scale climate change events, previous interglacials), hold great potential to improve

our understanding about the AMOC as a tipping point. Indeed, this might help to test early warning metrics coming from dynamical system theory in some past real-case conditions. These reconstructions might be based on several sources of proxy data to gain robustness (e.g. sortable silt in the deep ocean,  $^{231}\text{Pa}/^{230}\text{Th}$  in the deep ocean, radiocarbon in the deep versus surface ocean, surface and intermediate ocean fingerprints). Other open issues are to: (i) reconcile disagreements between paleo-reconstructions and model simulations, and (ii) develop improved fingerprints for creating historical reconstructions and monitoring the AMOC.

Current climate models suffer from imperfect representation of some important processes (such as eddies and mixing) and from biases which can impact the AMOC response to forcings. Hence we need to assess how important these issues are for representing AMOC stability, in particular, to understand how different feedbacks vary across models and are affected by modelling deficiencies. Given these issues, a robust assessment of the likelihood of an AMOC collapse is difficult, but based on the evidence presented, we assess that the AMOC features tipping dynamics with medium confidence. One potential way forward, given these uncertainties, is in developing observable precursors to a collapse that could be monitored.

## **2.2 North Atlantic Subpolar Gyre (SPG)**

The North Atlantic Subpolar Gyre (SPG) is an oceanic cyclonic (counter-clockwise in the northern hemisphere) flow to the south of Greenland (Figure 5), driven by wind and buoyancy forcing. The latter is linked to a site of deep ocean convection in the Labrador-Irminger Seas, i.e. sinking of the subsurface ocean waters to great depths, contributing to the AMOC (Figures 2, 5, 6). Some studies have suggested that the SPG could have a tipping point where the convection collapses, having profound impacts on the SPG system.

There are indications for change in the SPG, as observations show that Labrador Sea Water (LSW) formed during oceanic deep convection events after 2014 was less dense than the LSW formed between 1987 and 1994 (Yashayaev and Loder, 2016), potentially influencing the AMOC. Moreover, the observed ‘warming hole’ over the North Atlantic can be explained by AMOC slowdown (Drijfhout et al 2012, Caesar et al 2018, also see AMOC above) and has also been linked to SPG weakening in CMIP6 models (Sgubin et al 2017, Swingedouw et al 2021). In these models, a collapse of the oceanic convection causes a localised North Atlantic regional surface air temperature drop of  $\sim 2\text{--}3^\circ\text{C}$ . This cooling moderates warming over north-west Europe and eastern Canada in global warming scenarios, although it is smaller and less widespread than that associated with AMOC collapse.

Figure 5: Map showing the maximum ocean mixing depth in the North Atlantic (light to dark blue), showing deep water convection sites driving the AMOC and SPG east and south of Greenland respectively (with the Labrador-Irminger Seas convection area bordered by yellow). The pale arrows show surface water currents, with the anti-clockwise subpolar gyre occurring within the red bordered area. From Sgubin et al. (2017).

A northward-shift of the atmospheric jet stream, which is predicted to take place with SPG weakening, means more weather extremes in Europe (which may be linked to the unusual cooling and heat waves in recent years) (Osman et al., 2021) and southward shift of the intertropical convergence zone (ITCZ, see Figure 1) (Sgubin et al. 2017; Swingedouw et al. 2021). Models suggest potential impact of the SPG collapse on the European weather, precipitation regime and climate (Swingedouw et al., 2021). This change in the physical system may trigger changes in ecosystems with detrimental consequences for the North Atlantic spring bloom and the overall Atlantic marine primary productivity. Neither of these reverse to the preindustrial state even when the emissions do by the 2100s as the models show (Yool et al., 2015; Heinze et al., 2021). This would impose a strong impact on fisheries and biodiversity (Swingedouw et al., 2021), with expected wide societal implications (e.g., Holm et al., 2022). Last but not least, a transition between two SPG stable states has been suggested to explain the onset of the so-called ‘Little Ice Age’ in which colder conditions prevailed in Europe during the 16th-19th centuries (Lehner et al. 2013; Schleussner et al., 2015; Michel et al. 2022).

Ventilation of Labrador Sea Water (LSW) is accompanied by an uptake of oxygen. Starting in 2014, the convection in the Labrador Sea became more intense and reached depths of 1,500m and below. Consequently, oxygen in LSW is in general increased, but this increase did not penetrate the densest part of this water mass (Rhein et al., 2017). The oxygen concentrations in the deepest part of the LSW (around 2,000m) have decreased in the formation region and along the main export pathways (southward and eastward crossing the Mid-Atlantic Ridge) for more than 20 years. Most of the oxygen

390 from the export of newly formed LSW has been consumed north of the equator (Koelling et al., 2022), and the long-term  
 391 oxygen decline along the southward LSW pathway might have impacts on ecosystems in the tropics and subtropics over  
 392 longer timescales (e.g., Heinze et al., 2021).

393 The potential shutting-down of winter convection in the Labrador Sea (see Figure 6a,b and Swingedouw et al., 2021) will  
 394 also stop the production of Labrador Slope Water (LSLW). This water is next to the Labrador Sea continental slope and is  
 395 lighter and less deep than LSW. It contributes to AMOC and the Gulf Stream and can influence variability of the Atlantic  
 396 climate system overall (New et al., 2021). The LSLW is rich in nutrients and oxygen too, thereby affecting the ecosystems  
 397 on the North American continental shelf and shelf slope (e.g. Claret et al., 2018) and might affect tropical and subtropical  
 398 marine ecosystems on a timescale of several decades. Furthermore, the SPG takes up large amounts of atmospheric carbon  
 399 and exports it to the deep ocean (Henson et al., 2022).

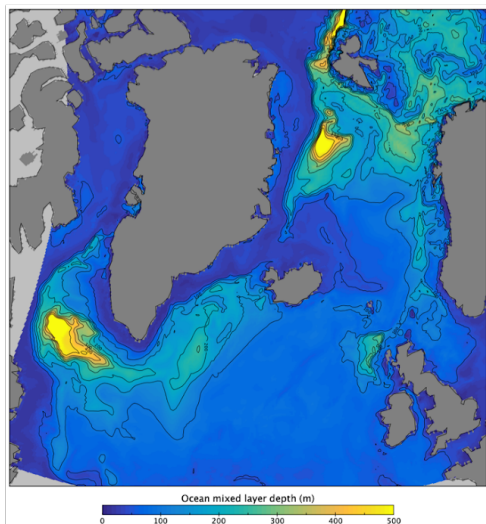

400 Shallowing of the SPG (Sgubin et al., 2017; Swingedouw et al., 2021) would directly increase regional CO<sub>2</sub> uptake but  
 401 negatively impact marine biology, for instance threatening the habitat of cold-water corals in the area due to higher acidity  
 402 with more CO<sub>2</sub> dissolved in the water (Fröb et al., 2019; Fontela et al., 2020; Garcia-Ibanez et al., 2021). Weakening or  
 403 collapse of the SPG would reduce the amount of carbon-depleted intermediate water being upwelled and newly  
 404 carbon-enriched water being convected, reducing export of anthropogenic CO<sub>2</sub> to the deep ocean (Halloran et al. 2015;  
 405 Ridge and McKinley 2020), which in turn might lead to an increase of atmospheric CO<sub>2</sub> concentration on the long term  
 406 (Schmittner et al. 2007). Declining SPG strength may also be reducing the currently high phytoplankton productivity in this  
 407 area (Osman et al., 2019; Henson et al. 2022), reducing the amount of biologically fixed carbon to deeper water too.

408 Changes in the overall Atlantic ocean circulation (AMOC and SPG) can impact the spread of Atlantic water into the Arctic  
 409 and affect marine ecosystems there. Summer sea ice decline reduces light limitation, rendering Arctic ecosystems more  
 410 similar to the present North Atlantic (Yool et al., 2015). Increased seasonal phytoplankton blooms will deplete nutrients in  
 411 the ocean, but increased inputs from rivers and coastal erosion can alleviate this, with Arctic primary production (i.e. the  
 412 turnover photosynthesising plankton biomass) projected to increase by about 30-50 per cent in this century. Invasive species  
 413 can also extend further into the Arctic habitat due to warming and current changes, e.g. in the Barents Sea and from the  
 414 Pacific (Kelly et al., 2020; Neukermans et al., 2018; Oziel et al., 2020; Terhaar et al., 2021).

415 In the North Atlantic, the AMOC can be defined as north-going warm ‘limb’ and saline upper waters and south-going,  
 416 colder, denser deep water ‘limb’ (Frajka-Williams et al. 2019). In contrast, in the Subpolar North Atlantic and the SPG, the  
 417 AMOC features a third ‘limb’ of a cold, fresh western boundary current with the origin in the Arctic Ocean and Nordic Seas  
 418 (Bacon et al., 2022). This is likely linked with the deep convection and winter oceanic mixing in the Labrador, Irminger and  
 419 Iceland seas, injecting waters into the deep, southward-flowing limb of the AMOC (Bower et al. 2019). Changes in SPG  
 420 circulation are associated with the shallowing of the oceanic mixed layer and convection (Figure 6a,b) in the SPG and link  
 421 the predicted future weakening of the North Atlantic subtropical gyre and a strengthening of the Nordic Seas gyre, pointing  
 422 to the influences of the upstream changes in the Arctic on the North Atlantic (Swingedouw et al., 2021).

429 Swingedouw et al. (2021) for the IPCC CMIP6 model results.

### 430 2.2.1 Evidence for tipping dynamics

431 Potential convection instability in the Labrador and Irminger Seas and the wider SPG is believed to be linked to lightening  
432 of the upper ocean waters due to reduced salinity (e.g., due to increased precipitation, Figure 6d), thus increasing  
433 ‘stratification’ – i.e. reduced mixing between layers of the water column. Warming (Figure 6c) also plays a role and could  
434 contribute to convection collapse (Armstrong McKay et al., 2022). Freshening and warming make surface waters more  
435 buoyant and thus harder to sink, which, beyond a threshold, can abruptly propel a self-sustained convection collapse  
436 (Drijfhout et al. 2015, Sgubin et al., 2017). This process can result in two alternative stable SPG states (Levermann and  
437 Born, 2007), with or without deep convection (Armstrong McKay et al., 2022). Similar to the AMOC, SPG stability is also  
438 strongly linked to the salt-advection feedback. When the SPG is ‘on’, it brings dense salty waters from the North Atlantic  
439 drift into the Irminger and Labrador Seas, allowing deep sinking and convection to occur (Born & Stocker, 2014; Born et al.,  
440 2016). When convection decreases due to stratification, the SPG weakens, fresher North Atlantic waters flows eastwards,  
441 and the convection is further weakened, which eventually leads to convection collapse in some models. SPG collapse leads  
442 to cooling across the SPG region, and so will impact marine biology and bordering regions.

443 A freshwater anomaly is currently building up in the Beaufort gyre – a pile-up of fresh water at the surface of the Beaufort  
444 Sea in the Arctic – due to increased freshwater input from rivers, sea ice and snow melting as well as the prevailing  
445 clockwise (anticyclonic in the northern hemisphere) winds over the sea (Haine, et al.. 2015; Reagan et al., 2019; Kelly et al.,  
446 2020). There is a considerable risk that this freshwater excess might flush into the SPG, disrupting the AMOC (Zhang and  
447 Thomas, 2021). The most recent changes in Beaufort gyre size and circulation (Lin et al. 2023) suggest flushing might occur  
448 very soon or has already started. The SPG system has recently experienced its largest freshening for the last 120 years in its  
449 eastern side due to changes in the atmospheric circulation (Holliday et al. 2020). In contrast, so far there is only limited  
450 evidence of Arctic freshwater fluxes impacting freshwater accumulation in the Labrador Sea (Florindo-Lopez et al., 2021).  
451 An increased freshwater input into SPG water mass formation regions from melting of Greenland’s glaciers can also inhibit  
452 deep water formation and reduce the SPG and AMOC (Dukhovskoy et al., 2021).

