## 9 Abstract

10 ~~Total alkalinity (TA) is an important chemical property playing a decisive role in the oceanic buffering capacity of CO<sub>2</sub>. The~~  
11 ~~oceanic buffering capacity total alkalinity (TA), as the major global CO<sub>2</sub> sink, is of growing scientific interest.~~ TA is mainly  
12 generated by weathering on land, and ~~further~~ by various anaerobic metabolic processes in water and sediments. The Wadden  
13 Sea, located in the southern North Sea is hypothesized to be a source of TA for the North Sea, but quantifications are scarce.  
14 This study shows observations of ed-TA, dissolved inorganic carbon (DIC), and nutrients in the Dutch Wadden Sea in May  
15 2019. Along several transects, surface samples were taken to investigate spatial distribution patterns and to compare them with  
16 data from the late 1980s. A tidal cycle was sampled to further shed light on TA generation and potential TA sources. We  
17 identified the Dutch Wadden Sea as a source of TA with an average TA generation of 7.6  $\mu\text{mol TA kg}^{-1} \text{h}^{-1}$ . ~~TA~~ during ebb tide  
18 in the Ameland Inlet. TA was generated in the sediments with deep pore water flow during low tide enriching the surface  
19 water. A combination of anaerobic processes and CaCO<sub>3</sub> dissolution were potential sources of TA in the sediments. We deduce  
20 ~~assume~~ that seasonality and the associated nitrate availability in particular influence TA generation by denitrification, which  
21 ~~we assume~~ is low in spring and summer.

Formatiert: Tiefgestellt

## 22 1 Introduction

23 As the regulator of the ocean carbon dioxide (CO<sub>2</sub>) sink, total alkalinity (TA) is of increasing scientific interest and is  
24 investigated worldwide in the so called "Anthropocene" (Abril and Frankignoulle, 2001; Bozec et al., 2005; Chen and Wang,  
25 1999; Dickson, 1981; Middelburg et al., 2020; Norbistrath et al., 2022; Renforth and Henderson, 2017; Thomas et al.,  
26 2004; 2009; Sabine et al., 2004). The "Anthropocene" describes the current era of our planet, when environmental changes,  
27 driven by humans, have become identifiable in geological records (Zalasiewicz et al., 2010; Crutzen, 2002). One of the most  
28 threatening changes for our climate is the anthropogenic driven increase in atmospheric greenhouse gases (GHG), such as  
29 CO<sub>2</sub>. To counteract the increasing atmospheric CO<sub>2</sub> concentrations and the ongoing climate warming, a combination of several

Formatiert: Tiefgestellt

30 pathways is needed. Beside a strict reduction of CO<sub>2</sub> emissions, also net-negative emissions are required, which capture the  
31 atmospheric CO<sub>2</sub> and store it either based on land or in the ocean (e.g., Keith et al., 2006;Matthews and Caldeira, 2008;Zhang  
32 et al., 2022). The climate and the increasing atmospheric CO<sub>2</sub> content is also naturally regulated by the open ocean, and around  
33 a quarter of the global anthropogenic CO<sub>2</sub> emissions are already removed by it (Friedlingstein et al., 2022). ~~The carbon storage  
34 capacity of the North Sea is an important atmospheric CO<sub>2</sub> sink as it exports the absorbed CO<sub>2</sub> in the deep layers of the Atlantic  
35 Ocean where it is stored on longer time scales (Borges et al., 2005;Bozec et al., 2005;Burt et al., 2016;Brenner et al., 2016;Hu  
36 and Cai, 2011;Schwichtenberg et al., 2020;Thomas et al., 2004;2009). Two important aspects of the oceanic climate regulation  
37 are the oceanic circulation and TA. TA, primarily consisting of bicarbonate and carbonate, is generated by chemical rock  
38 weathering (Suchet and Probst, 1993;Meybeck, 1987;Bernier et al., 1983), and in various stoichiometries by calcium carbonate  
39 (CaCO<sub>3</sub>) dissolution and anaerobic metabolic processes, such as denitrification, which is the reduction process of nitrate to  
40 dinitrogen gas in the nitrogen cycle (Hu and Cai, 2011;Wolf-Gladrow et al., 2007;Chen and Wang, 1999;Brewer and Goldman,  
41 1976). Since TA, CO<sub>2</sub> uptake and its export to the deep ocean are mainly disentangled in the open ocean, TA and the oceanic  
42 circulation interact closely in highly active and shallow ocean areas such coastal zones and continental and marginal shelves.  
43 The climate and the increasing atmospheric CO<sub>2</sub> content is mainly regulated by the open ocean. Around 30 % of the global  
44 anthropogenic CO<sub>2</sub> emissions are removed by the ocean (Gruber et al., 2019). ~~The carbon storage capacity of the North Sea is  
45 an important atmospheric CO<sub>2</sub> sink as it exports the absorbed CO<sub>2</sub> in the deep layers of the Atlantic Ocean where it is stored  
46 on longer time scales (Borges et al., 2005;Bozec et al., 2005;Burt et al., 2016;Brenner et al., 2016;Hu and Cai,  
47 2011;Schwichtenberg et al., 2020;Thomas et al., 2004;2009).~~  
48 Two important aspects of the oceanic climate regulation are the oceanic circulation and TA. Both interact well in highly active  
49 and shallow ocean areas such coastal zones and continental and marginal shelves. In these shallow areas, TA is very susceptible  
50 to changes due to various metabolic processes and the influence of adjacent zones like rivers, estuaries, marshes, and tidal flats  
51 (e.g., Norbistrath et al., 2022;2023;Wang et al., 2016;Voynova et al., 2019). A previous study by Norbistrath et al. (2022)  
52 showed that an enhanced riverine, metabolic alkalinity would lead to increasing CO<sub>2</sub> absorption in the coastal zones of the  
53 North Sea, highlighting the need to further investigate TA regulation in adjacent zones of coastal oceans.~~

54 Coastal zones, which are the direct interface between most, if not all, compartments of the Earth system (i.e., atmospheric,  
55 terrestrial, aquatic, and oceanic) and human societies, appear particularly vulnerable to environmental and climate change  
56 (Glavovic et al., 2015). This holds true for the Wadden Sea, the shallow, coastal sea along an approximately 500 km coastline  
57 of the Netherlands, Germany, and Denmark, in the southern North Sea, which is declared as an UNESCO world natural heritage  
58 site since 2009. Most of the Wadden Sea is located between the protecting barrier Islands and the Mainland, which makes it  
59 the world's largest uninterrupted stretch of tidal flats with multiple tidal inlets (Fig. 1). Due to the topography, the Wadden  
60 Sea is a highly dynamic ecosystem with influences from the mainland and the North Sea (Hoppema, 1993;Postma, 1954;van  
61 Raaphorst and van der Veer, 1990). Driving forces of the biogeochemical dynamics in the Wadden Sea are nutrient and organic  
62 matter (OM) imports by rivers and high suspended particulate matter (SPM) and organic matter (OM) imports from the North  
63 Sea (van Beusekom et al., 2019;van Beusekom et al., 2012;Postma, 1954). Physical sources of variability in the Wadden Sea

Formatiert: Nicht Hervorheben

Feldfunktion geändert

Formatiert: Tiefgestellt

Feldfunktion geändert

64 are oceanic driven wind, waves, and tidal currents, as well as the counterclockwise circulation of the North Sea (Elias et al.,  
65 2012). Large tidal amplitude and currents in conjunction with shallow water depths allow for vertical water column mixing  
66 and an exchange between the pelagic and benthic realms including deep pore water exchange (Røy et al., 2008). The ~~strong~~high  
67 tidal currents also impact the biogeochemistry of the North Sea (Postma, 1954), as they cause an exchange of water between  
68 the North Sea and the Wadden Sea and play an important role in the import of particulate matter from the North Sea (Burchard  
69 et al., 2008).

70 ~~TA, primarily consisting of bicarbonate and carbonate, is generated by chemical rock weathering (Suchet and Probst,~~  
71 ~~1993; Meybeck, 1987; Berner et al., 1983), and in various stoichiometries by calcium carbonate (CaCO<sub>3</sub>) dissolution and~~  
72 ~~anaerobic metabolic processes, such as denitrification, which is the reduction process of nitrate to dinitrogen gas in the nitrogen~~  
73 ~~cycle (Hu and Cai, 2011; Wolf Gladrow et al., 2007; Chen and Wang, 1999; Brewer and Goldman, 1976). Understanding of TA~~  
74 ~~sources have recently become increasingly important due to increasing anthropogenic CO<sub>2</sub> emissions, and the resulting demand~~  
75 ~~for ocean based net negative CO<sub>2</sub> emissions (e.g., Keith et al., 2006; Matthews and Caldeira, 2008; Zhang et al., 2022). In~~  
76 ~~p~~Previous studies ~~identified~~, the Wadden Sea ~~was identified~~ as a TA source for the North Sea with a loading between 39 Gmol  
77 yr<sup>-1</sup> (Schwichtenberg et al., 2020) and 73 Gmol yr<sup>-1</sup> (Thomas et al., 2009). Both studies suggested the entire Wadden Sea as  
78 one of the most important TA sources of the carbon storage capacity for the North Sea. Burt et al. (2016) highlighted the  
79 importance of coastal TA production for regulating the buffer system in the North Sea, and suggested denitrification as the  
80 major TA source. Due to the strong connection between the North Sea and the Wadden Sea, a better understanding of TA  
81 generation in the latter is required. Here, we focus on the Dutch Wadden Sea that has been well-studied during the past decades  
82 (Hoppema, 1990, 1991, 1993; De Jonge et al., 1993; Elias et al., 2012; Ridderinkhof et al., 1990; Postma, 1954; van Beusekom  
83 et al., 2019; Schwichtenberg et al., 2017). In particular Hoppema (1990); (1993) observed the spatial and temporal variability  
84 of TA in May ~~in the late 1980s~~, which we compare with our observed transect data to detect potential differences over the last  
85 30 years. In addition, we further ~~discussed shed light on~~ potential TA sources in the Dutch Wadden Sea.

