9 Abstract

10 Total alkalinity (TA) is an important chemical property playing a decisive role in the oceanic buffering capacity of CO₂. TA
11 is mainly generated by weathering on land, and by various anaerobic metabolic processes in water and sediments. The Wadden
12 Sea, located in the southern North Sea is hypothesized to be a source of TA for the North Sea, but quantifications are scarce.
13 This study shows observations of TA, dissolved inorganic carbon (DIC), and nutrients in the Dutch Wadden Sea in May 2019.
14 Along several transects, surface samples were taken to investigate spatial distribution patterns and to compare them with data
15 from the late 1980s. A tidal cycle was sampled to further shed light on TA generation and potential TA sources. We identified
16 the Dutch Wadden Sea as a source of TA ~~and estimated an export of 6.6 Mmol TA per tide to the North Sea with an average~~
17 ~~TA generation of 7.6 μmol TA kg⁻¹ h⁻¹ during ebb tide in the Ameland Inlet.~~ TA was generated in the sediments with deep
18 pore water flow during low tide enriching the surface water. A combination of anaerobic processes and CaCO₃ dissolution
19 were potential ~~TA~~ sources ~~of TA~~ in the sediments. We deduce that seasonality and the associated nitrate availability in
20 particular influence TA generation by denitrification, which is low in spring and summer.

21 1 Introduction

22 As the regulator of the ocean carbon dioxide (CO₂) sink, total alkalinity (TA) is of increasing scientific interest and is
23 investigated worldwide in the so called “Anthropocene” (Abril and Frankignoulle, 2001;Bozec et al., 2005;Chen and Wang,
24 1999;Dickson, 1981;Middelburg et al., 2020;Norbistrath et al., 2022;Renforth and Henderson, 2017;Thomas et al.,
25 2004;2009;Sabine et al., 2004). The “Anthropocene” describes the current era of our planet, when environmental changes,
26 driven by humans, have become identifiable in geological records (Zalasiewicz et al., 2010;Crutzen, 2002). One of the most
27 threatening changes for our climate is the anthropogenic driven increase in atmospheric greenhouse gases (GHG), such as
28 CO₂. To counteract the increasing atmospheric CO₂ concentrations and the ongoing climate warming, a combination of several
29 pathways is needed. Beside a strict reduction of CO₂ emissions, also net-negative emissions are required, which capture the

30 atmospheric CO₂ and store it either based on land or in the ocean (e.g., Keith et al., 2006; Matthews and Caldeira, 2008; Zhang
31 et al., 2022). The climate and the increasing atmospheric CO₂ content is also naturally regulated by the open ocean, and around
32 a quarter of the global anthropogenic CO₂ emissions are already removed by it (Friedlingstein et al., 2022). The carbon storage
33 capacity of the North Sea is an important atmospheric CO₂ sink as it exports the absorbed CO₂ in the deep layers of the Atlantic
34 Ocean where it is stored on longer time scales (Borges et al., 2005; Bozec et al., 2005; Burt et al., 2016; Brenner et al., 2016; Hu
35 and Cai, 2011; Schwichtenberg et al., 2020; Thomas et al., 2004; 2009). Two important aspects of the oceanic climate regulation
36 are the oceanic circulation and TA. TA, primarily consisting of bicarbonate and carbonate, is generated by chemical rock
37 weathering (Suchet and Probst, 1993; Meybeck, 1987; Berner et al., 1983), and in various stoichiometries by calcium carbonate
38 (CaCO₃) dissolution and anaerobic metabolic processes, such as denitrification, which is the reduction process of nitrate to
39 dinitrogen gas in the nitrogen cycle (Hu and Cai, 2011; Wolf-Gladrow et al., 2007; Chen and Wang, 1999; Brewer and Goldman,
40 1976). Since TA, CO₂ uptake and its export to the deep ocean are mainly disentangled in the open ocean, TA and the oceanic
41 circulation interact closely in highly active and shallow ocean areas such coastal zones and continental and marginal shelves.
42 In these shallow areas, TA is susceptible to changes due to various metabolic processes and the influence of adjacent zones
43 like rivers, estuaries, marshes, and tidal flats (e.g., Norbistrath et al., 2022; 2023; Wang et al., 2016; Voynova et al., 2019). A
44 previous study by Norbistrath et al. (2022) showed that an enhanced riverine, metabolic alkalinity would lead to increasing
45 CO₂ absorption in the coastal zones of the North Sea, highlighting the need to further investigate TA regulation in adjacent
46 zones of coastal oceans.