453 Although SPG changes are apparently linked to the AMOC, the SPG collapse can occur much faster than AMOC collapse,  
454 on the timescale of only a few decades (Armstrong McKay et al., 2022), and independently (Sgubin et al., 2017). Armstrong  
455 McKay et al. (2022) estimated global warming threshold of  $\sim 1.8^{\circ}\text{C}$  ( $1.1$  to  $3.8^{\circ}\text{C}$ ) for the SPG collapse (high confidence)  
456 based on climate models from CMIP5 and CMIP6. Abrupt future SPG collapse is diverse in the CMIP6 models, occurring as  
457 early as the 2040s ( $\sim 1$  to  $2^{\circ}\text{C}$ ) but in only a subset of models. However, as these models better represent some key processes,  
458 the chance of SPG collapse is estimated at 36–44 per cent (Sgubin et al., 2017; Swingedouw et al., 2021).

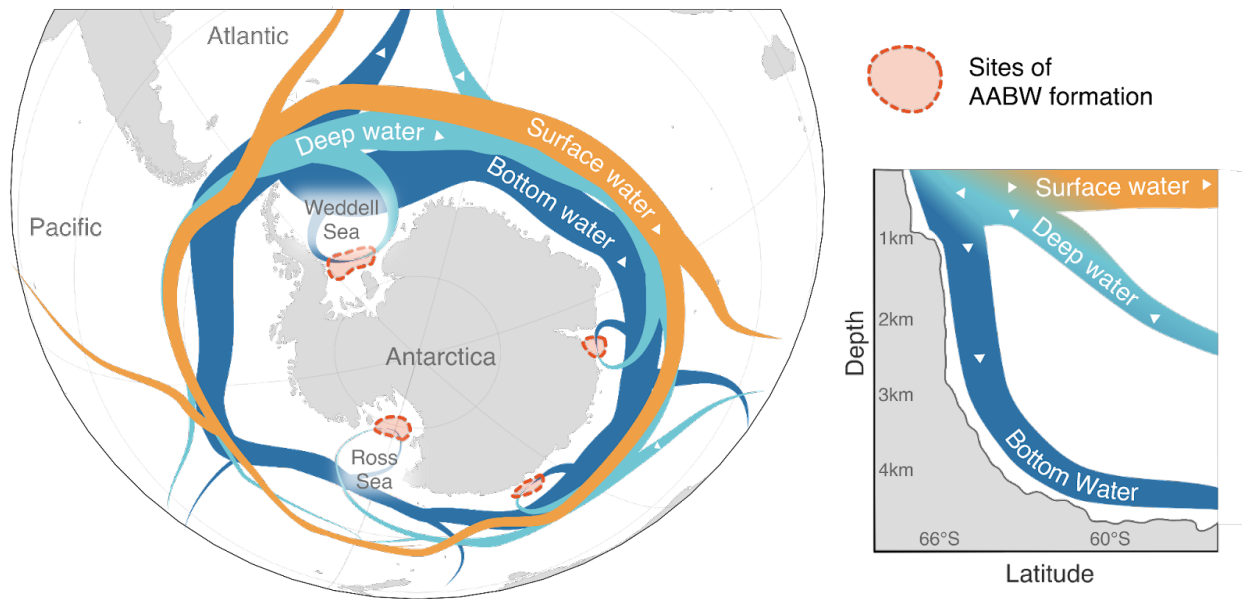

### 459 2.2.2 Assessment and knowledge gaps

460 Similar to Armstrong McKay et al. (2022), the SPG is classified as a tipping system with medium confidence. A global  
461 warming threshold for tipping that could be passed within the next few decades, and an estimated tipping timescale of years

462 to a few decades, raise reasons for concern. Furthermore, cessation of deep water production from other sources in the  
463 Labrador and Nordic Seas and the Arctic could also present other potential tipping points in the future North Atlantic  
464 (Sgubin et al., 2017).

### 465 **2.3 Southern Ocean circulation**

466 Two main tipping points in the Southern Ocean have been discussed in the past, which both could have large and global  
467 climate consequences. The first is the slowdown and collapse of the Antarctic Overturning Circulation; the second is the  
468 abrupt change in ocean circulation on the Antarctic continental shelf, leading to suddenly rising ocean temperature in contact  
469 with the Antarctic ice shelves fringing the ice sheet.

**Figure 7: Circulations and potential tipping systems in the Southern Ocean. Adapted from Li, England et al (2023) and IPCC SROCC Fig CB7.1**

Along with the AMOC, the Antarctic overturning circulation constitutes the second branch of the global ocean overturning circulation linking the surface to the abyssal ocean (Figure 7), forming Antarctic Bottom Water (AABW) through sinking of the shelf waters around the Antarctic continent. A key mechanism is brine rejection from sea-ice formation: very salty water that is left behind when ocean water freezes, which causes the ambient liquid water to become heavier and sink. This is maintained by offshore winds blowing away from the Antarctic continent, pushing sea ice away from the coast and forming areas of open water (so-called polynyas) supporting brine rejection. The formation of AABW sustains the operation of the lower branch of the Antarctic overturning circulation (Figure 7 and Abernathey et al., 2016).

In contrast to our understanding of the AMOC, any changes related to the future of the Antarctic Overturning Circulation has remained at low or medium confidence due to a persistent lack of process understanding (Fox-Kemper et al., 2021; Heuzé et al., 2021; Purich and England 2023). However, evidence of its ongoing decline has escalated in recent years, both from observations (Gunn et al., 2023; Zhou et al., 2023; including record low sea ice extent in 2022-2023) and numerical models (Lago & England, 2019; Liu et al. 2022; Li et al, 2023), linked to the changes in melt water, wind trends, sea ice transport and water mass formation (Holland et al., 2012).

Change or collapse in the Antarctic Overturning Circulation has the potential for widespread climate and ecosystem implications within this century. The Southern Ocean surface temperature is set by a delicate balance between ocean overturning strength, upper ocean stratification (the degree of mixing between ocean layers), air sea ice fluxes and sea ice cover. The Antarctic Overturning Circulation affects cloud feedbacks and has been shown to be a key regulator of Earth's

492 global energy balance, so much so that it is the main control on the timing at which the 2°C global warming threshold will be  
493 reached for a given emission scenario (Bronselaer et al., 2018; Dong et al., 2022; Shin et al., 2023).  
494 Reduced Antarctic overturning can also shift global precipitation patterns, resulting in drying of the Southern Hemisphere  
495 and wetting of the Northern Hemisphere (Bronselaer et al., 2018). Reduced Antarctic overturning also reduces the efficiency  
496 of the global ocean carbon sink, leaving more nutrient-rich water at the seafloor (Liu et al., 2022), and also affects global  
497 ocean heat storage (Li et al., 2023). Amplifying feedbacks to further shelf water warming and ice melt are also possible  
498 (Bronselaer et al., 2018; Purich and England 2023; Li et al., 2023).

### 499 2.3.1 Evidence for tipping dynamics

500 Different generation climate models consistently project a slowing or collapse of the Antarctic overturning under a warming  
501 climate (Heuzé et al., 2015, 2021; Lago and England, 2019; Meredith et al., 2019; Fox-Kemper et al., 2021; Liu et al., 2022).  
502 However, our confidence in these models to assess change in Antarctic overturning is limited due to known limitations in the  
503 representation of dense water formation (Purich and England 2023). Limitations come also from the lack of representation of  
504 increased Antarctic ice sheet meltwater in most models (Fox-Kemper et al., 2021). Armstrong McKay et al. (2022)  
505 identified the Antarctic Overturning Circulation as a potential but uncertain tipping system in the climate system, but gaps in  
506 process understanding meant a threshold remained uncertain. They estimated the Antarctic Overturning Circulation to be  
507 prone to collapse at a global warming level of 1.75-3°C based on Lago & England (2019).

508

509 Specifically designed model experiments aiming to bridge some of these limitations, in combination with evidence from  
510 observed changes (Gunn et al., 2023; Purkey and Johnson, 2013), suggest that we are currently heading toward a decline and  
511 possible collapse of the Antarctic Overturning Circulation (Li et al., 2023; Zhou et al., 2023). The rapidity of this decline  
512 might even be underestimated, according to recent observations (Gunn et al., 2023). The sensitivity of the overturning  
513 circulation to increases in upper ocean stratification is also consistent with paleo evidence. Observations from marine  
514 sediments suggest that AABW formation was vulnerable to freshwater fluxes during past interglacials (Hayes et al., 2014;  
515 Huang et al., 2020; Turney et al., 2020) and that AABW formation was strongly reduced (Skinner et al., 2010; Gottschalk et  
516 al., 2016; Jaccard et al., 2016) or possibly totally curtailed (Huang et al., 2020) during the Last Glacial Maximum and earlier  
517 transient cold intervals.

518 Local water mass characteristics and associated circulation regimes on the Antarctic continental shelf are setting the rate of  
519 ice shelf melt rates in ice ‘cavities’, the regions of ocean water covered by floating ice shelves. Relatively warm water  
520 reaching the continental shelf in west Antarctica causes high basal melt rates with severe consequences for the ice shelf, ice  
521 sheet dynamics, and sea level rise (Naughten et al., 2023). In contrast, the largest ice shelf cavities in the Weddell and Ross  
522 Seas are not exposed to this relatively warm water, and consequently have melt rates orders of magnitude smaller than in  
523 West Antarctica. Despite this, the Weddell and Ross Sea ice shelf cavities have been shown to exhibit tipping behaviour  
524 (Hellmer et al., 2012; 2017; Siahaan et al. 2022). Models show that they are prone to sudden warming of their cavity under

525 future climate change, dramatically increasing basal melting with important consequences for global sea level rise (Hellmer  
526 et al., 2012; 2017; Siahhaan et al. 2022). Once tipped into a warm state, such cavities could be irreversibly maintained in such  
527 a state, even when forcing is reduced (Hellmer et al., 2017). However, it remains unclear what threshold would need to be  
528 crossed to tip those cavities from a cold to warm state, and it may only occur under extreme climate change scenarios.