## 86 2 Methods

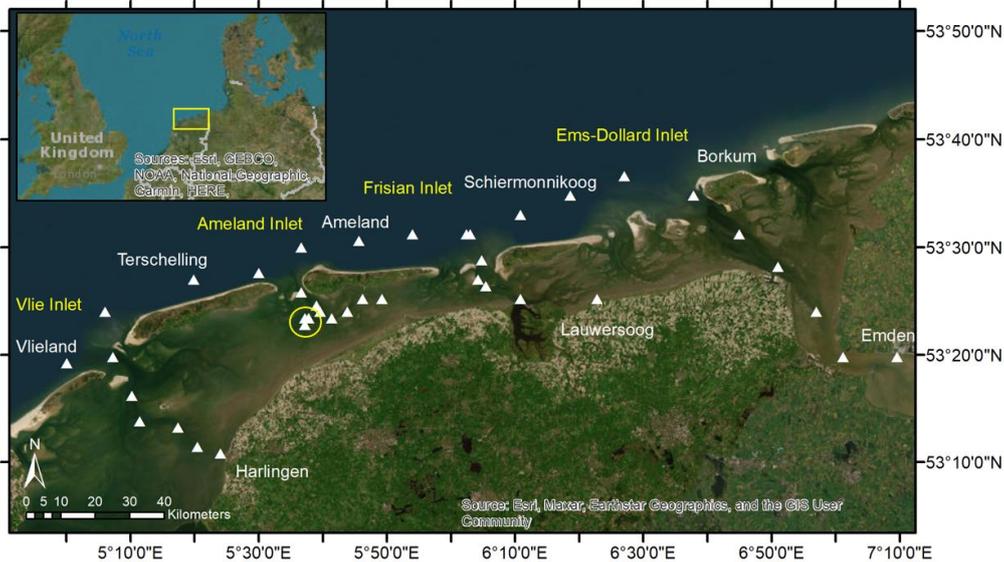

### 87 2.1 Study site and sampling

88 This study is based on samples collected on a research cruise (LP20190515) in the Dutch Wadden Sea (Frisian Islands) on RV  
89 *Ludwig Prandtl* in May 2019 (Fig. 1). We collected water samples in the Wadden Sea starting at Harlingen, through the Vlie  
90 Inlet ~~along around~~ the islands Vlieland and Terschelling, through the Ameland Inlet to Ameland Island, from there on via the  
91 Frisian Inlet to Lauwersoog, and around Schiermonnikoog Island via the Ems-Dollard Inlet to Emden. In addition, we sampled  
92 a ~~half~~ tidal cycle ~~during ebb tide (from high tide to low tide) on (21 May -05-2019. To set the range of ebb tide data in relation,~~  
93 ~~we also sampled a half tidal cycle during flood tide (from low tide to high tide) on 23 May 2019 for comparison.) and from~~  
94 ~~low tide to high tide (23-05-2019). Both half tidal cycles were sampled on each day~~ as an anchor station in the waterway at the  
95 western side of Ameland in the Ameland Inlet ~~on each day~~.

Formatiert: Nicht Hervorheben

Formatiert: Nicht Hervorheben

96 Nearly half-hourly, we **continuously** collected discrete surface (1.2 m depth) water samples with a bypass from the onboard  
 97 flow-through FerryBox system (Petersen et al., 2011), which also provided essential physical parameters such as salinity and  
 98 temperature.  
 99 For TA and DIC measurements we sampled water with overflow into 300 mL BOD (biological oxygen demand) bottles and  
 100 preserved them with 300  $\mu$ L saturated mercury chloride **solution** ( $\text{HgCl}_2$ ) to stop biological activity. Each BOD bottle was  
 101 filled without air bubbles and closed by using a ground-glass stopper coated in Apiezon® type M grease and a plastic cap. The  
 102 samples were stored in a cool dark environment until measurements in the lab.  
 103 Water for nutrient samples was filtered through pre-combusted (4 h, 450 °C) GF/F filters and the filtrate was stored frozen in  
 104 three 15 mL Falcon tubes for triplicate measurements in the lab.  
 105 To determine the total carbon (C), organic carbon ( $C_{\text{org}}$ ) and nitrogen (N) concentrations in SPM and associated  $C_{\text{org}}:N$  ratios,  
 106 we used pre-combusted (4 h, 450 °C) GF/F filters, which were dried after sampling at 50 °C to remove all humidity and were  
 107 stored frozen afterwards until measurement.

108  
 109 **Figure 1** Sampling site in the Dutch Wadden Sea. The sampling stations around the Frisian Islands in May 2019 are visualized  
 110 with white triangles. The yellow circle highlights the anchor stations for the tidal cycle sampling in the Ameland Inlet on two  
 111 days. During the sampling day from low tide to high tide, we had two samples that we took slightly more western due to  
 112 drifting. The island and city names are shown in white, the inlets in yellow. The tidal flats and sedimentary structures are well  
 113 visible between the barrier islands and the mainland.

## 114 2.2 Carbon species analyses

115 The parallel analyses of TA and DIC were carried out in March 2020 by using the VINDTA 3C (Versatile Instrument for the  
116 Determination of Total dissolved inorganic carbon and Alkalinity, MARIANDA - marine analytics and data), which measures  
117 TA by potentiometric titration and DIC by coulometric titration both with a measurement precision  $< 2 \mu\text{mol kg}^{-1}$  (Shadwick  
118 et al., 2011). ~~To ensure a consistent calibration of both measurements,~~ eCertified reference material (CRM batch # 187)  
119 provided by Andrew G. Dickson (Scripps Institution of Oceanography) was measured before and after the samples and used  
120 used-to ensure a consistent calibration of both measurements.  
121 The calcite and aragonite saturation states ( $\Omega$ ) and the pH were computed with the CO<sub>2</sub>SYS program (Lewis and Wallace,  
122 1998), using the measured parameters TA, DIC, salinity, temperature, silicate and phosphate as input variables, together with  
123 the dissociation constants from Mehrbach et al. (1973), as refit by Dickson and Millero (1987).

## 124 2.3 Nutrient analyses

125 The nutrients were measured with a continuous flow automated nutrient analyzer (AA3, SEAL Analytical) and a standard  
126 colorimetric technique (Hansen and Koroleff, 2007) for nitrate (NO<sub>3</sub><sup>-</sup>), nitrite (NO<sub>2</sub><sup>-</sup>), phosphate (PO<sub>4</sub><sup>3-</sup>), and silicate (Si), and  
127 a fluorometric method (K  rouel and Aminot, 1997) for ammonium (NH<sub>4</sub><sup>+</sup>) (Grasshoff et al., 2009). The nutrient samples were  
128 measured against reference materials VKI SW4.1B (NO<sub>x</sub>, NO<sub>2</sub> and NH<sub>4</sub><sup>+</sup>) and VKI SW4.2B (Si and PO<sub>4</sub>) in July 2019. The  
129 maximum standard deviations were 0.322  $\mu\text{mol L}^{-1}$  for NO<sub>3</sub><sup>-</sup>, 0.014  $\mu\text{mol L}^{-1}$  for NO<sub>2</sub><sup>-</sup>, 0.081  $\mu\text{mol L}^{-1}$  for NH<sub>4</sub><sup>+</sup>, 0.014  $\mu\text{mol}$   
130 L<sup>-1</sup> for PO<sub>4</sub><sup>3-</sup> and 0.165  $\mu\text{mol L}^{-1}$  for Si.-  
131 For the C<sub>org</sub> determination, filters were acidified with 1N HCl and dried overnight to remove all inorganic carbon content.  
132 Filters were measured with a CHN-elemental analyzer (Eurovector EA 3000, HEKAtech GmbH) in the Institute of Geology,  
133 University Hamburg, and calibrated against a certified acetanilide standard (IVA Analysentechnik, Germany). The standard  
134 deviations were 0.05 % for carbon and 0.005 % for nitrogen.

## 135 2.4 Data analyses

136 The data analyses were performed by using RStudio Version 1.3.1073    2009-2020 RStudio, PBC. The linear regression  
137 Model II was performed by using the “lmodel2” R package, and the plots were created with the “ggplot2” R package.

## 138 3 Results

### 139 3.1 Spatial parameter distribution

140 To investigate the spatial distribution of ~~total alkalinity (TA)~~ in the Dutch Wadden Sea and compare its general status with  
141 earlier studies (in particular Hoppema, 1990), we observed ~~the spatial distribution of~~ TA and related parameters in surface  
142 water along a transect from the coastal mainland towards the ~~open North Sea~~ North Sea as a surface water transect.

Formatiert: Hochgestellt

Formatiert: Nicht Hochgestellt/ Tiefgestellt

143 The temperatures varied between 12 and 16 °C with higher temperatures towards the coastal mainland (Fig. 2a).  
144 ~~We identified two main sub regions based on the salinity values. First the Ems-Dollard Inlet, which showed salinities lower~~  
145 ~~than 28 and with the minimum value of 20.25 at the most upstream station. And second, around Ameland Island and the~~  
146 ~~remaining of our investigated region in the Dutch Wadden Sea with salinities showing Salinity was relatively stable with only~~  
147 ~~minor differences varying from 28 to 33 (Fig. 2b). Lower salinities were only observed in the four sampling stations in the~~  
148 ~~Ems Estuary with the minimum value of 20.25 at the most upstream station.~~  
149 Spatial transect TA concentrations ranged from 2332  $\mu\text{mol TA kg}^{-1}$  to 2517  $\mu\text{mol TA kg}^{-1}$ . We observed lower concentrations  
150 on the ~~oceanic, i.e.,~~ North Sea side of the Frisian Islands with somewhat higher concentrations around Ameland (Fig. 2c). In  
151 contrast to the ~~North Sea oceanic~~ side, the values were higher ( $> 2380 \mu\text{mol TA kg}^{-1}$ ) in the Wadden Sea. ~~Only in~~ the Ems-  
152 ~~Dollard Inlet Estuary~~, the concentrations were even higher, with values up to 2517  $\mu\text{mol TA kg}^{-1}$  at the most upstream  
153 station. ~~Higher TA values in the Wadden Sea than in the open ocean, supporting the assumption of TA being generated in this~~  
154 ~~tidal flat area.~~  
155 Silicate (Si), showed ~~a similar pattern with~~ higher concentrations in the Wadden Sea and lower ones towards the ~~North Sea~~  
156 ~~ocean~~ (Fig. A1a). Highest concentrations were observed at the coastal mainland and in the Ems-~~Dollard Inlet Estuary~~. Silicate  
157 concentrations ~~ranged were~~ between 0.326 and 56.32  $\mu\text{mol Si L}^{-1}$ . Both, the calcite and aragonite saturation states ( $\Omega$ ) were  
158 supersaturated in the entire study ~~region site~~. Saturation state ~~v~~ values ranged from 2.3 to 4.6 for calcite (Fig. A1b), and from  
159 1.4 to 3.0 for aragonite (Table B1). Highest values were observed at the ~~North Sea side oceanic side~~ of the barrier islands ~~in~~  
160 ~~the North Sea. T, and he~~ lowest values ~~were observed~~ near Harlingen and in the Ems-~~Dollard Inlet Estuary~~. Like the calcite  
161 and aragonite saturation states, the pH values were higher in the North Sea, and lower in the Wadden Sea and near the coastal  
162 mainland (Fig. A1c). The pH values ranged from 7.86 to 8.19, ~~and The~~ lowest values were observed near Harlingen and in  
163 the Ems-~~Dollard Inlet Estuary~~. The nitrate ( $\text{NO}_3^-$ ) concentrations were in a ~~similarly~~ low range ( $< 3 \mu\text{mol NO}_3^- \text{L}^{-1} \text{NO}_3^-$ )  
164 throughout the ~~transect study region~~. Higher concentrations ( $< 6 \mu\text{mol NO}_3^- \text{L}^{-1} \text{NO}_3^-$ ) were observed only at a few stations  
165 close to land, and maximum concentrations ( $< 38 \mu\text{mol NO}_3^- \text{L}^{-1} \text{NO}_3^-$ ) were observed in the Ems-~~Dollard Inlet Estuary~~ (Fig.  
166 A1d). DIC concentrations ranged from 2097  $\mu\text{mol DIC kg}^{-1}$  to 2430  $\mu\text{mol DIC kg}^{-1}$  (Fig. A1e). DIC values showed a similar  
167 pattern as TA values, with higher concentrations near the coastal mainland and in the Ems-~~Dollard Inlet Estuary~~, and  
168 decreasing concentrations toward the North Sea, where DIC reached minimum values.