47 Coastal zones, which are the direct interface between most, if not all, compartments of the Earth system (i.e., atmospheric,
48 terrestrial, aquatic, and oceanic) and human societies, appear particularly vulnerable to environmental and climate change
49 (Glavovic et al., 2015). This holds true for the Wadden Sea, the shallow, coastal sea along an approximately 500 km coastline
50 of the Netherlands, Germany, and Denmark, in the southern North Sea, which is declared as an UNESCO world natural heritage
51 site since 2009. Most of the Wadden Sea is located between the protecting barrier Islands and the Mainland, which makes it
52 the world's largest uninterrupted stretch of tidal flats with multiple tidal inlets (Fig. 1). Due to the topography, the Wadden
53 Sea is a highly dynamic ecosystem with influences from the mainland and the North Sea (Hoppema, 1993; Postma, 1954; van
54 Raaphorst and van der Veer, 1990). Driving forces of the biogeochemical dynamics in the Wadden Sea are nutrient imports
55 by rivers and high suspended particulate matter (SPM) and organic matter (OM) imports from the North Sea (van Beusekom
56 et al., 2019; van Beusekom et al., 2012; Postma, 1954). Physical sources of variability in the Wadden Sea are oceanic driven
57 wind, waves, and tidal currents, as well as the counterclockwise circulation of the North Sea (Elias et al., 2012). Large tidal
58 amplitude and currents in conjunction with shallow water depths allow for vertical water column mixing and an exchange
59 between the pelagic and benthic realms including deep pore water exchange (Røy et al., 2008). The strong tidal currents also
60 impact the biogeochemistry of the North Sea (Postma, 1954), as they cause an exchange of water between the North Sea and
61 the Wadden Sea and play an important role in the import of particulate matter from the North Sea (Burchard et al., 2008).

62 Previous studies identified the Wadden Sea as a TA source for the North Sea with a loading between 39 Gmol yr⁻¹
63 (Schwichtenberg et al., 2020) and 73 Gmol yr⁻¹ (Thomas et al., 2009). Both studies suggested the entire Wadden Sea as one of

64 the most important TA sources of the carbon storage capacity for the North Sea. Burt et al. (2016) highlighted the importance
65 of coastal TA production for regulating the buffer system in the North Sea, and suggested denitrification as the major TA
66 source. Due to the strong connection between the North Sea and the Wadden Sea, a better understanding of TA generation in
67 the latter is required. Here, we focus on the Dutch Wadden Sea that has been well-studied during the past decades (Hoppema,
68 1990, 1991, 1993;De Jonge et al., 1993;Elias et al., 2012;Ridderinkhof et al., 1990;Postma, 1954;van Beusekom et al.,
69 2019;Schwichtenberg et al., 2017). In particular Hoppema (1990);(1993) observed the spatial and temporal variability of TA
70 in May in the late 1980s, which we compare with our observed transect data to detect potential differences over the last 30
71 years. In addition, we further discussed potential TA sources in the Dutch Wadden Sea.