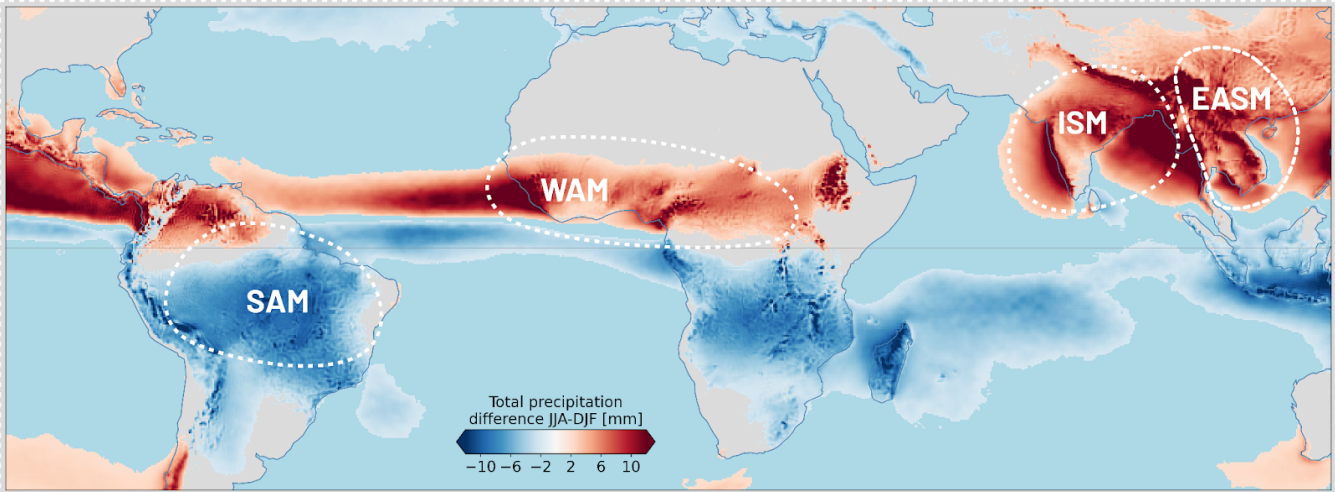

### 529 2.3.2 Assessment and knowledge gaps

530 In summary, the combination of process-based understanding and observational, modelling and paleoclimate evidence  
531 suggests that the Antarctic Overturning Circulation will continue to decline in the 21st Century. There is increasing evidence  
532 for positive amplifying feedback loops that can lead to a collapse of the overturning, with widespread global climate and  
533 ecosystem consequences. Closely linked to this is a potential tipping in continental shelf water temperature, driven by  
534 amplifying meltwater feedbacks once a regional temperature threshold is crossed. We therefore classify the Southern Ocean  
535 Circulation as a tipping system with medium confidence. However, its potential tipping thresholds remain uncertain.

## 536 3. Atmospheric Circulations: Monsoons

537 Monsoon circulations are large-scale seasonal changes in the direction and strength of prevailing winds over South Asia,  
538 East Asia, Africa, Australia and the Americas. Historically, monsoons were seen as large-scale sea breeze circulations driven  
539 by land-sea heating differences due to seasonal changes in incoming solar radiation (Figure 8). Currently, a perspective of a  
540 global monsoon has emerged (Trenberth et al., 2000; Wang & Ding, 2008), whereby the monsoon systems are seen as  
541 interconnected and driven by localised seasonal and more extreme migrations of the ITCZ (Gadgil, 2018; Geen et al., 2020,  
542 and references within). Monsoon regions in the world experience heavy precipitation in the summer months, and the global  
543 monsoon system is an integral part of the global hydrological cycle, contributing ~31 per cent of total precipitation over the  
544 globe (Wang and Ding, 2008).

545  
546

547  
548 **Figure 8: Monsoon systems.** Shown is the total precipitation difference between Northern hemisphere summer (June-August, JJA)  
549 and winter months (December-February, DJF), highlighting the dominant precipitation patterns over South America (SAM), West  
550 Africa (WAM), India (ISM) and East Asia (EASM). Based on data from ERA5 (Hersbach et al., 2023), with monthly averages over  
551 1980-2010.

552 There is a recent intensification trend in global monsoon precipitation, mainly due to enhanced northern hemisphere summer  
553 monsoon (Wang et al., 2012). It will likely continue in the future (high confidence, IPCC AR6, by ~1-3% per °C warming)  
554 because of increased water vapour related to warming driven by increased CO<sub>2</sub> in the atmosphere (Hsu et al., 2013; Lee and  
555 Wang, 2014; Chen et al., 2020; Moon and Ha, 2020; Wang et al., 2020), although a few studies conversely show that climate  
556 warming may lead to a weakened global monsoon circulation (Hsu et al., 2012, 2013). Climate simulations also project  
557 expansion of global monsoon domain areas with increasing CO<sub>2</sub> (Wang et al., 2020; Paik et al., 2023) and increased  
558 frequency of monsoon precipitation extremes in the 21<sup>st</sup> Century (Chevuturi et al., 2018; Ali et al., 2020, Modi and Mishra,  
559 2019; Moon and Ha, 2020; Katzenberger et al., 2021).

560 Monsoon precipitation is vital for agrarian populations and livelihoods in vast areas of South Asia, Africa, and South  
561 America, and changes to it could expose almost two thirds of the global population to disastrous effects (Wang et al., 2021).  
562 Hence it is crucial to understand the dynamics and potential nonlinear changes or tipping behaviour of monsoon systems  
563 under a changing climate. Here the ‘tipping’ of monsoon systems refers to a significant, feedback-driven shift in the  
564 precipitation state of the monsoon, with implications for the regional and global climate and ecosystems. In this discussion  
565 we assess if monsoon systems show any evidence of nonlinear (tipping or abrupt) responses to climate forcings based on  
566 available literature.

### 567 3.1 Indian summer monsoon (ISM)

568 During the summer season over South Asia (June-September), winds from the south west carry large amounts of water  
569 vapour from the Indian Ocean to the Indian subcontinent and cause heavy precipitation in the region, providing ~80 per cent  
570 of the total annual precipitation (Figure 8). ISM precipitation shows considerable intra-seasonal, interannual, and decadal  
571 variability, many times with precipitation extremes (leading to droughts, floods) during the season, and years and decades  
572 with above and below (in drought years) normal precipitation. Indian monsoon variability is strongly influenced by  
573 ocean-atmosphere interactions such as El Niño Southern Oscillation (ENSO), Indian Ocean Dipole events (irregular changes  
574 in the temperature gradients in the Indian Ocean, Cherchi et al., 2021; Chowdary et al., 2021; Hrudya et al., 2021), and  
575 cooler temperatures in the North Atlantic (Borah et al., 2020).

576 ISM precipitation declined in the second half of the 20th Century, attributed mainly to human-driven aerosol loading  
577 (Bollasina et al., 2011) and strong Indian Ocean warming (Roxy et al., 2015). Recent studies (Jin and Wang, 2017) suggest  
578 the ISM has revived since 2002, linked to enhanced warming over the Indian subcontinent due to reduced low clouds,  
579 resulting in an increased land-ocean thermal gradient. Future projections suggest increases in the ISM precipitation in future  
580 warming scenarios (by 5.3 per cent per celsius of global warming according to CMIP6 models, Katzenberger et al., 2021)  
581 and a longer monsoon duration (Moon and Ha, 2020).

#### 582 3.1.1 Evidence for tipping dynamics

583 Many periods of abrupt ISM transitions have been identified in past monsoon records in association with high-latitude  
584 climate events (Schulz et al., 1998; Morrill et al., 2003) such as during Heinrich events (glacial outbursts that temporarily  
585 shut down the AMOC) (McManus et al., 2004; Stager et al., 2011), the Younger Dryas (a temporary return to more intense  
586 glacial conditions between 12,900–11,700 years ago, Carlson et al., 2013; Cai et al., 2008), and several periods during the  
587 more recent Holocene (Gupta et al., 2003; Berkelhammer et al., 2012; Yan and Liu, 2019). However, the mechanisms of  
588 such abrupt transitions are not clearly understood. Efforts have been made to identify any Indian monsoon tipping  
589 mechanisms using simplified models (Zickfeld et al., 2005; Levermann et al., 2009).

590 An internal feedback mechanism, a “positive moisture advection feedback” (Zickfeld et al., 2005; Levermann et al., 2009;  
591 Schewe et al., 2012), has been suggested as responsible for abrupt transitions simulated using these analytical models. In this  
592 feedback, the atmospheric temperature gradient between the land and cooler ocean in summer leads to the onshore transport  
593 of moist air (advection), which then rises, forms clouds, and condenses into rain. The phase transition from vapour to liquid  
594 warms the surrounding air (through the release of latent heat, or ‘diabatic heating’), increasing the land-ocean temperature  
595 gradient, and sustaining this monsoon circulation. Any forcing that weakens this pressure gradient can therefore lead to  
596 monsoon destabilisation (Zickfeld et al., 2005). If monsoon winds weaken, advection and condensation reduce, and the  
597 threshold for a monsoon tipping is reached when the diabatic heating fails to balance the heat advection away from the  
598 region (Levermann et al., 2009).

Contrarily, follow-up studies (Boos and Storelvmo, 2016) challenge occurrence of any tipping in these simplified models, and rule out any abrupt monsoon responses to human-driven forcings in the future, and instead attribute past monsoon shifts to rapid forcings or vegetation feedbacks. Simplified models omit key aspects and feedbacks in the monsoon system (specifically, static stability of the troposphere in the models that simulated the monsoon tipping, Boos and Storelvmo, 2016; Kumar and Seshadri, 2023). Hence, more studies using models that represent the complexities of the monsoon and paleoclimate data are required for a clearer picture on any non-linear changes in the monsoon system.

Apart from climate change, aerosols pose another significant human-driven pressure on the Earth system. Aerosols influence the Earth's radiative budget, climate, and hydrological cycle by reflecting or absorbing solar radiation, changing the optical properties of clouds, and also by acting as cloud condensation nuclei. An increase in anthropogenic aerosols has been attributed as the major reason for the decline of Northern Hemispheric summer monsoon strength from the 1950s to 1980s (Cao et al., 2022), due to its dimming effect.

A large increase in regional aerosol loading over South and East Asia ( $>0.25$  Aerosol Optical Depth, AOD, Steffen et al., 2015) could potentially switch the Asian regional monsoon systems to a drier state. Further, hemispheric asymmetries in the aerosol loading ( $>0.15$  AOD Rockström et al., 2023), due to volcanic eruptions, human sources, or intentional geoengineering, could lead to hemispheric temperature asymmetries and changes in the location of the ITCZ, significantly disrupting regional monsoons over West Africa and South Asia (Haywood et al., 2013; Rockström et al., 2023; Richardson et al., 2023). However, there is no direct evidence of aerosols causing a tipping of the monsoon systems, and uncertainties in threshold estimates are large due to complex aerosol microphysics and aerosol-cloud interactions. Hence, systematic observational and modelling approaches would be needed to reduce the uncertainties, as well as additional assessments of interhemispheric asymmetries in the aerosol distribution.

### 3.1.2 Assessment and knowledge gaps

The Indian summer monsoon system was earlier classified as one of the Earth's tipping systems (Lenton et al., 2008), based on the threshold behaviour of the ISM in the past and the moisture-advection feedback (Levermann et al., 2009), which was refuted by later studies (Boos and Storelvmo, 2016; Seshadri, 2017). Most recently, Armstrong McKay et al. (2022) categorise ISM as an “uncertain potential [climate] tipping element” as global warming is not likely to cause tipping behaviour directly in ISM precipitation.

Based on this current literature, the chances for ISM exhibiting a tipping behaviour towards a new low-precipitation state under climate change are uncertain, warranting extensive studies on the subject. However, potential tipping behaviour in the AMOC (relation to global monsoon described in West African monsoon below) or increase in the interhemispheric asymmetry of aerosol loading in the atmosphere beyond potential threshold levels could lead to large disruptions to monsoon systems. This could cause calamitous effects on millions of people in the monsoon regions, even in the absence of tipping.