Formatiert: Nicht Hochgestellt/ Tiefgestellt

Formatiert: Nicht Hochgestellt/ Tiefgestellt

169

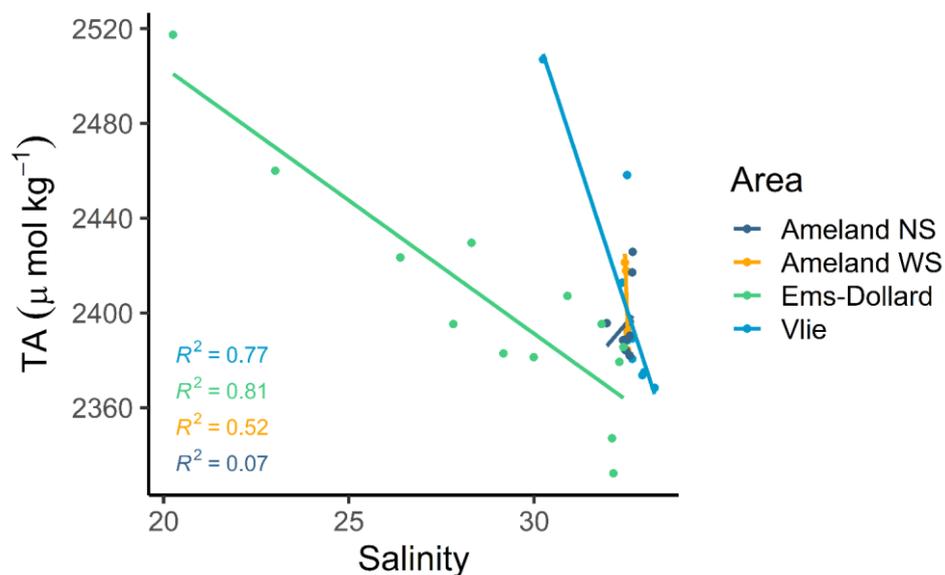

170 **Figure 2** Spatial ~~Latitudinal and longitudinal~~ distribution of a) temperature ( $^{\circ}\text{C}$ ), b) salinity, and c) total alkalinity (TA;  $\mu\text{mol}$   
 171  $\text{kg}^{-1}$ ) from surface water samples in May 2019.

172

173 Compared to the other transects of this study region, the strong influence from the inner Ems Estuary is visible at the  
174 most upstream station in the Ems-Dollard Inlet in all parameters, showing lowest pH and calcite saturation state values, and  
175 highest values of TA, DIC, nitrate, silicate and phosphate, with higher values in the outer estuary and its adjacent zones, or  
176 with lower values in case of pH and the calcite saturation state. Furthermore, we observed higher values around Ameland  
177 Island than in the western part of the transect starting from Harlingen towards the Vlie Inlet. At the oceanic side of  
178 the Vlie Inlet reflects the impact of the North Sea conditions with is visible through lower temperatures and higher salinities.  
179 The North Sea impact is also visible in the mixing plot between TA and salinity (Fig. 3). A relatively statistical significant  
180 linear mixing behavior was only observed in the transect through the Ems-Dollard Inlet ( $R^2 = 0.81$ ) and through the Vlie Inlet  
181 ( $R^2 = 0.77$ ), where TA concentrations decreased with increasing salinities from the mainland towards the North Sea ocean  
182 (Fig. 3); identifying the Dutch Wadden Sea as a source of TA. Whereas in the Ems-Dollard Inlet mixing is dominated by  
183 riverine water with high TA concentrations, the mixing in the Vlie Inlet showed a more prominent mixing of Wadden Sea and  
184 North Sea water. The TA concentrations in the Vlie Inlet and around Ameland, both at the North Sea side (Ameland NS) and  
185 the Wadden Sea side (Ameland WS) were higher than the TA concentration computed for the salinity end-member in the Ems-  
186 Dollard Inlet, suggesting the Dutch Wadden Sea as a source of TA (Fig. 3). Both the Ameland NS and WS data clearly indicated  
187 a non-conservative behavior with a range of TA concentrations at near constant salinities.  
188 In contrast to the TA concentration computed for the salinity end-member in the Ems-Dollard Inlet, we detected higher TA  
189 concentrations around Ameland, both at the North Sea side (Ameland NS) and the Wadden Sea side (Ameland WS), as well  
190 as in the Vlie Inlet, which further support additional TA sources in the Wadden Sea (Fig. 3). The Ameland NS and Ameland  
191 WS data clearly indicated non-conservative behavior with increasing TA concentrations at constant salinities.

Formatiert: Hochgestellt

192

193 **Figure 3** Mixing ~~plot of~~ total alkalinity (TA) and salinity in the ~~oceanic-North Sea~~ side of Ameland and the Frisian  
 194 Inlet (Ameland NS), in the Wadden Sea site of Ameland (Ameland WS), around Schiermonnikoog and in the Ems-Dollard  
 195 (Ems-Dollard) Inlet, and in the Vlie Inlet (Vlie).

196 **3.2 Tidal cycle**

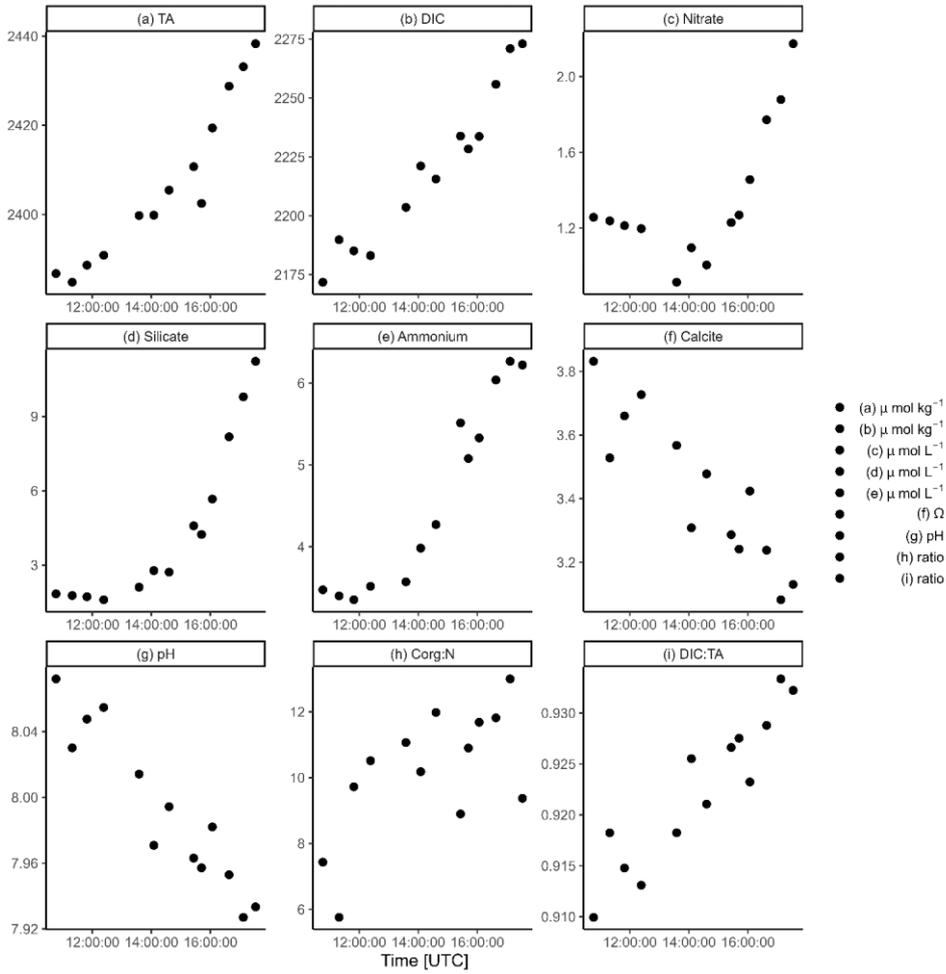

197 ~~To estimate TA generation in the Dutch Wadden Sea, to shed light on potential TA sources, and to estimate the potential TA~~  
 198 ~~amount that is exported to the North Sea, w~~we observed a half tidal cycle at an anchor station in the Ameland Inlet ~~on two~~  
 199 ~~days during flood tide and during ebb tide, respectively~~ to 1) identify potential TA sources and 2) to quantify potential TA  
 200 ~~export to the North Sea. Here, the focus is on ebb tide data that w~~we used to identify patterns in the several biogeochemical  
 201 parameters in ~~off-running~~ water leaving the tidal flats (Fig. 4, Table B1). Temperature increased from 13.25 to 14.7 °C (Fig.  
 202 4a). The salinity observations allow us to exclude addition by mixing with freshwater sources, since the ~~s~~salinity was constant  
 203 around between 32.50 and 32.52 (Fig. 4b, Table B1), which is in the range of southern North Sea water excluding admixture  
 204 of local fresh water sources. Salinity values were in the range of saline waters like water of the North Sea.