72 2 Methods

73 2.1 Study site and sampling

74 This study is based on samples collected on a research cruise (LP20190515) in the Dutch Wadden Sea (Frisian Islands) on RV
75 *Ludwig Prandtl* in May 2019 (Fig. 1). We collected water samples in the Wadden Sea starting at Harlingen, through the Vlie
76 Inlet along the islands Vlieland and Terschelling, through the Ameland Inlet to Ameland Island, from there on via the Frisian
77 Inlet to Lauwersoog, and around Schiermonnikoog Island via the Ems-Dollard Inlet to Emden. In addition, we sampled a half
78 tidal cycle during ebb tide (from high tide to low tide) on 21 May 2019. To set the range of ebb tide data in relation, we also
79 sampled a half tidal cycle during flood tide (from low tide to high tide) on 23 May 2019 for comparison. Both half tidal cycles
80 were sampled as an anchor station in the waterway at the western side of Ameland in the Ameland Inlet on each day.

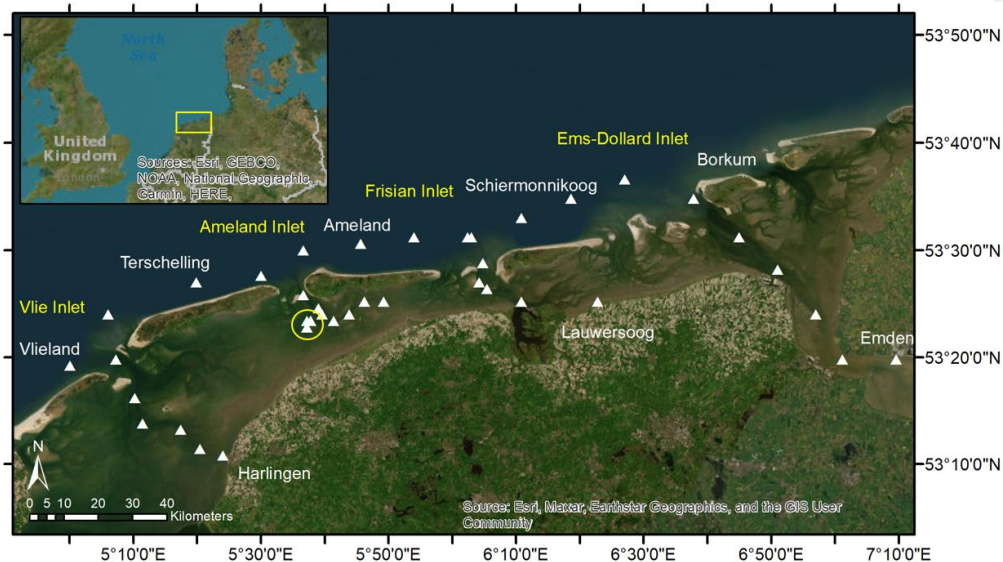

81 Nearly half-hourly, we collected discrete surface (1.2 m depth) water samples with a bypass from the onboard flow-through
82 FerryBox system, (Petersen et al., 2011), which also provided essential physical parameters such as salinity with an accuracy
83 of 0.02 (PSU) and temperature with an accuracy of 0.1 °C (Petersen et al., 2011). The FerryBox was cleaned and the system
84 checked prior to the cruise, and salinity is occasionally checked using discrete samples, which is considered sufficient for
85 gradients in near-shore investigations (pers. comm. Y. Voynova). We complemented our salinity and temperature data with
86 data from three Rijkswaterstaat stations (Dantziggat, Terschelling 10, and Vlietstroom; Table B3), which were close to our
87 stations.

88 For TA and DIC measurements we sampled water with overflow into 300 mL BOD (biological oxygen demand) bottles and
89 preserved them with 300 µL saturated mercury chloride solution (HgCl₂) to stop biological activity. Each BOD bottle was
90 filled without air bubbles and closed by using a ground-glass stopper coated in Apiezon® type M grease and a plastic cap. The
91 samples were stored in a cool dark environment until measurements in the lab.

92 Water for nutrient samples was filtered through pre-combusted (4 h, 450 °C) GF/F filters and the filtrate was stored frozen in
93 three 15 mL Falcon tubes for triplicate measurements in the lab.