## 630 3.2 West African monsoon (WAM)

631 The West African monsoon (WAM) controls hydroclimatic conditions, vegetation, and mineral-dust emissions of northern  
632 tropical and subtropical Africa, up to the semi-arid Sahel region at the southern edge of the Sahara Desert (Figure 8). The  
633 strength of the monsoon shows large variations over a range of timescales from interannual to decadal and longer. Albedo  
634 (reflectivity of the Earth's surface) changes caused by human-driven land-cover changes and desertification (Charney et al.,  
635 1975; Charney, 1975; Otterman, 1974) can affect rainfall: a less vegetated surface with higher albedo increases radiative  
636 loss, thereby reducing temperature and suppressing the rising and condensation of moist air into rainfall (i.e. convective  
637 precipitation). Variations of sea surface temperatures (SSTs) in different oceanic basins can also drive interannual and  
638 decadal variability in WAM precipitation (Rodríguez-Fonseca et al., 2015). Other major factors that affect WAM variability  
639 are land surface variability such as variations in soil moisture (Giannini et al., 2013; Zeng et al., 1999), vegetation (Charney  
640 et al., 1975; Kucharski et al., 2013; Otterman, 1974; Wang et al., 2004; Xue, 1997), high-latitude cooling (Collins et al.,  
641 2017), and dust emissions (Konare et al., 2008; Solmon et al., 2008; Zhao et al., 2011). Charney et al. (1975) proposed the  
642 vegetation-climate positive feedback mechanism to explain the decadal precipitation variability in the WAM. The feedback  
643 mechanism is explained as desertification leads to increased albedo, surface cooling, and increased stability in the  
644 atmosphere, hence, reduced convection and precipitation, thereby amplifying the initial response. It has since been suggested  
645 that additional factors such as evapotranspiration, dust emissions, and water vapour recycling related to the vegetation  
646 further contribute to the vegetation-climate feedback (Rachmayani et al., 2015; Pausata et al., 2016; Yu et al., 2017; Chandan  
647 and Peltier, 2020).

### 648 3.2.1 Evidence for tipping dynamics

649 Paleoclimate records underscore dramatic variations of the WAM in the more distant past, such as the periodic expansion of  
650 vegetation into the Sahara Desert during the so-called 'African humid periods' (AHPs) and are linked to the emergence of  
651 ancient cultures along the Nile. The vegetation-climate feedback likely played a significant role in amplifying and sustaining  
652 the wetter conditions and facilitating a green Sahara during AHPs (Pausata et al., 2016). Another example is the drought  
653 200–300 years ago, which caused the water level of Lake Bosumtwi in Ghana to fall by almost four times as much as it did  
654 during the drought of the 1970s and 1980s. Large past variations of the WAM, such as those during the AHPs, raise the  
655 question of whether present day anthropogenic global warming could have potentially significant impacts on the WAM.  
656 Although the nature and magnitude of radiative forcing were different during the AHPs than they are now (i.e. an external  
657 change in insolation due to orbital forcing versus an internal change from increased greenhouse gases), the fact that the  
658 AHPs occurred under a globally warmer climate than the pre-industrial period invites questions.  
659 Some paleoclimate archives show WAM precipitation changes that took place over several centuries (deMenocal et al.,  
660 2000; McGee et al., 2013), i.e. an order of magnitude faster than the orbital forcing. However, others show a much more  
661 gradual change (e.g. Kröpelin et al. 2008) with a time-varying withdrawal of the WAM from North to South following the

insolation changes (Shanahan et al., 2015). Because of geographic variability of the African landscape and African monsoon circulation, abrupt changes can occur in several, but not all, regions at different times during the transition from the humid to arid climate (Dallmeyer et al., 2021).

By inducing latitudinal movements of the ITCZ, change in the Atlantic Meridional Overturning Circulation (AMOC) is considered to play a role in shifts of global monsoon systems (Stager et al., 2011). Paleoclimate evidence suggests that glacial meltwater-induced weakening of the AMOC during Heinrich events in the last glacial period led to abrupt Asian and African monsoon weakening (Mohtadi et al., 2014; 2016). Similarly, the Younger Dryas led to a cool and dry state over Northern Hemisphere tropical monsoon regions, as well as the 8.2-kyr event during the Holocene (Alley and Ágústsdóttir, 2005). North Atlantic fresh water-hosing simulations using climate models (Lewis et al., 2010; Pausata et al., 2011; Kageyama et al., 2013) confirm these shifts in ITCZ can occur as a result of substantial glacial meltwater release. These influences of AMOC on the monsoon systems have also been studied in the context of the South American monsoon (see below). Hence, a collapse of AMOC has the potential to cause disruptions to the regional monsoon systems and other tropical precipitation systems over Asia, Africa, and South America (Gupta et al., 2003; IPCCAR6; Ben-Yami et al., 2024). Additionally, location and intensity of the tropospheric jet streams have been identified as processes modulating the strength and position of the African rainbelt (e.g., Farnsworth et al., 2011, Nicholson and Dezfuli, 2013).

### 3.2.2 Assessment and knowledge gaps

Abrupt changes in one region can be induced by abrupt changes in other regions, a process sometimes referred to as “induced tipping” (Pausata et al., 2020). The AHP transition of the Sahara was slow with respect to timescales of individual humans and local ecosystems, but regionally rapid with respect to changes in the driver. Based on the record of large past variations of WAM precipitation patterns (including collapse), and the existence of positive amplifying feedbacks, we classify WAM as a tipping system with low confidence. This is in line with previous assessments (Armstrong McKay et al., 2022), in which a lower tipping threshold of 2°C global warming was estimated but attributed low confidence due to limited model resolution of vegetation shifts, and model disagreements in future trends. The timescale of abrupt shifts is estimated to range from decades as observed in CMIP5 models (Drijfhout et al., 2015) to centuries based on paleorecords (Hopcroft and Valdes, 2021; Shanahan et al., 2015). Potential additional destabilisation through AMOC weakening and atmospheric aerosol loading, and the far-reaching implications of WAM tipping call for intensified research efforts on this system.

### 3.3 South American Monsoon (SAM)

The South American Monsoon (SAM) system is characterised by strong seasonality in precipitation, even though it does not show a reversal of low-level winds like the Asian monsoon (Zhou and Lau, 1998; Vera et al., 2006; Liebmann and Mechoso, 2011; Carvalho et al., 2012). Studies on the SAM system are relatively few compared to the Asian and African monsoon systems, as it was not classified as a monsoon system until a couple of decades ago (Zhou and Lau, 1998).

693 A mature SAM system (from December to February) shows features such as enhanced northeastern trade winds, increased  
694 land-ocean thermal gradient, and the development of an active convective zone (the South Atlantic Convergence Zone)  
695 (Figure 8; Zhou and Lau, 1998). The SAM system affects vast areas of tropical South America all the way to southern  
696 Brazil, and provides more than 50 % of the annual precipitation to these regions (Vera et al., 2006) including most of the  
697 Amazon rainforest. SAM precipitation varies from interannual to orbital timescales (Chiessi et al., 2009; Liebmann and  
698 Mechoso, 2011; Carvalho and Cavalcanti, 2016; Hou et al., 2020).

699 The influence of anthropogenic climate change on the SAM precipitation is ambiguous (Douville et al., 2021), and many  
700 CMIP5/CMIP6 models are noted for their poor representation of SAM precipitation (Jones and Carvalho, 2013; Douville et  
701 al., 2021). IPCC AR6 finds high confidence in delayed onset of the SAM precipitation since the 1970s associated with  
702 climate change, which could worsen with increased CO<sub>2</sub> levels (Douville et al., 2021). However, the projected future change  
703 in total SAM precipitation is uncertain, as the models show low agreement on the projections (Douville et al., 2021).

### 704 3.3.1 Evidence for tipping dynamics

705 Orbital timescale changes (i.e. over 10s of 1000s of years) in SAM precipitation seem to be largely controlled by changes in  
706 insolation and respond linearly to it (Cruz et al., 2005; Hou et al., 2020). Millennial-scale changes (i.e. over 1000s years) in  
707 the SAM are thought to be associated with variations in the strength of the AMOC as described for the West African  
708 monsoon (see above). In particular, paleo evidence indicates that an increase in tropical South American precipitation to the  
709 south of the equator followed a weakening of the AMOC related to Heinrich stadials (Mulitza et al., 2017; Zhang et al.,  
710 2017; Campos et al., 2019). Similarly, meltwater flux from the Laurentide Ice Sheet during the Younger Dryas probably led  
711 to wet anomalies over tropical South America to the south of the equator (McManus et al., 2004; Broecker et al., 2010;  
712 Venancio et al., 2020; Brovkin et al., 2021). Earth system model projections of AMOC collapse impacts on tropical South  
713 American rainfall are model dependent, but generally find a reduction in rainfall over northernmost South America and an  
714 increase over tropical South America to the south of the equator (Bellomo et al., 2023; Nian et al., 2023; Orihuela-Pinto et  
715 al., 2022a; Liu et al., 2020).

716 Deforestation of the Amazon rainforest may force a tipping dynamic in the SAM system. In a non-linear model for moisture  
717 transport, deforestation over 30-50 % of the Amazon rainforest led to a tipping point in the SAM system, causing  
718 precipitation reductions of up to 40 % in non-forested parts of the western Amazon (Boers et al., 2017). This reduction in  
719 SAM precipitation is caused by the breakdown of a positive amplifying feedback mechanism present in Amazonian  
720 precipitation that involves latent heat of condensation over the Amazon rainforest due to transpiration (i.e. water lost from  
721 plants) and water vapour transport from the Atlantic. Reduced transpiration due to deforestation can no longer sufficiently  
722 provide water vapour to sustain the latent heat required, thereby reducing the inflow of oceanic water vapour, and leading to  
723 a SAM tipping in this model (Boers et al., 2017). In addition to deforestation, transpiration over northern Amazon may be  
724 reduced due to an increase in seasonal tropical vegetation related to an AMOC slowdown (Akabane et al., 2024), further  
725 curtailing moisture availability for the SAM.

### 726 3.3.2 Assessment and knowledge gaps

727 A combination of climate change and deforestation could lead to substantial changes in the SAM system, affecting many  
728 millions of people. Additionally, a decrease in AMOC strength could potentially trigger major changes in tropical South  
729 American precipitation (see Wunderling et al., 2023). However, the current scarcity of research in the subject limits our  
730 ability to fully understand and assess the tipping potential of the SAM system, and we classify the possibility of SAM  
731 tipping to be uncertain.

### 732 3.4 East Asian Summer Monsoon (EASM)

733 Beyond the major tropical monsoon systems, there are other subtropical monsoon systems which ostensibly share similar  
734 characteristics, such as the East Asian Summer Monsoon (EASM), which is a part of the South Asian Monsoon. Unlike the  
735 tropical monsoon systems which are driven by the ITCZ movement and characterised by heavy summer rainfall, the  
736 precipitation and wind patterns of the EASM are linked to mid-latitude frontal systems and the jet stream, and its interaction  
737 with the Tibetan Plateau (Molnar et al., 2010; Son et al., 2019). A recent study on CMIP6 projections of EASM by  
738 Katzenberger and Levermann (2024) finds that the future precipitation and interannual variability in the EASM region is  
739 projected to consistently increase under various climate change scenarios. They suggest these changes are primarily driven  
740 by thermodynamic responses to global warming, rather than major shifts in atmospheric circulation patterns. Further, the  
741 same study finds an increased frequency of extreme wet seasons based on the CMIP6 simulations.