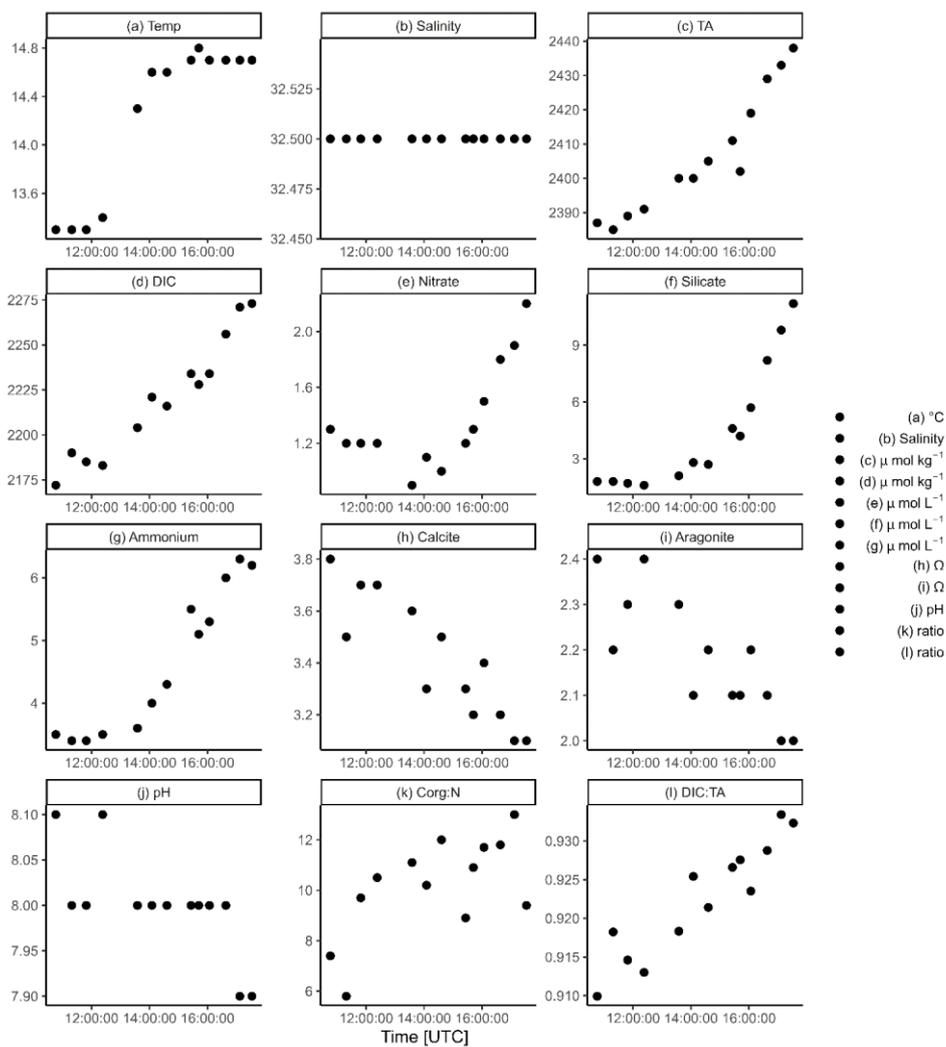

205 During ebb tide, TA ranged from ~~high tide with~~ 2387  $\mu\text{mol TA kg}^{-1}$  ~~TA during high tide to low tide with~~ 2438  $\mu\text{mol TA kg}^{-1}$   
 206 ~~TA during low tide~~ (Fig. 4ca). We ~~observed identified~~ an increase of 51.6  $\mu\text{mol TA kg}^{-1}$  ~~TA~~ ( $\Delta\text{TA}$ ) ~~over a duration of 6.8 h~~  
 207 during ebb tide (6.8 h), resulting in a TA increase of 7.6  $\mu\text{mol TA kg}^{-1} \text{ h}^{-1}$  ~~TA~~ at the sampling location.  
 208 DIC concentrations ~~behaved were~~ similar to TA with minimum values at high tide (2172  $\mu\text{mol DIC kg}^{-1}$  ~~DIC~~), and ~~maximum~~  
 209 ~~highest~~ values (2273  $\mu\text{mol DIC kg}^{-1}$  ~~DIC~~) at low tide, ~~resulting in~~. ~~During ebb tide, we observed~~ an increase of 101.3  $\mu\text{mol}$   
 210 ~~DIC kg}^{-1}~~ ~~DIC~~ ( $\Delta\text{DIC}$ ) ~~or resulting in a DIC increase of~~ 14.9  $\mu\text{mol DIC kg}^{-1} \text{ h}^{-1}$  ~~DIC~~ (Fig. 4db). DIC increased almost twice as  
 211 much as TA.  
 212 ~~Nitrate concentrations approached seawater concentrations~~ (Neumann et al., 2017) with an observed minimum of 1.26  $\mu\text{mol}$   
 213  ~~$\text{L}^{-1} \text{NO}_3^-$  and a maximum of 2.17  $\mu\text{mol L}^{-1} \text{NO}_3^-$~~  (Fig. 4e). ~~During ebb tide, nitrate slightly increased during ebb tide~~ by 0.92  
 214  $\mu\text{mol NO}_3^- \text{ L}^{-1}$   ~~$\text{NO}_3^-$  ( $\Delta\text{NO}_3^-$ )~~, ~~from a minimum of 1.26  $\mu\text{mol NO}_3^- \text{ L}^{-1}$  to a maximum of 2.17  $\mu\text{mol NO}_3^- \text{ L}^{-1}$~~  (Fig. 4e),  
 215 resulting in a nitrate increase of 0.13  $\mu\text{mol NO}_3^- \text{ L}^{-1} \text{ h}^{-1}$ .  
 216 ~~In s~~ Silicate ~~showed~~, a similar pattern with low values (1.8  $\mu\text{mol Si L}^{-1}$  ~~Si~~) at high tide ~~and~~ increasing ~~concentrations~~ during  
 217 ebb tide to a maximum of 11.2  $\mu\text{mol Si L}^{-1}$ . ~~Si was detected. The resulting in a silicate increase ( $\Delta\text{Si}$ ) of 9.4  $\mu\text{mol Si L}^{-1}$  Si~~  
 218 ~~resulted in a silicate increase of or~~ 1.4  $\mu\text{mol Si L}^{-1} \text{ h}^{-1}$  ~~Si~~ during ebb tide (Fig. 4fd).  
 219 Ammonium increased from 3.47  $\mu\text{mol NH}_4^+ \text{ L}^{-1}$   ~~$\text{NH}_4^+$~~  to 6.22  $\mu\text{mol NH}_4^+ \text{ L}^{-1}$   ~~$\text{NH}_4^+$~~  during ebb tide (Fig. 4ge), ~~resulting in~~.  
 220 ~~We observed~~ an ammonium increase ( $\Delta\text{NH}_4^+$ ) of 2.74  $\mu\text{mol NH}_4^+ \text{ L}^{-1}$ , ~~or  $\text{NH}_4^+$  resulting in an increase of~~ 0.4  $\mu\text{mol NH}_4^+ \text{ L}^{-1}$   
 221  $\text{h}^{-1}$   ~~$\text{NH}_4^+$~~ .  
 222 The calcite and aragonite saturation states had maximum values ( $\Omega_{\text{Ca}} = 3.8$ ,  $\Omega_{\text{Ar}} = 2.4$ ) at high tide and decreased to their  
 223 minimum ( $\Omega_{\text{Ca}} = 3.1$ ,  $\Omega_{\text{Ar}} = 2.0$ ) during ebb tide (Fig. 4h, if, Table B1). The ~~influence of the North Sea is indicated by the~~  
 224 ~~observed~~ maximum at high tide, ~~which indicated the influence of the North Sea that~~ decreased during the ebb.  
 225 Like omega, the ~~maximum pH was 8.07 had maximum values (8.07)~~ at high tide and decreased to a minimum (7.93) during  
 226 ebb tide (Fig. 4jg).  
 227  $\text{C}_{\text{org}}:\text{N}$  ratios of SPM increased during ebb tide (Fig. 4kh). A minimum  $\text{C}_{\text{org}}:\text{N}$  ratio of 5.6 was observed around high tide and  
 228 increased to a maximum of 13.0 during ebb tide. Simultaneously, the SPM concentration increased during ebb tide, from 12.8  
 229  $\text{mg SPM L}^{-1}$  ~~SPM~~ to a maximum of 82.4  $\text{mg SPM L}^{-1}$  ~~SPM~~ at the second last station (Table B1).

### 237 3.3 TA generation

238 Tidal forcing leads to a bi-diurnal exchange between The Dutch Wadden Sea is exposed to strong tidal forcing by the and  
239 North Sea water leading to a bi-diurnal exchange of water. The strong tidal forcing also induces a strong benthic-pelagic  
240 coupling (Huettel et al., 2003; Røy et al., 2008). Many studies support that the outflowing water exports material from the  
241 sediment including remineralization products from organic matter (e.g., Billerbeck et al., 2006; Røy et al., 2008). Here, we  
242 focus on the hypothesis that the sediments are a significant source of TA. To support our assumption of a sediment source of  
243 TA, we further investigated potential TA sources.

244 For a first rough estimate of a maximum TA export during ebb tide, we used the mean observed TA increase ( $\Delta\text{TA} / 2$ ) of  
245  $25.851.6 \mu\text{mol TA kg}^{-1}$  TA during ebb tide (in the Ameland Inlet, part of the Borndiep tidal basin), and the tidal prism of  $478$   
246  $\cdot 10^6 \text{ m}^3$  of the Borndiep tidal basin, and a share of intertidal flats of 53 % Ameland Inlet (Louters and Gerritsen, 1994).  
247 Assuming that only the intertidal sediments exchange TA, we estimated a TA export of 6.6 Mmol TA per tide to the North  
248 Sea. Assuming two ebb tides and a lunar cycle of 24.8 hours this would result in a daily export of 12.7 Mmol TA. With this  
249 estimate, we obtained a rough TA export on the order of 23.9 mol TA during ebb tide from the Ameland Inlet into the North  
250 Sea. With a tidal duration of 6.8 h, the estimated TA export of 23.9 mol would result in a TA export of  $3.5 \text{ mol h}^{-1}$  TA.

251 Based on the significant correlation of TA and silicate ( $R^2 = 0.93$ ), and on the insignificant nonlinear relation between  
252 both, TA and salinity ( $R^2 = 0.32$ ), as well as silicate and salinity ( $R^2 = 0.21$ ), suggest that we were able to determine whether  
253 TA originates from the tidal flats in this part of the Dutch Wadden Sea and is not from admixture carried or is carried by river  
254 runoff. The significant correlation between TA and silicate both during ebb tide. Both TA and silicate increased almost  
255 proportionally during ebb tide, pointing to the same source origin (Fig. 5b). The non-conservative behavior of TA over salinity  
256 and silicate over salinity rules out any sources due to freshwater dilution and river runoff (Table B1).