Formatiert: Schriftart: (Standard) +Textkörper (Times New Roman), Nicht Kursiv, Schriftfarbe: Automatisch, Englisch (Vereingte Staaten)

94 To determine the total carbon (C), organic carbon (C_{org}) and nitrogen (N) concentrations in SPM and associated $C_{org}:N$ ratios,
 95 we used pre-combusted (4 h, 450 °C) GF/F filters, which were dried after sampling at 50 °C to remove all humidity and were
 96 stored frozen afterwards until measurement.

97
 98 **Figure 1** Sampling site in the Dutch Wadden Sea. The sampling stations around the Frisian Islands in May 2019 are visualized
 99 with white triangles. The yellow circle highlights the anchor stations for the tidal cycle sampling in the Ameland Inlet on two
 100 days. During the sampling day from low tide to high tide, we had two samples that we took slightly more western due to
 101 drifting. The island and city names are shown in white, the inlets in yellow. The tidal flats and sedimentary structures are well
 102 visible between the barrier islands and the mainland.

103 2.2 Carbon species analyses

104 The parallel analyses of TA and DIC were carried out in March 2020 by using the VINDTA 3C (Versatile Instrument for the
 105 Determination of Total dissolved inorganic carbon and Alkalinity, MARIANDA - marine analytics and data), which measures
 106 TA by potentiometric titration and DIC by coulometric titration both with a measurement precision < 2 $\mu\text{mol kg}^{-1}$ (Shadwick
 107 et al., 2011). Certified reference material (CRM batch # 187) provided by Andrew G. Dickson (Scripps Institution of
 108 Oceanography) was measured before and after the samples and used to ensure a consistent calibration of both measurements.

109 The calcite and aragonite saturation states (Ω_c and Ω_a) and the pH_t and the seawater partial pressure of CO_2 ($p\text{CO}_2$) were computed
 110 with the CO_2SYS program (Lewis and Wallace, 1998), using the measured parameters TA and DIC, and salinity, temperature,

Formatiert: Tiefgestellt

Formatiert: Schriftart: Kursiv

Formatiert: Tiefgestellt

111 silicate and phosphate as input variables, together with the dissociation constants from Mehrbach et al. (1973), as refit by
112 Dickson and Millero (1987). Reported calculation uncertainties are ± 0.0062 for pH (Millero et al., 1993), ± 4.9 % for the
113 aragonite saturation state and ± 3.5 % for $p\text{CO}_2$ (Orr et al., 2018).

114 2.3 Nutrient analyses

115 The nutrients were measured with a continuous flow automated nutrient analyzer (AA3, SEAL Analytical) and a standard
116 colorimetric technique (Hansen and Koroleff, 2007) for nitrate (NO_3^-), nitrite (NO_2^-), phosphate (PO_4^{3-}), and silicate (Si), and
117 a fluorometric method (K  rouel and Aminot, 1997) for ammonium (NH_4^+) (Grasshoff et al., 2009). The nutrient samples were
118 measured against Euofins reference materials VKI SW4.1B (for NO_x , NO_2 and NH_4) and VKI SW4.2B (for Si and PO_4) in
119 July 2019. The maximum standard deviations were $0.322 \mu\text{mol L}^{-1}$ for NO_3^- , $0.014 \mu\text{mol L}^{-1}$ for NO_2^- , $0.081 \mu\text{mol L}^{-1}$ for
120 NH_4^+ , $0.014 \mu\text{mol L}^{-1}$ for PO_4^{3-} and $0.165 \mu\text{mol L}^{-1}$ for Si.

121 For the C_{org} determination, filters were acidified with 1N HCl and dried overnight to remove all inorganic carbon content.
122 Filters were measured with a CHN-elemental analyzer (Eurovector EA 3000, HEKAtech GmbH) in the Institute of Geology,
123 University Hamburg, and calibrated against a certified acetanilide standard (IVA Analysentechnik, Germany). The standard
124 deviations were 0.05 % for carbon and 0.005 % for nitrogen.

125 2.4 Data analyses

126 The data analyses were performed by using RStudio Version 1.3.1073    2009-2020 RStudio, PBC. The linear regression
127 Model II was performed by using the “lmodel2” R package, and the plots were created with the “ggplot2” R package.