#### 742 3.4.1 Evidence for tipping dynamics

743 Speleothem and loess records from China, and analyses based on these records (Wang et al., 2008; Thomas et al., 2015;  
744 Rousseau et al., 2023) reveal that the EASM has undergone periods of abrupt changes on millennial timescales. These  
745 changes are more sudden than the change in Northern Hemisphere summer insolation that is thought to be the primary  
746 driver, and this suggests a potential tipping behaviour in the EASM. Schewe et al. (2012) proposed a mechanism involving  
747 moisture advection feedback to explain these abrupt changes in the past, and suggests that a minimum threshold of specific  
748 humidity over the ocean is essential to sustain monsoon precipitation over the land. The changes in insolation may trigger  
749 changes in sea-surface temperature and evaporation, hence specific humidity over the ocean. According to the conceptual  
750 model proposed by Schewe et al. (2012), gradual, insolation-driven changes in oceanic humidity lead to abrupt transitions-  
751 the system suddenly switches between states that can or cannot sustain a strong monsoon circulation whenever the oceanic  
752 specific humidity crosses the threshold. Although paleoclimate records show evidence of past abrupt shifts in the EASM, the  
753 mechanism detailed in Schewe et al. (2012) was contested by a later study by Boos and Storelvmo (2016). They highlight  
754 that the underlying theory in Schewe et al. (2012) omitted the static stability of the troposphere. Modeling experiments by  
755 Boos and Storelvmo (2016), primarily examining decadal timescales, find a more linear monsoon response to forcings. They

756 suggest that the mechanisms behind orbital-scale abrupt changes might involve very large forcings or slow-acting  
757 components like ice sheets and large-scale vegetation changes.

758

759 Further, like the Indian, African, and South American monsoons, the EASM could be affected by a potential collapse of the  
760 AMOC (Sun et al., 2012; Ben-Yami et al., 2024). Freshwater hosing experiments using climate models that mimic AMOC  
761 slowdown show increased temperature gradients between the equator and the poles, and suggest northern westerlies acting  
762 as a pathway in transmitting climate change signals from the North Atlantic to the Asian monsoon regions (Sun et al., 2012).

### 763 3.4.2 Assessment and knowledge gaps

764 While paleoclimate records provide compelling evidence for EASM's tipping behaviour in the past, a deeper understanding  
765 of the underlying mechanisms and internal feedback is crucial for assessing its vulnerability to future tipping points. We  
766 therefore classify this system as uncertain.

### 767 3.5 Summary

768 The major monsoon systems discussed here share some similar, underlying dynamics, as they are complex phenomena  
769 emerging from the interplay of global and regional factors. As such, questions around potential tipping largely relate to the  
770 susceptibility of changes in the global monsoon to anthropogenic forcing, e.g. either directly via interhemispheric differences  
771 in aerosol loading or indirectly via climate-change driven AMOC collapse. In principle, regional feedbacks may maintain or  
772 significantly shift a monsoon regime but there is insufficient evidence across the discussed systems, with exception of the  
773 West African monsoon. This system does not only feature strong positive feedbacks involving vegetation and dust, but has  
774 also reportedly collapsed abruptly several times in the past. Overall, we therefore classify tipping of the West African  
775 monsoon as possible with low confidence, and South American, East Asian and Indian monsoons as uncertain.

## 776 4. Global atmospheric circulations

### 777 4.1 Tropical clouds, circulation, and climate sensitivity

778 Clouds play an important role in the climate system, as they contribute to the regulation of Earth's energy budget. In general,  
779 the altitude and composition of clouds determines the amount of shortwave radiation to reach the planet's surface, as well as  
780 the longwave radiation (heat) escaping to space. For example, low, thick clouds have a net cooling effect as they deflect  
781 large fractions of incoming sunlight, while also having a weak greenhouse warming effect due to their low altitude (i.e.  
782 having a comparable temperature to the ground). A changing climate, which causes changes in temperature, humidity, and  
783 circulation patterns, affects the formation and dynamics of clouds. This, in turn, can influence the climate and how much  
784 warming results from increased atmospheric CO<sub>2</sub> concentrations (i.e. 'climate sensitivity').

#### 785 4.1.1 Evidence for tipping dynamics

786 Literature on cloud-induced tipping points is very limited. Yet cloud-forming processes exhibit strong hysteresis on weather  
787 timescales. Indeed, a cloud droplet forms when water starts to stick to a particle after a certain level of humidity (in which a  
788 so-called hygroscopic aerosol particle crosses a humidity tipping point into an unstable condensational growth phase); and  
789 precipitation, once initiated, is a self-reinforcing cascade where larger particles fall faster and hence grow faster by  
790 collisions. Coupling of these micro-scale processes to atmospheric dynamics can lead to spontaneous and irreversible  
791 transitions at the intermediate mesoscale – in particular, the transition of shallow cloud layers from closed to open-cell  
792 geometries (honeycomb-like cloud patterns formed by convecting air) (Feingold et al. 2015), driven by a self-sustaining  
793 process involving precipitation-induced downdraft, subsequent updraft and new cloud formation (Yamaguchi and Feingold,  
794 2015). Another example is self-aggregation of deep convection, apparently driven by radiative and moisture feedback loops  
795 (Müller et al. 2022). Both of these significantly decrease cloud cover and albedo, potentially enabling climate interactions.  
796 Could further coupling out to planetary scales produce climate-relevant tipping behaviour? Complicating this question is the  
797 fact that cloud-related processes are not well represented in current climate models, limiting their ability to guide us.  
798 The most discussed possibility has been the extreme case of a global climate runaway. If the atmosphere became sufficiently  
799 opaque to infrared (i.e. if it became harder for longwave heat energy to escape due to overcast high cloud, very high  
800 humidity, or CFC-like greenhouse gases filling in spectral absorption windows), the planet could effectively lose its ability  
801 to cool to space, producing a Venus-like runaway. Although general circulation models (GCMs) and paleoclimate evidence  
802 suggest climate sensitivity rises as climate warms (Sherwood et al., 2020), calculations show virtually no chance of runaway  
803 warming on Earth at current insolation levels (LeConte et al. 2013).  
804 A more plausible scenario is unexpectedly strong global positive amplifying radiative feedback from clouds and high  
805 climate sensitivity. Although presumably reversible, this would be serious. With respect to high clouds, suggested missing  
806 feedbacks (due to novel microphysical or aggregation mechanisms) have generally been negative (e.g. Mauritsen and  
807 Stevens 2015). Low clouds are a greater concern: one recent study using a multiscale atmospheric model found a strong and  
808 growing positive amplifying feedback from rapid disappearance of these clouds (Schneider et al. 2019), highlighting the  
809 possibility of nonlinear cloud behaviour and surprises (Bloch-Johnson et al., 2015, Caballero and Huber 2013). Although  
810 various observations generally weigh against high-end climate sensitivities above 4oC per CO2 doubling, they cannot rule  
811 them out (Sherwood et al., 2020).  
812 A final possibility is surprising reorganisations of tropospheric circulation. Innovative atmospheric models (Carlson and  
813 Caballero 2016, Seeley and Wordsworth 2021) and geologic evidence (Tziperman and Farrell, 2009, Caballero and Huber  
814 2010) have suggested possible “super-MJO” (the ‘Madden-Julian Oscillation’ being the dominant mode of ‘intraseasonal’  
815 variability in the tropical Indo-Pacific, and is characterised by the eastward spread of enhanced or suppressed tropical  
816 rainfall lasting less than a season) and/or reorganisation of the tropical atmospheric circulation in a warmer climate due to  
817 cloud-circulation coupling. These scenarios are supported by little evidence, but if they did occur they could massively alter

hydrology in many regions. Poor representation of tropical low clouds has also likely inhibited coupled model simulations of decadal variability or regional trends (Bellomo et al. 2014, Myers et al. 2018), raising the possibility that even if clouds cannot drive tipping points they might amplify other tipping points in ways that are missing from current models.

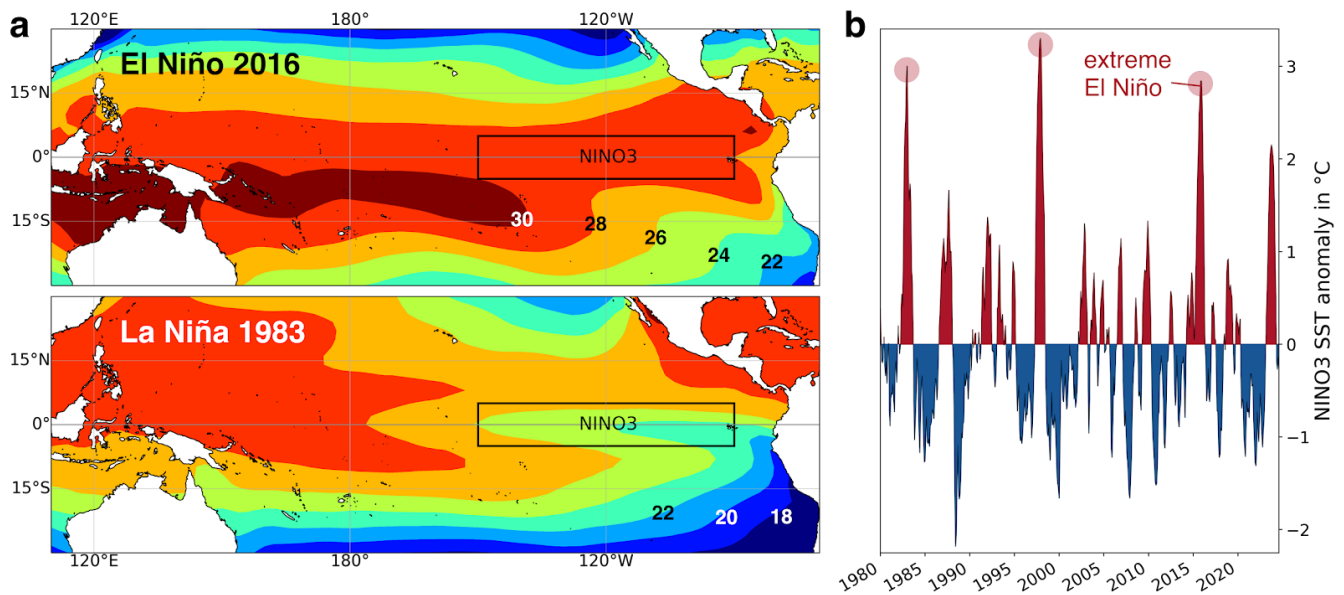

#### 4.1.2 Assessment and knowledge gaps

In summary, concern about cloud-driven tipping points is relatively low. Cloud feedbacks will however likely affect the strength of climate responses, including for many tipping points. For example, they could potentially amplify variability, and current models may not be capturing this well. High climate sensitivity from strongly positive cloud feedbacks also cannot be ruled out.

#### 4.2 El Niño-Southern Oscillation (ENSO)

The El Niño-Southern Oscillation (ENSO) is the dominant interannual mode of variability in Earth's climate. It originates in the tropical Pacific, where it affects sea surface temperatures (SST), trade winds, rainfall, and many other climate variables. El Niño events typically happen every 3 to 5 years (hence the term 'interannual'). The tropical Pacific average climate is characterised by a strong east-west gradient along the equator of about 5-6°C, with warmer SSTs in the west and colder SSTs in the east maintained by easterly Pacific trade winds. During El Niño, the warm phase of this oscillation, this gradient weakens, while during La Niña, its cold phase, it intensifies (examples are shown in Figure 9a). Both phases of this oscillation have far-reaching impacts on global climate and weather patterns, ecosystems, and human health (e.g. McPhaden et al. 2020).

The impacts of ENSO become especially pronounced during the strongest events, often referred to as extreme El Niños (Figure 9b). At their peak, these events can eliminate the east-west ocean temperature gradient along the equator, leading to a temporary collapse of the trade winds. Additionally, an extreme El Niño causes an increase in global mean surface temperature of up to 0.25 °C (e.g. Hu and Fedorov 2017), contributing to the prevalence of heat waves around the globe. While only a few El Niño events reach large magnitudes, the global impacts of these events result in billions of dollars in damage (e.g. Callahan and Mankin 2023).