257 To further elucidate potential TA sources in the Dutch Wadden Sea, we correlated TA with DIC, silicate, nitrate, and  
258 ammonium in the half tidal cycle from high tide to low tide, respectively (Fig. 5). The first four samples on the left side of the  
259 plots in Fig. 5 show values probably at the tipping point of high tide, whereby we recommend neglecting these samples in the  
260 interpretation of ebb tide samples.

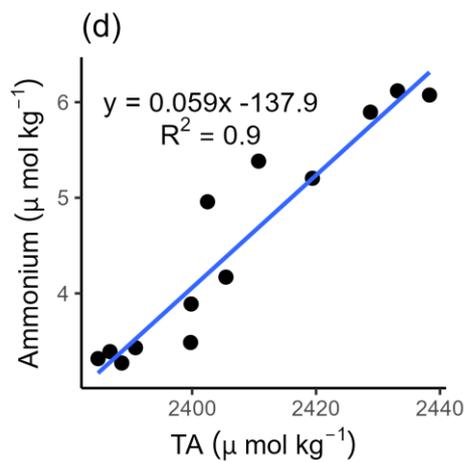

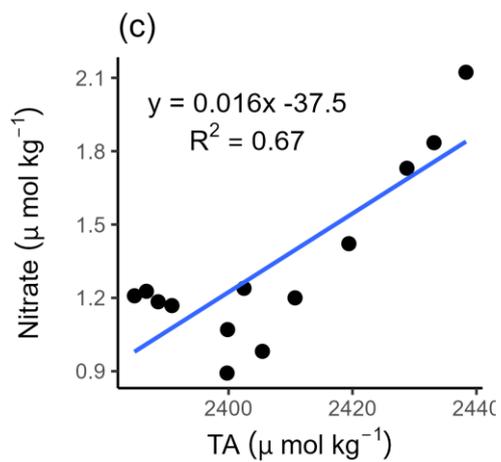

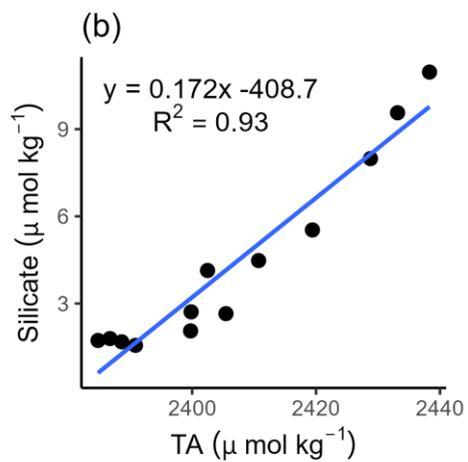

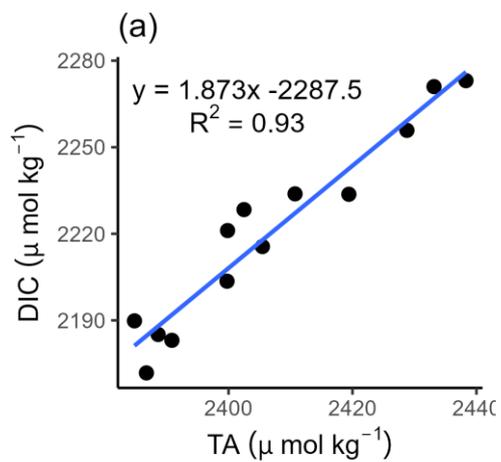

261 The correlation between TA and DIC is a measure between anaerobic and aerobic processes. Our data show a strong positive  
262 correlation between DIC and TA ( $R^2 = 0.93$ ) with TA concentrations being higher than DIC concentrations (Fig. 5a). We  
263 observed a release excess of DIC compared to TA as indicated by the slope of 1.89 and by an increase in DIC ( $\Delta\text{DIC} = 101.3$   
264  $\mu\text{mol kg}^{-1}$ ) almost twice as high as TA ( $\Delta\text{TA} = 51.6 \mu\text{mol kg}^{-1}$ ) (Fig. 5a).

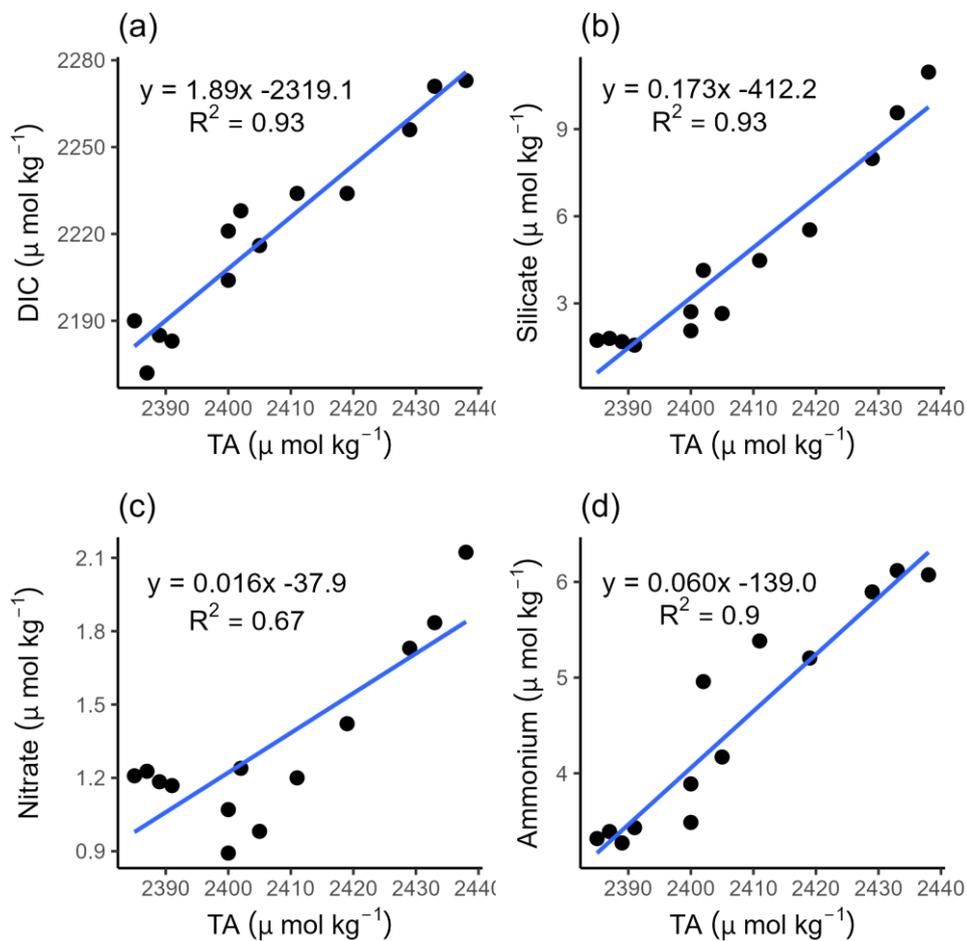

265 First, the correlation between TA and DIC reveals the ratio between anaerobic and aerobic processes, which identifies a strong  
266 positive correlation between DIC and TA ( $R^2 = 0.93$ ) with TA concentrations higher than DIC concentrations (Fig. 5a).  
267 However, even with concentrations of TA higher than DIC, the slope of 1.87 indicated DIC release excess with an increase in

Formatiert: Nicht Hervorheben

268 DIC ( $\text{ADIC} = 101.3 \mu\text{mol kg}^{-1}$ ) almost twice as high as TA ( $\text{ATA} = 51.6 \mu\text{mol kg}^{-1}$ ) (Fig. 5a). This excess DIC may be caused  
269 by strong  $\text{CO}_2$  production due to high aerobic OM degradation, or by uptake from the atmosphere due to water movement by  
270 tidal forcing. However, given the heterotrophic nature of the Wadden Sea (e.g., van Beusekom et al., 2012), a  $\text{CO}_2$   
271 undersaturation is unlikely. The TA increase can be fueled by various processes which we will discuss below. We detected an  
272 almost linear positive correlation of increasing TA and silicate ( $R^2 = 0.93$ ) during ebb tide, supporting ~~the~~ pore water outflow  
273 (Fig. 5b) as pore water is the major Si source during summer (van Bennekom et al., 1974). A stronger influence of the pore  
274 water with ongoing ebb tide is indicated by increasing values. The positive correlation between nitrate and TA ( $R^2 = 0.67$ )  
275 (Fig. 5c) was less strong than the correlations between TA and DIC, and TA and Si, which could be traced back on an effect  
276 of the first four samplings points that were probably at the tipping point from high tide to low tide, as mentioned above. In the  
277 remaining samples, the increasing nitrate and TA concentrations suggest a stronger ~~effect of~~ TA generation than nitrate  
278 production, balancing TA that may be consumed by nitrification (i.e., nitrate production).

 282 tide in the Ameland Inlet.

## 283 4 Discussion

### 284 4.1 Spatial TA variability

285 Hoppema (1990) reported TA distributions in the westernmost part of the Dutch Wadden Sea around the barrier islands Texel,  
286 Vlieland, and Terschelling. He focused on the tidal basins drained by the tidal inlets Marsdiep and Vlie located more to the  
287 west than our sampling stations (not visible on the map). Hoppema (1990) did not observe an continuous increase of salinity  
288 in the Wadden Sea from the fresh water source towards the North Sea ocean and associated this to the influence of tidal  
289 differences and an arbitrary sampling scheme. The presence (dominance) of North Sea seawater in the Dutch Wadden Sea and  
290 on the tidal flats is supported by our transect data, which show relatively high salinities at coastal North Sea level. Brackish  
291 salinities were only detected in the large Ems-Dollard Inlet Estuary, which receives high discharges of fresh water from the  
292 river Ems, and also close to Harlingen and Lauwersoog, which have direct fresh water inflows by smaller rivers and streams.  
293 The absence of clear salinity gradients in the more eastern this part of the Dutch Wadden Sea investigated in our study suggest  
294 that most of the IJsselmeer discharge was exchanged with the North Sea through the Marsdiep (e.g., Duran-Matute et al.,  
295 2014).

296  
297 The spatial TA data by Hoppema (1990), show lower TA concentrations at stations with more fresh water influence and higher  
298 TA concentrations in the tidal inlets. The data of this study also show high TA concentrations in the tidal inlets, suggesting  
299 TA generation in sediments, which is possibly fueled by high imports of nutrients and OM (van Beusekom and De Jonge,  
300 2002). The even higher TA concentrations at stations with lower salinities close to the mainland observed in this study also  
301 show the influence from the catchment area on the coast, and possibly TA generation in the shallow sediments near the coast.  
302 In May (1986), Hoppema's (1990) found data showed TA concentrations ranging between 2319 and 2444  $\mu\text{mol TA kg}^{-1}$  TA  
303 at salinities between 18.62 and 29.17. Our, while our lowest observed TA concentration was 2332  $\mu\text{mol TA kg}^{-1}$  TA at a  
304 salinity of 32.14, and our highest TA concentration was 2517  $\mu\text{mol TA kg}^{-1}$  TA at a salinity of 20.25 close to the coastal  
305 mainland. A Comparison of both studies, one can say shows that the general TA levels of TA was are in a similar range,  
306 but that the spatial gradients are opposite.