128 3 Results

129 3.1 Spatial parameter distribution

130 To investigate the spatial distribution of TA in the Dutch Wadden Sea and compare its general status with earlier studies (in
131 particular Hoppema, 1990), we observed TA and related parameters in surface water along a transect from the coastal mainland
132 towards the North Sea.

133 The temperatures varied between 12 and 16   C with higher temperatures towards the coastal mainland (Fig. 2a). We identified
134 two main sub regions based on the salinity values. First the Ems-Dollard Inlet, which showed salinities lower than 28 and with
135 the minimum value of 20.25 at the most upstream station. And second, around Ameland Island and the remaining of our
136 investigated region in the Dutch Wadden Sea with salinities showing only smaller-minor variationsdifferences varying from
137 28 to 33 (Fig. 2b).

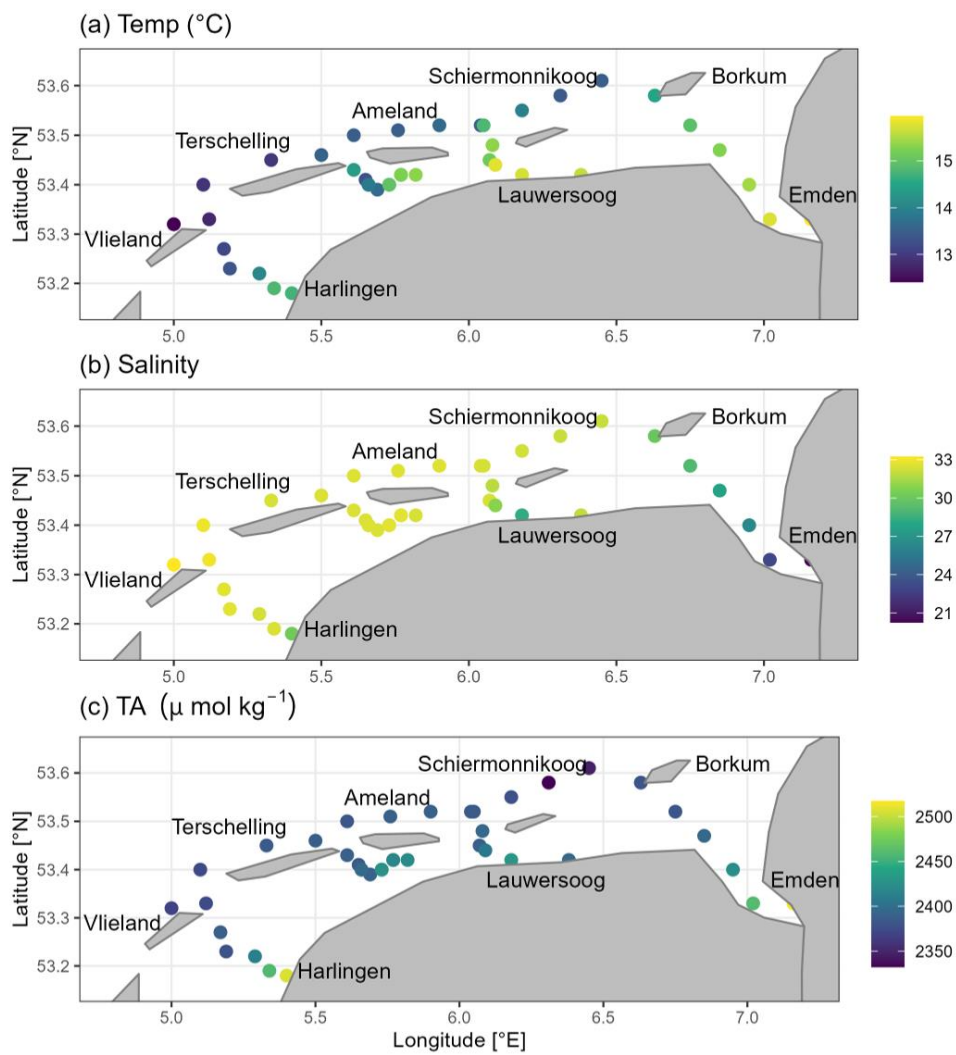

138 Spatial transect TA concentrations ranged from $2332 \mu\text{mol TA kg}^{-1}$ to $2517 \mu\text{mol TA kg}^{-1}$. We observed lower concentrations
139 on the North Sea side of the Frisian Islands with somewhat higher concentrations around Ameland (Fig. 2c). In contrast to the