842

843 **Figure 9: ENSO warm and cold phases and observational record. a** Examples of strong La Niña (top) and El Niño (bottom) events  
 844 seen in the tropical Pacific surface temperature (SST) distribution, with characteristic strong and weak SST gradient along the  
 845 equator, respectively. **b** ENSO record since the 1980s. Observed SST variations in the eastern equatorial Pacific since 1980. Note  
 846 the three extreme events of the past four decades (1982, 1997 and 2015) and the weakening of ENSO variability between years  
 847 2000 and 2015. Temperature is averaged for the NINO3 region (5°C-5°N, 150°W-90°W) in the eastern equatorial Pacific. Based on  
 848 NOAA Extended Reconstructed SST V5 data (Huang et al., 2017).

#### 849 4.2.1 Evidence for tipping dynamics

850 Extensive research conducted since the 1980s has significantly advanced our understanding of the physics behind El Niño,  
 851 leading to improved predictive capabilities of climate models (L’Heureux et al., 2017). ENSO is now recognised as a  
 852 large-scale, irregular, internal oscillatory mode of variability within the tropical climate system influenced by atmospheric  
 853 noise (Timmermann et al., 2018). The spatial pattern of ENSO is determined by ocean-atmosphere feedbacks, while its  
 854 timescale is determined by ocean dynamics. In particular, it is a sequence of self-reinforcing feedbacks between SSTs,  
 855 changes in zonal surface winds, equatorial upwelling, zonal equatorial currents, and ocean thermocline depth that promotes  
 856 the growth of El Niño anomalies and contributes to the positive Bjerknes feedback (McPhaden et al. 2020) .

857

858 Coral-based proxy data indicate that the amplitude and frequency of ENSO events has gradually increased during the  
 859 Holocene (Grothe et al., 2019; Lawman et al., 2022), possibly due to an increase in strong El Niño events. All extreme El  
 860 Niños in the observational record (1982, 1997, and 2015) occurred during the accelerated growth of global mean  
 861 temperatures. This raises the question whether this trend is indicative of upcoming changes in the tropical Pacific to  
 862 conditions with more frequent extreme El Niño events.

In the context of tipping points, the question arises: is there a critical threshold with an abrupt and/or irreversible transition to such a new state? While there are no indications so far for a tipping point in ENSO behavior, several recent studies (e.g. Cai et al. 2018, 2022; Heede and Fedorov 2023a) have indeed suggested that El Niño magnitude and impacts may intensify under global warming (Figure 10), even though there is still no model consensus on the systematic future change in ENSO as IPCC AR6 and the results in Figure 10 suggest.

**Figure 10: Overview of projected changes in extreme El Niño events in CMIP6 climate models. The bar chart shows the time-mean frequency of extreme El Niño events (the number of events per decade) for several idealised and more realistic global warming experiments (abrupt-4xCO<sub>2</sub>, 1pctCO<sub>2</sub>, SSP5-8.5 and SSP1-2.6) next to the pre-industrial Control simulation (piControl). From Heede and Fedorov 2023a (cropped).**

It is projected that the eastern equatorial Pacific will warm faster than the western part of the basin, leading to an eastern equatorial Pacific (EEP) warming pattern or El Niño-like mean conditions, associated with weaker Pacific trade winds. Most climate model future projections exhibit this pattern (e.g. DiNezio et al. 2009; Xie et al. 2010; Heede and Fedorov 2021), and increased ENSO variability is prevalent in models that simulate stronger nonlinear (Bjerknes) feedbacks (Cai et al. 2022). A recent comprehensive study of CMIP6 models and scenarios concluded that although a common mechanism to explain a change in ENSO activity across models is missing, its increase under warming scenarios is robust (Heede and Fedorov, 2023a).

Furthermore, during the warm Pliocene epoch approximately 3-5 million years ago when global surface temperature were ~3°C above pre-industrial, the east-west SST gradient was indeed reduced (Wara et al. 2005; Fedorov et al. 2006, 2013, 2015; Tierney et al. 2019). This state is often referred to as ‘permanent El Niño-like’ conditions, which does not indicate ENSO changes but rather a consistent mean decrease in the east-west SST gradient. While debates on this topic are ongoing, estimates for this gradient reduction range from 1.5 to 4°C, depending on the time interval, proxy data, and the definition of this gradient.

#### 4.2.2 Assessment and knowledge gaps

Therefore, there is a general expectation of a future reduction in the Pacific's east-west SST gradient by the end of the 21st century. Together with other contributing factors, such as the strengthening of the Madden-Julian Oscillation (MJO), the

888 dominant intraseasonal mode in the tropical Indo-Pacific, Arnold and Randall 2015), this reduction is expected to amplify  
889 ENSO (Heede and Fedorov 2023a). Additionally, a warmer atmosphere can hold more water vapor, which could result in  
890 stronger precipitation and heating anomalies in the atmosphere, leading to greater remote impacts of El Niño events.  
891 Consequently, the collective evidence implies an increase of El Niño magnitude and impacts under global warming. There  
892 is, however, insufficient indication for a critical transition associated with an abrupt or irreversible regime shift towards a  
893 new, more extreme, or persistent ENSO state, such that ENSO is not considered a tipping system with medium confidence  
894 (see also Armstrong McKay et al., 2022). However, it is well connected to other Earth system components (e.g. affecting  
895 tropical monsoon rainfall), thereby possibly playing a role in tipping cascades linking different tipping elements via global  
896 teleconnections (Wunderling et al., 2023).  
897 Notably, the projections of a future EEP warming pattern, weaker mean trade winds, and stronger El Niño events contradict  
898 the recent decadal trends in the tropical climate over the past 30 years or so. In fact, since the early 1990s, the Pacific trade  
899 winds have strengthened, and the eastern equatorial Pacific has become colder (e.g. Ma and Zhou. 2016; Seager et al. 2022;  
900 Wills et al. 2022; Heede and Fedorov 2023b). Whether these trends reflect an ocean thermostat-like response to global  
901 warming, internal variability of the system, or both, remains an open question. Similarly, the magnitude of ENSO events has  
902 been generally weaker since the 2000s compared to the 1980s and 1990s (Fig. 1B; also Capotondi et al. 2015 or Fedorov et  
903 al. 2020).  
904 Therefore, debates on the future of the tropical Pacific and ENSO revolve around the question of when the transition to a  
905 mean EEP pattern and weaker trade winds may occur, likely leading to a stronger El Niño and more frequent extreme events.  
906 Simulations with global climate models including strongly eddying ocean components (Wieners et al. 2019; Chang et al.,  
907 2020) and the recently developing 2023-2024 El Niño are expected to help reduce persistent model tropical biases in SST,  
908 precipitation, and ocean thermocline, and to resolve some of the unresolved issues.

#### 909 4.3 Mid-latitude atmospheric dynamics

910 The mid-latitude atmospheric circulation is characterised by a band of strong westerly winds, with the largest velocities at an  
911 altitude of 7-12 km. In the Northern Hemisphere, these form the so-called polar ‘jet-stream’. The jet serves as a separation of  
912 cold air masses at high-latitudes in the North from temperate air masses further south. Large meanders in the jet are referred  
913 to as Planetary, or Rossby waves. In most cases, these waves move over large distances and decline over timescales of a few  
914 days. When persisting for a prolonged time over the same location (referred to as ‘quasi-stationary’ waves) they can lead to  
915 high-impact climate extremes, including temperature extremes or heavy precipitation. An example is the record breaking  
916 heatwave of 2021 in the North American Pacific Northwest (Philip et al., 2021).

Figure 11: Potential changes in mid-latitude atmospheric circulations under global warming, exemplary for the Northern Hemisphere. Reduction of AMOC, atmospheric blocking events, arctic warming and other drivers can modify the jet stream. Potential consequences are a northward shift, slowdown and enhanced meandering, related to increases in extreme weather phenomena.

Atmospheric features such as blocks (quasi-stationary high-pressure regions that divert, or “block” the large-scale atmospheric flow on timescales of several days to weeks) are intimately linked to these persistent meanders in the jet. A widely discussed effect of climate change is a poleward shift of the mid-latitude jet, although this may be season and location dependent (Oudar et al. 2020), and smaller than previously thought (Curtis et al., 2020) (Figure 11).

#### 4.3.1 Evidence for tipping dynamics

In climate models, the magnitude of the jet’s meridional shift strongly depends on the reduction of the overturning circulation in the Atlantic (AMOC). Models with a strong AMOC reduction in the future tend to project a stronger poleward shift of the jet than models with a weaker AMOC reduction, which sometimes even display an equatorward shift (Bellomo et al., 2021). This is because a strong weakening of the AMOC might amplify the latitudinal temperature gradient that drives the strength and position of the zonal jet. As a consequence, the extent of AMOC change is a large contributor to atmospheric circulation uncertainty in regional climate change projections (Bellomo et al., 2021).

Furthermore, it has been suggested that the mid-latitude flow might weaken, leading to more persistent and slower moving weather patterns (Coumou et al. 2015, Kornhuber & Tamarin-Brodsky 2021). A possible driver is Arctic amplification, namely the fact that the Arctic is warming more rapidly than the rest of the planet, driven by a variety of mechanisms (Previdi et al., 2021) including temperature- and sea ice-related feedbacks (Dai et al., 2019). Arctic amplification reduces the equator–pole temperature contrast, and could result in a weakening and enhanced meandering of the jet stream (e.g. Francis

937 and Vavrus, 2015). This, in turn, could potentially lead to an even larger reduction in the latitudinal temperature contrast,  
938 further weakening the jet and so on. While Arctic amplification is most evident during winter, such increase in waviness  
939 may also be occurring during the summer season (Coumou et al., 2018). However, evidence that the occurrence of  
940 large-amplitude atmospheric waves is increasing is debated (e.g. Screen and Simmonds, 2013; Blackport and Screen, 2020;  
941 Riboldi et al., 2020), and mechanisms which would reduce blocking in the future have also been proposed (e.g. Kennedy et  
942 al., 2016).

943 As part of this debate, it has been proposed that several weather extremes in recent decades were associated with a  
944 quasi-stationary, quasi-resonant wave pattern. This results from the interaction of climatological waves that are perpetually  
945 forced by orography (mountain geography) and land-sea contrasts with transient meanders of the jet stream (Petoukhov et  
946 al., 2013), given a set of favourable conditions (White et al. 2022). Petoukhov et al. (2013) also hypothesised that Arctic  
947 amplification and the associated weakened, wavier jet may provide increasingly favourable conditions for the occurrence of  
948 quasi-resonance. This can result in circulation features which accelerate regional extreme weather occurrence trends, for  
949 example heatwave trends in Europe (Rousi et al. 2022), although the direction of causality is debated (Wirth and Polster,  
950 2021). If recent extreme events are indeed associated with a resonance mechanism that only is triggered when the jet crosses  
951 a certain threshold in waviness, a tipping point might be involved. However, it is uncertain whether this would be associated  
952 with hysteresis and irreversibility or would just be a reversible, but abrupt, shift of the atmosphere towards enhanced  
953 large-amplitude mid-latitude waves.

954 More generally, there is no robust evidence that continued climate change and Arctic amplification will lead to a tipping  
955 towards a wavy-jet state, systematically higher amplitude and/or more frequent planetary waves, or blocks. Equally, there is  
956 no robust evidence that these hypothetical changes would be self-sustaining. Indeed, while a number of large changes in  
957 atmospheric dynamical features may occur under climate change, these are typically discussed as gradual changes, without  
958 explicit hysteresis or tipping behaviour. Similarly, there is no robust evidence pointing to tipping-like behaviour in the jet  
959 stream's latitudinal location, although gradual, long-term shifts may occur.