307 A conservative mixing between TA and salinity is only visible in the Ems-Dollard Inlet and the Vlie Inlet (Fig. 3). While the  
308 conservative mixing in the Ems-Dollard Inlet is more dominated by the fresh water discharge from the Ems River, (The  
309 conservative mixing in the Vlie Inlet is more dominated by North Sea water passing through this deep inlet and allowing more  
310 North Sea water to be transported towards the coast, can be explained by the fact that more North Sea water pass through the  
311 deeper inlets and transport more seawater towards the coast. After the Marsdiep Inlet, the The Vlie Inlet has the highest average  
312 tidal prism and is the second largest inlet after the Marsdiep Inlet in the Dutch Wadden Sea (Elias et al., 2012). Similar to our  
313 findings, Hoppema (1990) noted a linear mixing of TA and salinity in the Vlie Inlet, and suspected a lower fresh water  
314 contribution there as well, which is in accordance with model data (Duran-Matute et al., 2014).

315 In the Ems-Dollard Inlet, conservative mixing was observed, indicating minor contributions from other sources. In a previous  
316 study, Norbistrath et al. (2023) observed very high TA concentrations and TA generation in the upper tidal river of the highly  
317 turbid Ems Estuary, which may explain the high levels of TA in the Ems-Dollard Inlet estuary (at low salinities) observed in  
318 this study.

319 Hoppema (1990) also ~~observed a range of identified varying~~ TA concentrations within the Dutch Wadden Sea and related  
320 these to different sinks and sources. TA sinks can be calcium carbonate (CaCO<sub>3</sub>) precipitation, or extraction of seawater  
321 carbonate by mollusks (e.g., Chen and Wang, 1999; Hoppema, 1990). Variable fresh water inflows can either serve as a sink  
322 or a source (e.g., Chen and Wang, 1999; Hoppema, 1990). Other TA sources can be CaCO<sub>3</sub> dissolution, anaerobic metabolic  
323 processes in the sediment, or erosion of TA enhancing sediments (e.g., Hoppema, 1990; Chen and Wang, 1999).

324 ~~Since we observed~~ Except for the Ems-Dollard Inlet and close to Harlingen, we observed mainly ~~constant~~ marine salinities (>  
325 30); ~~but and~~ higher TA values in the Dutch Wadden Sea than in the North Sea. ~~We~~ therefore exclude possible TA sinks and  
326 focus only on TA sources. According to Hoppema (1990), the main causes for TA variations in the Dutch Wadden Sea were  
327 fresh water inflows and sources in the sediment. In our study, fresh water inflows with high TA concentrations were only  
328 observed in the ~~Ems Estuary and~~ Ems-Dollard Inlet, but not around the islands and the tidal flats. For a further TA source  
329 identification in the Dutch Wadden Sea, we investigated the TA variability during ~~ebb tide in a tidal channel - a tidal cycle~~  
330 close to Ameland.

#### 331 4.2 Determination of TA generation

332 ~~Burt et al. (2016) and Schwichtenberg et al. (2020) indicated assumed~~ TA generation in the Wadden Sea as an important source  
333 for the North Sea's carbon storage capacity. Here, we want to further identify TA generation and potential TA sources.

334 In a study from the ~~late 1980s-early 1990s~~, Hoppema (1993) observed a tidal cycle in the Marsdiep in May and September.  
335 Focusing on TA, DIC, and oxygen, he also observed increasing TA values during ebb tide and assumed the tidal flats and  
336 discharging rivers and canals as TA sources. ~~Comparing our present TA data and the historical TA data, there is not a large~~  
337 ~~difference in the range of values observed during a tidal cycle. Our present TA data and the historical TA data show no large~~  
338 ~~differences in the range of values observed during a tidal cycle.~~ However, a ~~further n~~ in-depth interpretation and comparison  
339 of both TA data sets ~~is limited by the low number of data, would exceed the capacity of these data,~~ leading us to focus on TA  
340 generation during our cruise.

341 ~~Our observation of a TA generation of 7.6 μmol kg<sup>-1</sup> h<sup>-1</sup> TA during ebb tide supports the assumption of the Wadden Sea being~~  
342 ~~a TA source for the North Sea. With the tidal prism of the Ameland Inlet estimated by Louters and Gerritsen (1994), we~~  
343 ~~estimated an upper bound TA export from the Dutch Wadden Sea into the North Sea on the order of 23.9 mol TA during ebb~~  
344 ~~tide (3.5 mol h<sup>-1</sup> TA) between spring and summer. This TA export is a rough maximum estimate, because some waters in the~~  
345 ~~main tide channels have no direct contact to the areas of the tidal flats. We made a very rough first estimate of the daily TA~~  
346 ~~export. By using a 3D ecosystem model,~~ Schwichtenberg et al. (2020) ~~estimated assumed~~ an annual export of 10 to 14 Gmol  
347 TA yr<sup>-1</sup> TA for the entire Dutch Wadden Sea. ~~Given that the Borndiep tidal basin covers about 14% of the Dutch Wadden Sea~~

Formatiert: Englisch (Vereinigte Staaten)

348 ~~and assuming no seasonal dynamics, our estimate of 12.7 Mmol d<sup>-1</sup> compares well with the annual averaged model estimate~~  
349 ~~of 4.6 Mmol TA d<sup>-1</sup>, but the overestimation suggests that seasonal dynamics may be involved. However, Since our TA export~~  
350 ~~based only on a half tidal observation, thean inclusion of it our TA export into the model used by Schwichtenberg et al. (2020)~~  
351 ~~would be unreliable, since our TA export based only on one tidal observation~~ (personal communication J. Pätsch, 2022). To  
352 test whether the observed TA generation matches their suggested TA export, ~~more~~ observational data of at least each season  
353 ~~are required. We suggest at least seasonal observational data in order~~ to run the model and gain a representative result (personal  
354 ~~communication J. Pätsch, 2022). as future work.~~

### 355 4.3 TA source attribution

#### 356 4.3.1 Local sediment outwash

357 In order to gain further insight into potential sources of TA, we compared our TA and nutrient data. included nutrients in our  
358 ~~investigation.~~The main focus was on dissolved silicate (Si) as van Bennekom et al. (1974) showed that this nutrient is depleted  
359 in the Wadden Sea during the spring diatom blooms and further showed that pore water is the main source of dissolved Si  
360 during summer. It is important to note that winter concentrations in the Rhine (main contributor to the IJsselmeer) have not  
361 changed much since the 1970s and showing maximum concentrations of about 125 μmol Si L<sup>-1</sup> in winter and clear seasonal  
362 dynamics due to uptake by diatoms (unpublished results based on data provided by Pätsch (2024); available through  
363 https://wiki.cen.uni-hamburg.de/ifm/ECOHAM/DATA\_RIVER). ~~silicate that we used as a natural tracer since it is not directly~~  
364 ~~provided anthropogenically and allowed us to determine the silicate source (van der Zee and Chou, 2005). van Bennekom et~~  
365 ~~al. (1974)We identified a silicate increase of 1.4 μmol Si L<sup>-1</sup> h<sup>-1</sup> Si during ebb tide. Silicate originates from dissolution of~~  
366 ~~diatoms and pore water exchange in the Wadden Sea (van Bennekom et al., 1974;van der Zee and Chou, 2005). Here, we relate~~  
367 ~~the silicate increase to pore water exchange, because it markedly increased during ebb tide. This assumption is supported by~~  
368 ~~van Bennekom et al. (1974), who suggested silicate diffusion from interstitial water in the sediment as potential source, since~~  
369 ~~very high silicate concentrations were found in deeper sediment layers (Rutgers van der Loeff, 1974). Due to the absence of~~  
370 large estuaries nearby and salinity consistently being above 32 at our tidal sampling station around the island of Ameland, we  
371 exclude fresh water runoff as a major silicate source. ~~This can be supported by the relation between silicate and salinity in~~  
372 ~~which we observed a non-conservative behavior (Table B1) and indicate . Since TA behaves also non-conservative relative to~~  
373 ~~salinity (Table B1), the silicate observations support the occurrence of TA sources in the tidal flats of within the Wadden~~  
374 Sea.

375 Submarine groundwater discharge (SGD) was identified as a source for nutrient fluxes in tidal flat ecosystems in previous  
376 studies (e.g., Billerbeck et al., 2006;Røy et al., 2008;Santos et al., 2021;Waska and Kim, 2011;Wu et al., 2013). ~~Waska and~~  
377 ~~Kim (2011) identified strong SGD contributing up to 50 to 70 % of the nutrient fluxes that fuel primary production in a tidal~~  
378 ~~embayment (Hampyeong Bay) in southwest Korea. In May, they observed low salinities indicating freshwater. However, in~~  
379 ~~September they observed constant marine salinities referring them to be exclusively composed of recirculating seawater. Since~~

380 we ~~constantly~~ observed relatively constant marine salinities, we suspect that deep pore water flow (e.g., Røy et al.,  
381 ~~recirculating marine groundwater~~ enriched with nutrients act as a source for our observed increasing TA and nutrients  
382 parameters. TA generation in tidal flats was also observed by Faber et al. (2014), who focused on a large macro tidal  
383 embayment in southern Australia. They also found increasing TA values during ebb tide, associated the TA increase with a  
384 higher fraction of pore water, and determined the tidal cycle as the controlling force for pore water exchange. Their findings  
385 and the observed silicate outwash support our assumption that TA is generated in the sediments of the tidal flats and is washed  
386 out during ebb tide. In addition, we exclude lateral advected signals from more western regions as the Vlie Inlet, since the TA  
387 concentrations in the surface transect samples in the Vlie Inlet (except of the two samples close to the coastal mainland near  
388 Harlingen) were in the same range as the other observed TA concentrations and were smaller than below the increasing TA  
389 concentrations during ebb tide. Both increases in TA and silicate are clearly tidal signals, and we clearly identify TA generation  
390 in the sediments of the tidal flats here as the major local TA sources.