Formatiert: Schriftart: Kursiv

Formatiert: Tiefgestellt

140 North Sea side, the values were higher ($> 2380 \mu\text{mol TA kg}^{-1}$) in the Wadden Sea. In the Ems-Dollard Inlet, the concentrations
141 were even higher, with values up to $2517 \mu\text{mol TA kg}^{-1}$ at the most upstream station.

142 Silicate (Si) showed higher concentrations in the Wadden Sea and lower ones towards the North Sea (Fig. A1a). Highest
143 concentrations were observed at the coastal mainland and in the Ems-Dollard Inlet. Silicate concentrations ranged between 0.3
144 and $56.3 \mu\text{mol Si L}^{-1}$. Both, the calcite and aragonite saturation states (Ω) were supersaturated in the entire study region.
145 Saturation state values ranged from 2.3 to 4.6 for calcite (Fig. A1b), and from 1.4 to 2.8 for aragonite (Table B3). Highest
146 values were observed at the North Sea side of the barrier islands, and lowest values near Harlingen and in the Ems-Dollard
147 Inlet. Like the calcite and aragonite saturation states, the pH values were higher in the North Sea, and lower in the Wadden
148 Sea and near the coastal mainland (Fig. A1c). The pH values ranged from 7.86 to 8.19, and lowest values were observed near
149 Harlingen and in the Ems-Dollard Inlet. The nitrate (NO_3^-) concentrations were in a low range ($< 3 \mu\text{mol NO}_3^- \text{L}^{-1}$) throughout
150 the study region. Higher concentrations ($< 6 \mu\text{mol NO}_3^- \text{L}^{-1}$) were observed only at a few stations close to land, and maximum
151 concentrations ($< 38 \mu\text{mol NO}_3^- \text{L}^{-1}$) were observed in the Ems-Dollard Inlet (Fig. A1d). DIC concentrations ranged from 2097
152 $\mu\text{mol DIC kg}^{-1}$ to $2430 \mu\text{mol DIC kg}^{-1}$ (Fig. A1e). DIC values showed a similar pattern as TA values, with higher concentrations
153 near the coastal mainland and in the Ems-Dollard Inlet, and decreasing concentrations toward the North Sea, where DIC
154 reached minimum values.

155

156 **Figure 2** Spatial distribution of a) temperature ($^{\circ}\text{C}$), b) salinity (PSU), and c) total alkalinity (TA; $\mu\text{mol kg}^{-1}$) from surface
 157 water samples in May 2019.

158 Compared to the other transects of this study region, the strong influence of the inner Ems Estuary is visible at the most
 159 upstream station in the Ems-Dollard Inlet, showing lowest salinity, lowest pH and calcite saturation state values, and highest
 160 values of TA, DIC, nitrate, silicate and phosphate. The outer side of the Vlie Inlet reflects the North Sea conditions with lower
 161 temperatures and higher salinities. The North Sea impact is also visible in the mixing plot between TA and salinity (Fig.
 162 3). Statistical significant linear mixing behavior was observed in the transect through the Ems-Dollard Inlet ($R^2 = 0.81$) and
 163 through the Vlie Inlet ($R^2 = 0.77$), where TA concentrations decreased with increasing salinities from the mainland towards
 164 the North Sea (Fig. 3). Whereas in the Ems-Dollard Inlet mixing is dominated by riverine water with high TA concentrations,
 165 the mixing in the Vlie Inlet showed a more prominent mixing of Wadden Sea and North Sea water. The TA concentrations in
 166 the Vlie Inlet and around Ameland, both at the North Sea side (Ameland NS) and the Wadden Sea side (Ameland WS) were
 167 higher than the TA concentration computed for the salinity end-member in the Ems-Dollard Inlet, suggesting the Dutch
 168 Wadden Sea as a source of TA (Fig. 3). Both the Ameland NS and WS data clearly indicated a non-conservative behavior with
 169 a range of TA concentrations at near constant salinities.