960 It should nonetheless be noted that atmospheric circulation responses to climate change are characterised by large model  
961 uncertainty and are possibly biased by the relatively low resolution of global climate models compared to e.g.  
962 weather-prediction models (Shepherd, 2019). Indeed, there is indication that for models to exhibit tipping in atmospheric  
963 blocking, they need to involve a sensitive sea-ice model and sufficient resolution to capture the sea-ice-atmosphere-AMOC  
964 feedback driving the transition (Drijfhout et al., 2013).

#### 965 4.3.2 Assessment and knowledge gaps

966 Although theoretically possible, there is thus no robust evidence for tipping point behaviour in mid-latitude atmospheric  
967 circulations in the near future. At the same time, a number of relevant physical processes are currently debated or  
968 ill-constrained, not least by large model uncertainty. We thus evaluate the mid-latitude atmosphere as not displaying tipping  
969 points, with low confidence.

970 The mid-latitude large-scale circulation itself may nonetheless be affected by tipping behaviour of other components of the  
 971 Earth system to which it is coupled. An example is the Greenland ice sheet, whose topography is important for determining  
 972 the atmospheric circulation in the North Atlantic sector (White et al., 2019). A collapse of the Greenland ice sheet may  
 973 trigger tipping-like changes in the atmospheric circulation in the region. The mid-latitude large-scale circulation may also  
 974 contribute to tipping behaviour elsewhere in the Earth System. For example, joint non-tipping changes in mid-latitude  
 975 atmospheric dynamics, the associated surface climate, and other components of the Earth system, may lead to tipping point  
 976 behaviour in vegetation (Lloret and Batllori, 2021). Similarly, drier soils, a strengthened land-atmosphere coupling, and a  
 977 contribution from large-scale circulation anomalies recently triggered a shift to hotter and drier conditions in inner East Asia  
 978 (Zhang et al., 2020). Both the vegetation and dryness changes could in turn feed back onto the atmospheric circulation.  
 979 Due to such feedbacks and interactions between the atmospheric circulation and other components of the Earth system, and  
 980 due to its role in weather and climate extremes, an improved understanding of the physical processes underlying changes in  
 981 mid-latitude atmospheric dynamics under recent and future climate change appears pivotal in a tipping point context. Large  
 982 model uncertainty in projecting abrupt regional atmospheric circulation changes conditioned by changes in the ocean,  
 983 cryosphere, or land surface would lend itself eminently for a storyline approach (Zappa and Shepherd, 2017). Tipping of the  
 984 atmospheric circulation, and associated weather extremes, would then be conditioned by threshold behaviour in other,  
 985 connected systems.  
 986 Finally, we argue for the need to investigate whether recent, record-breaking weather extremes can be explained by the  
 987 gradual changes in likelihood distribution due to the recent and ongoing climate change, or whether they are signs of  
 988 abruptly changing likelihood distributions. Such a shift in the distribution of extremes could be diagnosed using extreme  
 989 value theory. Although a shift cannot be associated with a global tipping point, it would suggest that the extreme value  
 990 distribution of (a) certain type(s) of extreme weather did witness regional tipping, whether or not reversible, in the sense of a  
 991 large nonlinear change in response to a small and gradual change in forcing, potentially driven by self-sustaining feedbacks.

## 992 **5. Discussion and Outlook**

993 In general, the circulation systems discussed in this review are driven by gradients in, e.g., temperature, salinity or pressure,  
 994 and interconnect various parts of the Earth system. They are therefore very susceptible to the multitude of changes that  
 995 humans are causing to all planetary spheres, disrupting established equilibria and dynamics. Alongside the significant input  
 996 of additional energy to the Earth system via greenhouse gas emissions, large-scale land-use change, injection of aerosols to  
 997 the atmosphere and other drivers directly and indirectly impact the atmospheric and oceanic circulation systems, all of which  
 998 show signs of change (IPCC AR6, 2021).  
 999 In this review, we have investigated the potential for tipping in these systems, anchored to a tipping definition of strong  
 1000 positive, reinforcing feedbacks that lead to a large change beyond a forcing threshold (following Armstrong McKay et al. ,  
 1001 2022). Synthesis Table 1 summarises our findings, listing key drivers of change and destabilisation for each circulation

1002 system, as well as ensuing impacts following a state shift. Importantly, we highlight a number of positive feedbacks that  
1003 could give rise to self-reinforcing change beyond a forcing threshold. Finally, we collate evidence for signature tipping  
1004 characteristics like hysteresis and abruptness, and classify each potential tipping system along the criteria defined in the  
1005 introduction.

1006

1007 We classify the oceanic overturning circulations - the subpolar gyre (SPG), the Atlantic Meridional Overturning Circulation  
1008 (AMOC) and Antarctic Overturning Circulation - as tipping systems with medium confidence. There are signs of a  
1009 weakening overturning in the AMOC and of the SPG circulation, and a projected decline of all three under a warming  
1010 climate. One common main driver of this change is the freshwater influx, primarily from melting of the ice sheets, disrupting  
1011 the buoyancy conditions at the overturning sites. Other contributing factors include warming oceans, and changes in wind  
1012 and precipitation patterns. While process understanding, modelling and paleo evidence suggest a possible bistability in these  
1013 systems, the assessment of exact tipping thresholds is difficult. Current climate models suffer from imperfect representation  
1014 of some important processes (such as eddies and mixing) and from biases which can impact the response to forcings. In  
1015 particular, the representation of deep convection in the Southern Ocean is deficient, with convection occurring in the open  
1016 ocean rather than shelf seas (Heuzé et al., 2021; Purich and England, 2021). It has further been shown that the model  
1017 representation of SPG tipping can be dependent on biases in stratification in the North Atlantic (Sgubin et al., 2017). For the  
1018 AMOC, various studies have suggested that it tends to be too stable in many climate models because of biases in simulating  
1019 salinity dynamics and the intertropical convergence zone (ITCZ) (Liu et al., 2017; Mecking et al 2017, Swingedouw et al.  
1020 2022). As observational time scales are short compared to the natural variability timescales of the oceanic overturning  
1021 circulations, paleo reconstructions have proven indispensable for understanding potential long-term changes. Indeed, the  
1022 early warning methodology, increasingly applied to the North Atlantic (Boers, 2021; Ditlevsen and Ditlevsen, 2023; Michel  
1023 et al., 2022), is highly dependent on these historical proxies. Albeit being subject to ongoing debate (Michel et al., 2023),  
1024 these warnings add to the reasons for concern regarding the possible tipping of ocean circulation systems.

1025 Moving to the monsoon systems, our review highlights that there are multiple drivers beyond (direct or indirect)  
1026 anthropogenic climate change that influence these systems. Land-use change on large scales and aerosol emissions have  
1027 direct impacts on the monsoon dynamics, potentially through positive feedback loops. For example, the vegetation-albedo  
1028 coupling is identified as a critical feedback having led to past abrupt shifts in the West African monsoon (WAM), linked to  
1029 drastic changes in the Sahara vegetation states. However, limitations in modelling vegetation shifts and model disagreements  
1030 on future trends call for improved assessments. We thus consider the WAM as a tipping system, yet with low confidence.  
1031 Evidence for tipping is limited for the other monsoon systems under consideration over Asia and South America. Hence, we  
1032 attribute an uncertain status to them. Studies on the Indian summer monsoon (ISM) tipping so far have employed simplified  
1033 analytical models that fail to represent the full spectrum of feedbacks and processes within this complex monsoon system  
1034 (Boos and Storelvmø, 2016; Kumar and Seshadri, 2023). Similar arguments apply to the East Asian summer monsoon  
1035 (EASM). Current climate models further inadequately capture South American monsoon (SAM) precipitation, and the

1036 impact of climate change on SAM precipitation remains uncertain (Jones and Carvalho, 2013; Douville et al., 2021). Further  
1037 research utilising paleoclimate evidence, climate model reconstructions of past monsoons, and comprehensive modelling of  
1038 the system's responses to various forcing thresholds are required to clarify any non-linear changes within both the Indian and  
1039 South American monsoon systems. Critically, the dynamics of the global monsoon are substantially influenced by the  
1040 AMOC, the position of the ITCZ and interhemispheric aerosol loadings, such that a global, coupled approach is promising  
1041 for more insights into potential tipping of the monsoon systems.

1042 Finally, we have considered global atmospheric circulation systems. Although theoretically possible, there is no robust  
1043 evidence for tipping point behaviour in mid-latitude atmospheric circulations. Nonetheless, there are some physical  
1044 mechanisms, such as enhanced jet stream meandering and planetary wave resonance, which may lead to tipping-like  
1045 behaviour. However, their physical interpretation and relevance for tipping are debated. In more general terms, the  
1046 atmospheric circulation responses to climate change are characterised by large model uncertainty (Shepherd, 2019), and  
1047 mid-latitude circulations may be affected by tipping behaviour of other components of the Earth system (Orihuela-Pinto et  
1048 al., 2022). We thus categorise the mid-latitude atmosphere as not displaying tipping points, albeit with low confidence.  
1049 Similarly, there is insufficient indication for a state shift in El Niño Southern Oscillation (ENSO) towards a state with more  
1050 persistent or extreme El Niño events. An increase of El Niño magnitude and impacts is expected under global warming,  
1051 however, not abruptly or irreversibly. For these reasons and a lack of a comprehensive mechanism across models to explain  
1052 a change in future ENSO activity (Heede and Fedorov, 2023a), we classify ENSO as no tipping system with medium  
1053 confidence. Residual uncertainties remain due to divergence of model predictions, and known model biases in SST,  
1054 precipitation and ocean thermocline (Wieners et al. 2019; Chang et al., 2020). With similar confidence we can rule out  
1055 cloud-driven tipping points. Although large scale reorganisations are in principle conceivable, conjectures of strong positive  
1056 feedbacks leading to extreme climate sensitivity, e.g. runaway warming or rapid disappearance of low clouds, are deemed  
1057 unlikely based on current models and understanding (LeConte et al. 2013). In summary, we rate the concern about tipping of  
1058 these global circulation systems as low with medium to low confidence. This, however, does not rule out non-linear  
1059 amplification of trends or interactions with other tipping systems in the Earth system, like the high-latitude cryosphere.

1060 The review presented here was conducted by an expert group, drawing on multiple lines of evidence, including observational  
1061 data, coupled models of low and high complexity and paleo records. It presents a broad overview of the present state of  
1062 knowledge on the subject of circulation tipping points, while acknowledging the challenges and limitations discussed below  
1063 One general difficulty in assessing tipping points is the inherent need to map out and quantify relevant amplifying and  
1064 dampening feedback loops. Naturally, this requires understanding and modelling nonlinearities of the underlying systems,  
1065 which becomes increasingly challenging conceptually when the relevant feedbacks involve many diverse systems (as they  
1066 typically do for coupled ocean and atmosphere circulations). This conceptual issue translates into a numerical one, where  
1067 model complexity needs to be traded-off against computational runtimes. Partly for these reasons, there is currently only a  
1068 limited evidence base on systematic assessments of destabilising drivers on potential tipping systems, such as NAHosMIP  
1069 exploring freshwater impacts on the AMOC (Jackson et al., 2023).