#### 391 4.3.2 TA generating processes

392 The observed TA generation of  $7.6 \mu\text{mol TA kg}^{-1} \text{h}^{-1}$  TA and the silicate increase of  $1.4 \mu\text{mol Si L}^{-1} \text{h}^{-1}$  Si indicated an excess  
393 of TA (also Fig. 5b). A given a TA:silicate ratio of 2:1 (Marx et al. 2017), ~~and under the condition of silicate being bound in~~  
394 ~~minerals, which would then~~ account for a TA generation of  $2.8 \mu\text{mol TA kg}^{-1} \text{h}^{-1}$  TA. ~~However, when silicate occurred~~  
395 ~~dissolved in water it does not contribute to TA generation (Meister et al., 2022). A TA excess related to silicate was also~~  
396 ~~observed in the correlation between TA and silicate (Fig. 5b).~~ High Si concentrations in tidal flat pore water (Rutgers van der  
397 Loeff, 1974) and in situ production of Si from dissolving diatom frustules are the most probable sources of the Si (e.g., van  
398 Bennekom et al., 1974). Since we observed more TA generated than silicate being washed out, other biogeochemical processes  
399 must be responsible for the TA generation in the sediments of the tidal flats in the Dutch Wadden Sea.

400  
401 ~~We With the observed omega values, we~~ exclude  $\text{CaCO}_3$  dissolution as TA source in the overlying water, since the  $\Omega$  omega  
402 values were clearly supersaturated with  $\Omega > 1$  (Fig. 4h, if, Table B1). The continuous calcite supersaturation nicely indicated  
403 the inflow and dominance of North Sea water during the flood, with  $\Omega$  omega values similar to previously observed North Sea  
404 values ( $\Omega \sim 3.5$  to 4) (Charalampopoulou et al., 2011; Carter et al., 2014). ~~However, because of the  $\Omega$  supersaturation of the~~  
405 ~~overlying water and a lack of pore water data, we were unable to determine if TA generation by  $\text{CaCO}_3$  dissolution occurs in~~  
406 ~~deeper sediment layers. There, In pore water, carbonate undersaturation and associated  $\text{CaCO}_3$  dissolution can only be driven~~  
407 ~~metabolically, due to, when  $\text{CO}_2$  is production by ed during OM remineralization, or due to the reoxidation of compounds~~  
408 ~~reduced previously by anaerobic processes when reduced compounds that were previously produced during anaerobic~~  
409 ~~processes are oxidized and lead to undersaturation with respect to carbonates~~ (Brenner et al., 2016; Jahnke et al., 1994).  
410 Other potential sources of TA generation in the sediments can be further narrowed down by a more detailed interpretation of  
411 changes both in DIC (ADIC) and TA ( $\Delta$ TA) during ebb tide, and their combination with various nutrient ratios.

412 ~~A more detailed interpretation of  $\Delta$ DIC,  $\Delta$ TA, and various nutrient ratios, further narrows down the potential sources of TA~~  
413 ~~generation in the sediments and used an upper bound estimate for  $\text{CaCO}_3$  dissolution.~~ The correlation of DIC and TA reveals  
414 an excess of released DIC compared to TA (Fig. 5a), as indicated by the slope of 1.87, while we observed an increase in DIC  
415 ( $\Delta$ DIC) almost twice as high as in TA ( $\Delta$ TA). The high  $\Delta$ DIC points to high aerobic OM degradation and remineralization,  
416 resulting in high  $\text{CO}_2$ -~~production~~~~export~~. High aerobic OM degradation was also previously observed in the heterotrophic  
417 Wadden Sea (e.g., De Beer et al., 2005; van Beusekom et al., 1999), assuming an OM degradation and remineralization  
418 occurring in the water and sediment in about equal parts (van Beusekom et al., 1999). High OM degradation is ~~also~~ indicated  
419 by the increasing  $C_{\text{org}}:\text{N}$  ratios of SPM during ebb tide (Fig. 4~~kh~~, Table B1). Because we observed constant coastal North Sea  
420 salinities, we rule out fresh water runoff and terrestrial signals as source for the increasing  $C_{\text{org}}:\text{N}$  ratios of SPM. We assume  
421 that fresh OM is rapidly degraded in the water column, and the older OM settles on and in the sediment where the degradation  
422 continues and where it is resuspended ~~at the low prevailing water levels during ebb by the water exchange with outflowing~~  
423 ~~water~~. Therefore, we assume that the increase of SPM concentrations and their  $C_{\text{org}}:\text{N}$  ratios is an indicator for older and more  
424 refractory OM. The increase in TA concentrations point to anaerobic processes,  $\text{CaCO}_3$  dissolution, or a combination thereof  
425 as TA sources occurring in the sediments.

426

427 For ~~the an~~ upper bound estimate ~~of sedimentary  $\text{CaCO}_3$  dissolution as source of TA, we considered a DIC:TA ratio of 1:2.  $\gamma$~~   
428 ~~we assumed  $\text{CaCO}_3$  dissolution in the sediments with the DIC:TA ratio of 1:2 as source of TA.~~ Considering this ratio and the  
429 observed  $\Delta$ TA of  $51.6 \mu\text{mol TA kg}^{-1}$ , ~~TA,  $\text{CaCO}_3$  dissolution would lead to a potential  $\Delta$ DIC of  $25.8 \mu\text{mol DIC kg}^{-1}$ ,  $\Delta$ DIC of~~  
430 ~~the observed  $\Delta$ TA would be produced by  $\text{CaCO}_3$  dissolution.~~ The remaining potential  $75.5 \mu\text{mol DIC kg}^{-1}$  ( $101.3 - 25.8$   
431  $\mu\text{mol DIC kg}^{-1}$ ) of the observed ( $\Delta$ DIC) could then be produced by OM degradation and remineralization, and would,  
432 using the expected Redfield ratio of C:N (6.6), correspond to an estimated potential dissolved inorganic nitrogen (DIN)  
433 production of  $11.4 \mu\text{mol DIN kg}^{-1}$ . However, this estimated potential DIN production ( $11.4 \mu\text{mol DIN kg}^{-1}$ ) of OM  
434 degradation and remineralization exceeds the observed increase of  $\Delta$ DIN ( $3.97 \mu\text{mol DIN L}^{-1}$ ; Table B1, sum of  $\text{NO}_3^-$   
435 ,  $\text{NO}_2^-$  and  $\text{NH}_4^+$ ) during ebb tide. ~~Based on~~ ~~With~~ this estimation and the assumption that all DIN produced is released and thus  
436 lost, TA is probably produced by  $\text{CaCO}_3$  dissolution and anaerobic metabolic processes other than denitrification in the  
437 sediment. In addition to that, and with a N-focused perspective, the DIN loss also hints to the occurrence of other processes  
438 that consume nitrogen species but have no net effect on TA, such as anammox and coupled nitrification-denitrification (Hu  
439 and Cai, 2011; Middelburg et al., 2020). The suggested DIN loss can be supported by considering the marine DIN:Si ratio,  
440 which is supposed to be about 1:1 (Brzezinski, 1985). We observed DIN:Si ratios decreasing from 2.7 to 0.8 ~~during ebb from~~  
441 ~~high tide to low tide, showing that~~. ~~The decreasing ratios show that~~ both parameter concentrations increased ~~during ebb tide~~,  
442 whereby DIN concentrations increased ~~less~~ ~~lower~~ than silicate concentrations. ~~We observed a~~ ~~The~~ silicate excess with respect  
443 to DIN at the end of ebb tide; supporting the DIN loss.

444 Denitrification, the anaerobic irreversible reduction of  $\text{NO}_3^-$  to  $\text{N}_2$  that generates 0.9 mole TA by using 1 mole  $\text{NO}_3^-$  as electron  
445 acceptor (Chen and Wang, 1999) is a net TA source. Denitrification depends on the supply of nitrate, which seasonally varies

Formatiert: Tiefgestellt

Formatiert: Tiefgestellt

Formatiert: Nicht Hochgestellt/ Tiefgestellt

446 (van der Zee and Chou, 2005 and references therein). Generally, nitrate is depleted in summer due to high photosynthetic  
447 activity turnover rates and occurs in higher concentrations in winter (Kieskamp et al., 1991; Jensen et al., 1996; van der Zee and  
448 Chou, 2005). This seasonality lead to denitrification rates also being lower in summer and higher in winter (Kieskamp et al.,  
449 1991; Jensen et al., 1996). In previous studies, Faber et al. (2014) identified denitrification as a minor source of TA due to low  
450 denitrification rates, and also Kieskamp et al. (1991) observed low denitrification rates in the Wadden Sea, with low nitrate  
451 concentrations ( $< 2.5 \mu\text{mol L}^{-1}$ ) in the overlying water. We observed nitrate concentrations ( $< 2.17 \mu\text{mol L}^{-1}$ ) lower than the  
452 concentration sufficient for denitrification assumed by Kieskamp et al. (1991). Therefore, we do not exclude denitrification,  
453 but suspect it as a minor source of TA in the Dutch Wadden Sea at least in spring and summer due to the seasonal lack of  
454 nitrate. Thomas et al. (2009) detected TA seasonality in the southern bight of the North Sea, which is also influenced by the  
455 TA generation in the Wadden Sea. We support their findings of lowered TA generation by denitrification in late spring and  
456 early summer. In addition, the calculated potential DIN excess compared to the observed DIN not only hints to other N  
457 consuming processes that have no effect on TA, but also suggests that allochthonous nitrate would be needed to fuel the TA  
458 increase by denitrification. In addition, the albeit low availability of nitrate indicates to predominantly aerobic metabolic  
459 activity during the time of our observations, which is in line with earlier studies reporting an enhanced relevance of anaerobic  
460 activity later in summer (Luff and Moll, 2004; Thomas et al., 2009).

461  
462 The simultaneous increase of ammonium and TA (Fig. 4c, 4d, 5d) is important to notice, because under oxic conditions the  
463 occurrence of ammonium is coupled with nitrification, a process that consumes ammonium and also TA (Chen and Wang,  
464 1999).

465 However, under anoxic conditions, such as in deeper sediment layers, ammonium cannot be reoxidized, accumulates and is  
466 washed out during ebb tide. Since we observed low nitrate concentrations and rule out terrestrial nitrate inputs here, the increase  
467 in ammonium and TA implies the occurrence of other anaerobic processes of the redox system, such as sulfate and iron  
468 reduction, to generate TA in the deeper, anoxic sediment layers in the Dutch Wadden Sea.