170

171 **Figure 3** Mixing plot of total alkalinity (TA) and salinity (PSU) in the North Sea side of Ameland and the Frisian Inlet
172 (Ameland NS), in the Wadden Sea site of Ameland (Ameland WS), around Schiermonnikoog and in the Ems-Dollard Inlet
173 (Ems-Dollard), and in the Vlie Inlet (Vlie).

174 3.2 Tidal cycle

175 We observed a half tidal cycle at an anchor station in the Ameland Inlet during ebb tide, to 1) identify potential TA sources
176 and 2) to quantify potential TA export to the North Sea. We identified patterns in several biogeochemical parameters in water
177 leaving the tidal flats (Fig. 4, Table B1). Temperature increased from 13.25 to 14.7 °C (Fig. 4a). Salinity was constant around
178 32.5 (Fig. 4b, Table B1), which is in the range of coastal southern North Sea water excluding admixture of local fresh water
179 sources.

180 During ebb tide, TA ranged from 2387 $\mu\text{mol TA kg}^{-1}$ during high tide to 2438 $\mu\text{mol TA kg}^{-1}$ during low tide (Fig. 4c). We
181 observed an increase of 51.6 $\mu\text{mol TA kg}^{-1}$ (ΔTA) during ebb tide (6.8 h), resulting in a TA increase of 7.6 $\mu\text{mol TA kg}^{-1} \text{ h}^{-1}$
182 at the sampling location.

183 DIC concentrations behaved similar to TA with minimum values at high tide (2172 $\mu\text{mol DIC kg}^{-1}$), and maximum values
184 (2273 $\mu\text{mol DIC kg}^{-1}$) at low tide, resulting in an increase of 101.3 $\mu\text{mol DIC kg}^{-1}$ (ΔDIC) or 14.9 $\mu\text{mol DIC kg}^{-1} \text{ h}^{-1}$ (Fig. 4d).
185 DIC increased almost twice as much as TA.

186 Nitrate increased during ebb tide by 0.92 $\mu\text{mol NO}_3^- \text{ L}^{-1}$ (ΔNO_3^-) from a minimum of 1.26 $\mu\text{mol NO}_3^- \text{ L}^{-1}$ to a maximum of
187 2.17 $\mu\text{mol NO}_3^- \text{ L}^{-1}$ (Fig. 4e), resulting in a nitrate increase of 0.13 $\mu\text{mol NO}_3^- \text{ L}^{-1} \text{ h}^{-1}$.

188 Silicate showed a similar pattern with low values (1.8 $\mu\text{mol Si L}^{-1}$) at high tide increasing during ebb tide to a maximum of
189 11.2 $\mu\text{mol Si L}^{-1}$, resulting in a silicate increase (ΔSi) of 9.4 $\mu\text{mol Si L}^{-1}$ or 1.4 $\mu\text{mol Si L}^{-1} \text{ h}^{-1}$ during ebb tide (Fig. 4f).

190 Ammonium increased from 3.47 $\mu\text{mol NH}_4^+ \text{ L}^{-1}$ to 6.22 $\mu\text{mol NH}_4^+ \text{ L}^{-1}$ during ebb tide (Fig. 4g), resulting in an ammonium
191 increase (ΔNH_4^+) of 2.74 $\mu\text{mol NH}_4^+ \text{ L}^{-1}$, or 0.4 $\mu\text{mol NH}_4^+ \text{ L}^{-1} \text{ h}^{-1}$.