1070 In recent years, however, there has been a surge of numerical experiments with models of ever-increasing complexity and  
1071 resolution (e.g., Liu et al., 2017, Mecking et al 2017, Chang et al., 2020, Li et al., 2023). These experiments shed light on so  
1072 far under-represented important feedback processes and small-scale dynamics, and identify potential model biases towards  
1073 simulating too stable conditions. Model resolution will affect the type of instabilities which can be represented. For example,  
1074 on ocean circulations, once the spatial resolution of an ocean model is smaller than the internal Rossby deformation radius,  
1075 baroclinic instabilities can be represented leading to ocean eddies. The presence of these eddies will also lead to  
1076 modification of the mean flow and associated transports, and hence affect its stability properties. However, this has only  
1077 been systematically analysed for very idealised cases, such as wind-driven ocean circulation (Berloff and McWilliams,  
1078 1999). Moreover, there was no relationship found between the presence of weak AMOC states (that are stable for at least a  
1079 hundred years) and ocean resolution in a set of CMIP6 GCMs (Jackson et al 2023). Therefore, although higher resolution  
1080 captures important dynamics, its effect on model stability remains an active area of investigation. Model complexity, if  
1081 meant as to include additional processes, can strongly affect the stability of an ocean flow. For example, by including a  
1082 sea-ice component into an ocean model, the multi-stability regime of the AMOC will be affected (Van Westen and Dijkstra,  
1083 2023; Van Westen et al., 2024). Along similar lines, recent work demonstrates that high-resolution modelling of ocean  
1084 eddies impacts mid-latitude atmospheric patterns and storm tracks (Zhou and Cheng, 2022; Czaja et al., 2019), albeit with no  
1085 explicit investigation on potential tipping.

1086 Building on this progress, with respect to tipping in ocean and atmosphere circulations, future research should intensify its  
1087 efforts to address these key research questions:

1088

- 1089 (1) Are circulation systems susceptible to tipping? Where tipping is in principle conceivable, is its absence in  
1090 numerical simulations a deficit of the model or can physical stabilising feedbacks be identified? This involves  
1091 bridging the gap between physical process understanding and conceptual models (which clearly allow for tipping)  
1092 on one hand, and high-complexity and -resolution numerical models that might be biased towards stability on the  
1093 other hand. Paleo reconstructions provide an essential resource for this, along with continued observations at high  
1094 spatial and temporal resolutions.
- 1095 (2) At which levels of forcing are tipping thresholds expected based on systematic uncertainty assessment? Such an  
1096 analysis should take into account different forms of uncertainties such as on model initial conditions,  
1097 parameterisation and model structure as well as in data products from Earth observations and paleoclimate  
1098 reconstructions. New methodologies need to be developed to propagate these uncertainties transparently towards  
1099 providing reliable and interpretable estimates of tipping threshold distributions.
- 1100 (3) What are the impacts of tipping point transgressions? Tipping of any of the discussed systems would entail  
1101 significant consequences for Earth and human systems. As for the AMOC, a state shift can cause disruptions in  
1102 many other systems across the globe, including shifts in precipitation patterns in the Northern hemisphere and in the  
1103 tropics with significant expected impacts on agriculture, human settlements and other infrastructure adapted to

1104 pre-tipping climate conditions. An understanding of the tipping dynamics and the anticipated biophysical states  
1105 after tipping can serve as foundation for standardised impact modelling, or for storyline approaches on extreme  
1106 climate change.

1107

1108 An initiative designed to explicitly investigate these research questions in a systematic way is the now established Tipping  
1109 Points Modelling Intercomparison Project ([TIPMIP](#); Winkelmann et al., 2025). To that end, it is designed to study the  
1110 occurrence of tipping across a range of biophysical systems, investigating the critical thresholds and aspects like  
1111 irreversibility, rate-induced tipping and spatio-temporal scales. TIPMIP builds on domain-specific endeavours (e.g.  
1112 NAHosMIP, ISMIP, ...), thereby complementing general modelling initiatives addressing parts of these questions in ongoing  
1113 programs (e.g. CMIP). In addition, updated expert elicitations on e.g. tipping interactions (Kriegler et al., 2008) can serve as  
1114 a valuable complement to numerical modelling efforts. Overall, the multi-faceted questions on the tipping potential of  
1115 circulation systems may be answered by studying the hierarchy of models. This way, the effects of small-scale processes  
1116 (model resolution) and additional large-scale feedback processes (model complexity) on the tipping behaviour can be  
1117 systematically assessed (Dijkstra, 2013). Relatedly, theoretical advances shed light on new properties to be studied in tipping  
1118 systems such as a shifted focus from stable long-term attractors to the change in relative basin widths when studying  
1119 rate-induced tipping (Ashwin et al., 2012; Feudel, 2023). The former is anyways often-times regarded as oversimplification  
1120 that does not fully hold up to time-varying, continuous drivers (Bathiany et al., 2018) or in systems with spatial degrees of  
1121 freedom (Rietkerk et al., 2004). Steps forward can build on insights from hydrodynamic theory such as critical transitions in  
1122 turbulence on multiple scales (van Kan and Alexakis, 2020; van Kan, 2024) or transitions between multiple- stable states in  
1123 aquaplanets (Brunetti et al., 2019; Ragon et al., 2022). Of particular importance in the context of circulation systems is the  
1124 role of interactions between different parts of the Earth system, and the implications for reciprocal (in-)stability and aspects  
1125 like early warning signals (Klose et al., 2021). Overall, it is needed to advance not only resolution and complexity of  
1126 numerical models but also to further pursue fundamental, conceptual research in nonlinear Earth system dynamics for a  
1127 better understanding of the underlying mechanisms and relevant uncertainties in climate tipping points. Finally, an improved  
1128 understanding of how to monitor tipping systems is needed, to eventually establish early warning systems for mitigation and  
1129 adaptation purposes (Swingedouw et al., 2020; Wood et al., 2024).

1130 Table 1. Summary of evidence for tipping dynamics, key drivers, and biophysical impacts in each system considered in this  
 1131 review. Key: +++ Yes (high confidence), ++ Yes (medium confidence), + Yes (low confidence), - - - No (high confidence), -  
 1132 - No (medium confidence), - No (low confidence) Primary drivers are bolded, DC: Direct Climate driver (via direct  
 1133 impact of emissions on radiative forcing); CA: Climate-Associated driver (including second-order & related effects of  
 1134 climate change); NC: Non-Climate driver, PF: positive (amplifying) feedback, NF: negative (damping) feedback. Drivers  
 1135 can enhance (↑) the tipping process or counter it (↓)

Key drivers	Key biophysical impacts	Key feedbacks	Abrupt / large rate change?	Critical threshold(s)?	Irreversible? (timescale)	Tipping system
OCEAN CIRCULATIONS						
Atlantic Meridional Overturning Circulation (AMOC) Shutdown/collapse

1139 *Code and data availability.* There is no data or code that has been produced for this review article.

1140

1141 *Author contributions.* SL and D.I.A.M have designed the overall structure and scope. All authors have contributed to the  
1142 writing. SL and YA produced the figures with input from the authors. All authors have reviewed and edited the final version  
1143 of the manuscript.

1144

1145 *Competing Interests.* Some authors are members of the editorial board of the journal Earth System Dynamics. Otherwise, the  
1146 authors have no other competing interests to declare.

1147

1148 *Acknowledgements.* This review article has been carried out within the framework of the Global Tipping Points Report 2023.  
1149 We would like to thank Norman Steinert for developing the original concept of the tipping systems overview figure (Fig 1)  
1150 and for providing the basemap. S.L. and D.I.A.M. acknowledge financial support from the Earth Commission. The work of  
1151 the Earth Commission, a program of Future Earth, is made possible through the support of the Global Commons Alliance, a  
1152 sponsored project of Rockefeller Philanthropy Advisors. Furthermore, D.I.A.M. acknowledges financial support via the  
1153 Global Tipping Points Report project, funded by the Bezos Earth Fund. Y.A., S.R. and B.S. acknowledge funding from the  
1154 project COMFORT (grant agreement no. 820989) under the European Union’s Horizon 2020 research and innovation  
1155 programme, and from the EC Horizon Europe project OptimESM “Optimal High Resolution Earth System Models for  
1156 Exploring Future Climate Changes”, grant 101081193 and UKRI grant 10039429, CANARI (NE/W004984/1),  
1157 UKRI/NERC HighLight Topic Projects “Interacting ice Sheet and Ocean Tipping - Indicators, Processes, Impacts and  
1158 Challenges (ISOTIPIC)”, grant NE/Y503320/1, and “Consequences of Arctic Warming for European Climate and Extreme  
1159 Weather” (ArctiCONNECT, NE/V004875/1). Y.A. and S.R. also acknowledge funding support from the UK NERC projects  
1160 LTS-M BIOPOLE (NE/W004933/1). The work of Y.A. is also funded by the UKRI (grant [10038003](#)) as part of the EPOC  
1161 project (Explaining and Predicting the Ocean Conveyor; grant number: 101059547). Views and opinions expressed are  
1162 however those of the author(s) only and do not necessarily reflect those of the European Union. Neither the European Union  
1163 nor the granting authority can be held responsible for them. Y.A. and S.R. acknowledge the use of the ARCHER UK  
1164 National Supercomputing and JASMIN. For the use of the data from the NEMO-MEDUSA 1/4 degree high resolution  
1165 model simulations in this paper we acknowledge authorship of Drs Andrew Coward, Andrew Yool, Katya Popova and  
1166 Stephen Kelly from the National Oceanography Centre UK (NOC). D.S. acknowledges funding from the project TipESM,  
1167 EU grant 10111337673 and Advanced Research + Invention Agency (ARIA)’s UK projects SORTED and AdvanTIP  
1168 (SCOP-PR01-P003 - Advancing Tipping Point Early Warning AdvanTip). For the EU projects the work reflects only the  
1169 authors’ view; the European Commission and their executive agency are not responsible for any use that may be made of the  
1170 information the work contains. C.M.C. acknowledges the financial support from FAPESP (grants 2018/15123-4 and  
1171 2019/24349-9) and CNPq (grant 305285/2025-4). HD acknowledges financial support from the European Research Council  
1172 through the ERC-AdG project TAOC (project 101055096). J.F.D. acknowledges financial support from the European  
1173 Research Council Advanced Grant project ERA (Earth Resilience in the Anthropocene, ERC-2016-ADG-743080) and by  
1174 the project CHANGES funded by the German Federal Ministry for Education and Research (BMBF) within the framework  
1175 ‘PIK\_Change’ under grant 01LS2001A. M.H.E. acknowledges support from the Australian Research Council (ARC), Grant  
1176 Nos. SR200100008 and DP190100494. A.V.F. acknowledges support from the ARCHANGE project of the “Make our planet  
1177 great again” program (ANR-18-MPGA-0001), France, and from National Aeronautics and Space Administration  
1178 (80NSSC21K0558), National Oceanic and Atmospheric Administration (NA20OAR4310377), National Science Foundation  
1179 (AGS-205309), and Department of Energy (DE-SC0023134, DE-SC0024186), USA. LJ was supported by the Met Office  
1180 Hadley Centre Climate Programme funded by DSIT and by TiPES. This project is TiPES contribution no. 262, and this  
1181 project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant

1182 agreement no. 820970. GM acknowledges funding from the Swedish Research Council Vetenskapsrådet (proj. No.  
 1183 2022-06599). T.T acknowledges funding from the Department of Science and Technology, India through the ‘INSPIRE  
 1184 Faculty Fellowship’. This is ClimTip contribution 40, the ClimTip project has received funding from the European Union's  
 1185 Horizon Europe research and innovation programme under grant agreement No. 101137601: Funded by the European  
 1186 Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the  
 1187 European Union or the European Climate, Infrastructure and Environment Executive Agency (CINEA). Neither the  
 1188 European Union nor the granting authority can be held responsible for them. JBS was supported by OCEAN ICE, which is  
 1189 funded by the European Union, Horizon Europe Funding Programme for research and innovation under grant agreement Nr.  
 1190 101060452.