469 Another source of TA in sediments is aerobic OM respiration with the associated formation of ammonium while consuming  
470  $\text{H}^+$  (Blackburn and Henriksen, 1983; Berner et al., 1970; Brenner et al., 2016). The observed increasing ammonium  
471 concentrations (Fig. 4c) could be associated with aerobic OM degradation leading to ammonium formation. The resulting  
472 ammonium formation in the upper oxygenated sediment layers would increase DIC by the production of  $\text{CO}_2$ , and increase  
473 TA by the consumption of  $\text{H}^+$  (Fig. 5) (Brenner et al., 2016). In sediments, the production of one mole ammonium (from  
474 ammonia) would then generate one mole TA (Berner et al., 1970; Meister et al., 2022). In contrast, in the water column, the  
475 aerobic respiration of OM produce  $\text{CO}_2$  and increase DIC, also visible in decreasing pH values (Fig. 4g), but consume TA and  
476 would not produce ammonium (Chen and Wang, 1999). Therefore, aerobic OM respiration in the water column could only  
477 explain the higher increase in DIC than in TA, but not the simultaneous increase in TA and ammonium (Fig. 5). Based on this,  
478 we assume that OM respiration associated with TA generation occurs in the sediments, leading to TA and DIC generation and  
479 also to ammonium production, being washed out during ebb tide. The produced ammonium is then also accessible for

480 nitrification that produces nitrate. A slightly increased nitrate concentration in the most upper sediment layers was observed  
481 by Beck et al. (2008a) in the German Wadden Sea. This observation, a potential nitrate reservoir, nitrate production due to OM  
482 degradation and nitrification occurring in the upper oxygenated sediment layers (Martin and Sayles, 1996), or a combination  
483 thereof could explain the observed low increasing nitrate concentrations during ebb tide. However, as we rule out terrestrial  
484 nitrate imports as nitrate source here, the simultaneous increase of TA and nitrate is noticeable for us, because nitrification  
485 consumes TA (Brenner et al., 2016). We assume that potential nitrification has a minor effect on TA, since we observed only  
486 low nitrate concentrations and a really low increase of nitrate compared to the increase of ammonium and TA during ebb tide.  
487 Low nitrate concentrations resulting in a reduced availability of bound oxygen, i.e., electron acceptors. This promotes the  
488 occurrence of other anaerobic processes of the redox system to generate TA in the deeper, anoxic sediment layers in the Dutch  
489 Wadden Sea, such as sulfate and iron reduction.

490 Sulfate reduction followed by iron reduction and the formation and burial of pyrite are net sources of TA, since TA  
491 consumption by reoxidation is excluded when buried in sediments (Berner et al., 1970;Faber et al., 2014). Whether these  
492 processes contribute to TA generation in the deeper sediments of the Dutch Wadden Sea cannot be further identified without  
493 the necessary data. However, sulfate reduction was also mentioned as source of TA by Thomas et al. (2009). The temporary  
494 slight appearance of noticeable sulfuric odor could be another indirect indicator for the occurrence of sulfate reduction. In  
495 previous studies of tidal flats in the German Wadden Sea, Beck et al. (2008a);(2008b) observed increasing TA concentrations  
496 with depth and identified sulfate reduction as the most important process for anaerobic OM remineralization in pore water  
497 cores. Sulfate reduction releases 1.14 mole TA with the oxidation of one mole carbon of POC, and iron reduction releases  
498 8.14 mole TA with the oxidation of one mole carbon of POC, indicating that both processes are large sources of TA generation  
499 (Brenner et al., 2016), but further studies are needed to support this.

500  
501 A strict comparison of the northern and the western parts of the Wadden Sea is difficult because the areas vary in terms of OM  
502 import and eutrophication effects (van Beusekom et al., 2019), sediment composition, and extent between the barrier islands  
503 and the mainland, all of which influence the occurrence and interaction of biogeochemical processes (Schwichtenberg et al.,  
504 2020). The area characteristics of the northern and western Wadden Sea differ especially in terms of OM turnover being lower  
505 in the northern Wadden Sea. A previous study by Brasse et al. (1999) identified high TA and DIC concentrations in the sediment  
506 of the North Frisian Wadden Sea and identified  $\text{CaCO}_3$  dissolution and sulfate reduction as major TA sources, which is  
507 consistent with our findings.

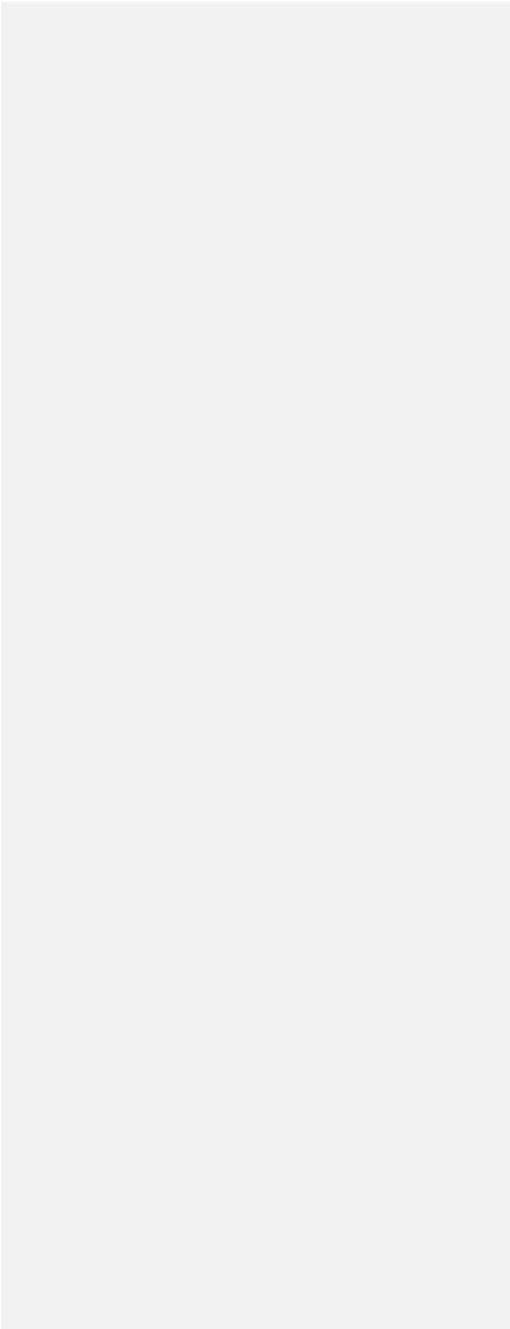

## 508 5 Conclusion

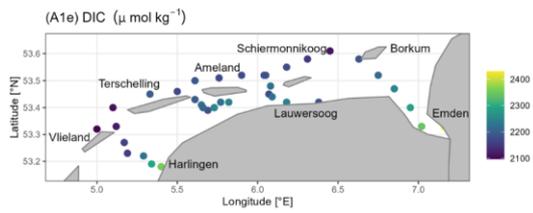

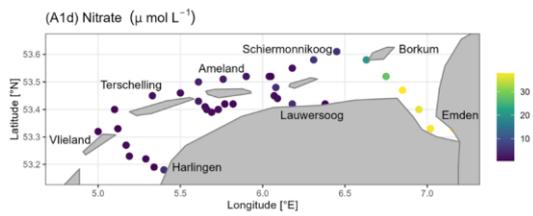

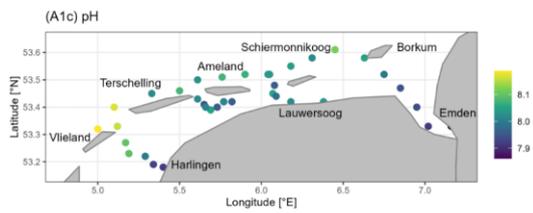

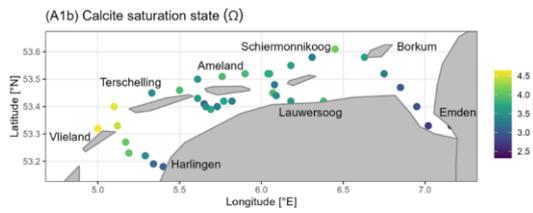

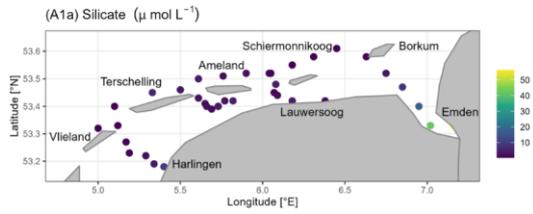

509 The Dutch Wadden Sea is a unique and highly dynamic ecosystem. While observing the spatial TA distribution and TA  
510 generation in the Dutch Wadden Sea, we observed detected higher TA values in the Dutch Wadden Sea than in the North  
511 Sea and identified the Dutch Wadden Sea clearly as a TA source for the North Sea's carbonate system. Compared to previous

512 studies (Hoppema, 1990, 1993), the TA values we observed were in a similar range, with high TA values in the tidal basins.  
513 Beside the need for seasonal observations, future work should also focus on ~~the tidal end members to better understand the~~  
514 ~~general regional~~ and seasonal ~~impacts influence~~ of fresh water inflows ~~of TA~~ on the TA status in the Dutch Wadden Sea.  
515 By observing salinity and using ~~dissolved~~ silicate as a tracer, we excluded fresh water ~~dilution~~ and river runoff as ~~significant~~  
516 TA sources on the tidal flats, and instead, ~~deduced identified~~ local outwash from the sediments as sources of TA. ~~Considering~~  
517 ~~various stoichiometries, we suggest that a~~ Aerobic ~~metabolic processes such as~~ CaCO<sub>3</sub> dissolution ~~and ammonium formation~~  
518 ~~seem to dominate generates~~ TA ~~generation~~ in the upper oxic sediment layers ~~and the overlying water, and while~~ anaerobic,  
519 metabolic processes such as denitrification, sulfate and iron reduction are potential TA sources in the deeper anoxic sediment  
520 layers. However, in spring and early summer, denitrification seems to play a minor role in generating TA in the sediments of  
521 the Dutch Wadden Sea due to seasonality and associated limited nitrate availability.

#### 540 Data availability

541 The data of this study are either presented in the article or are available upon request from the corresponding author.

#### 542 Author Contributions

543 MN wrote the manuscript, did the carbon sampling and sample measurement, analyzed and evaluated the data, and led the  
544 study. JvB led the research cruise. JvB and HT contributed with editorial and scientific recommendations. MN prepared the  
545 manuscript with contribution from all co-authors.

#### 546 Competing interests

547 The contact author has declared that none of the authors has any competing interests.

#### 548 Acknowledgement

549 We thank the crew from RV *Ludwig Prandtl* for their support during the cruise. We thank Leon Schmidt for the nutrient  
550 sampling and measurements, and Marc Metzke for the C/N measurements. We further thank [the Editor Xiping Hu](#) and two  
551 anonymous reviewers for their constructive comments, which greatly improved this manuscript.

#### 552 Financial support

553 This research has been funded by the German Academic Exchange Service (DAAD, project: MOPGA-GRI, grant no.  
554 57429828), which received funds from the German Federal Ministry of Education and Research (BMBF).