192 The calcite and aragonite saturation states had maximum values ($\Omega_{\text{Ca}} = 3.8$, $\Omega_{\text{Ar}} = 2.4$) at high tide and decreased to their
193 minimum ($\Omega_{\text{Ca}} = 3.1$, $\Omega_{\text{Ar}} = 2.0$) during ebb tide (Fig. 4h*i*). The influence of the North Sea is indicated by the observed
194 maximum at high tide, which decreased during the ebb.

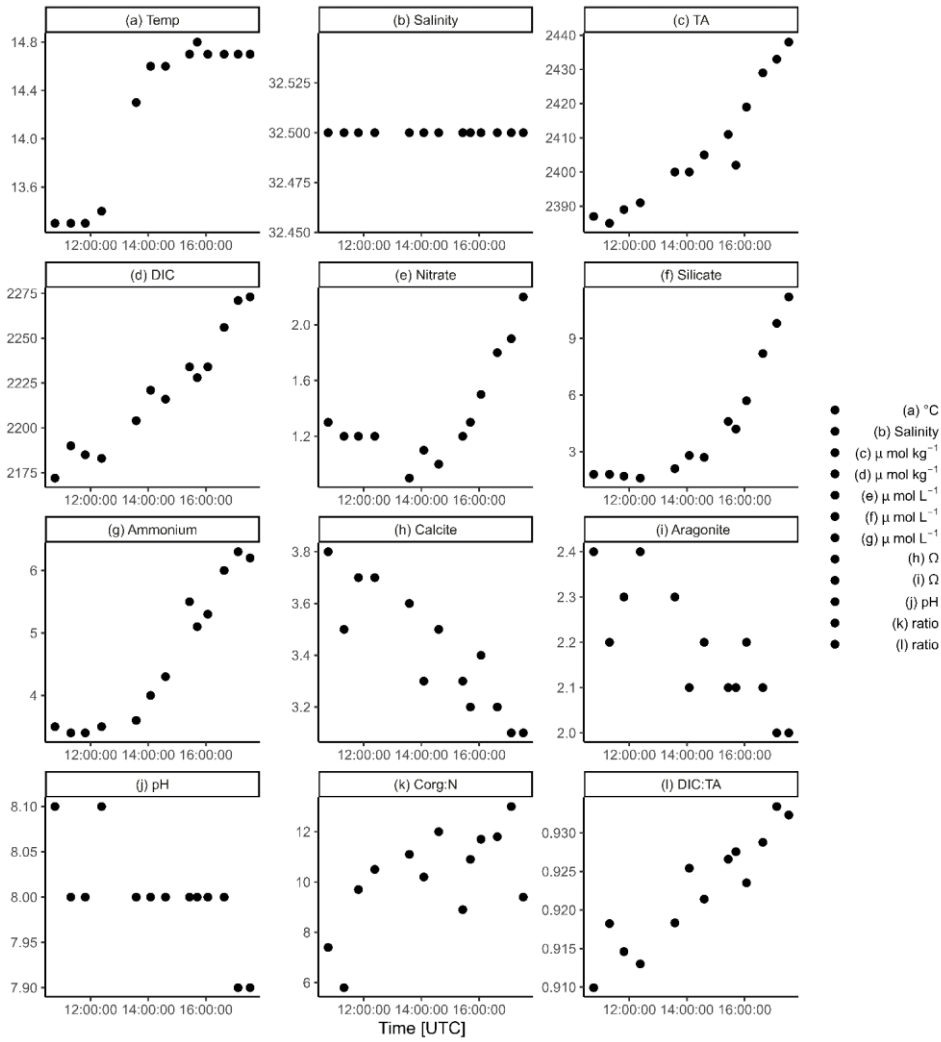

195 The seawater $p\text{CO}_2$ had minimum values at high tide (385.1 μatm) and increased up to 576.6 μatm during low tide (Fig. 4i).

196 Like Ω -omega, the maximum pH was 8.07 at high tide and decreased to a minimum (7.93) during ebb tide (Fig. 4j).

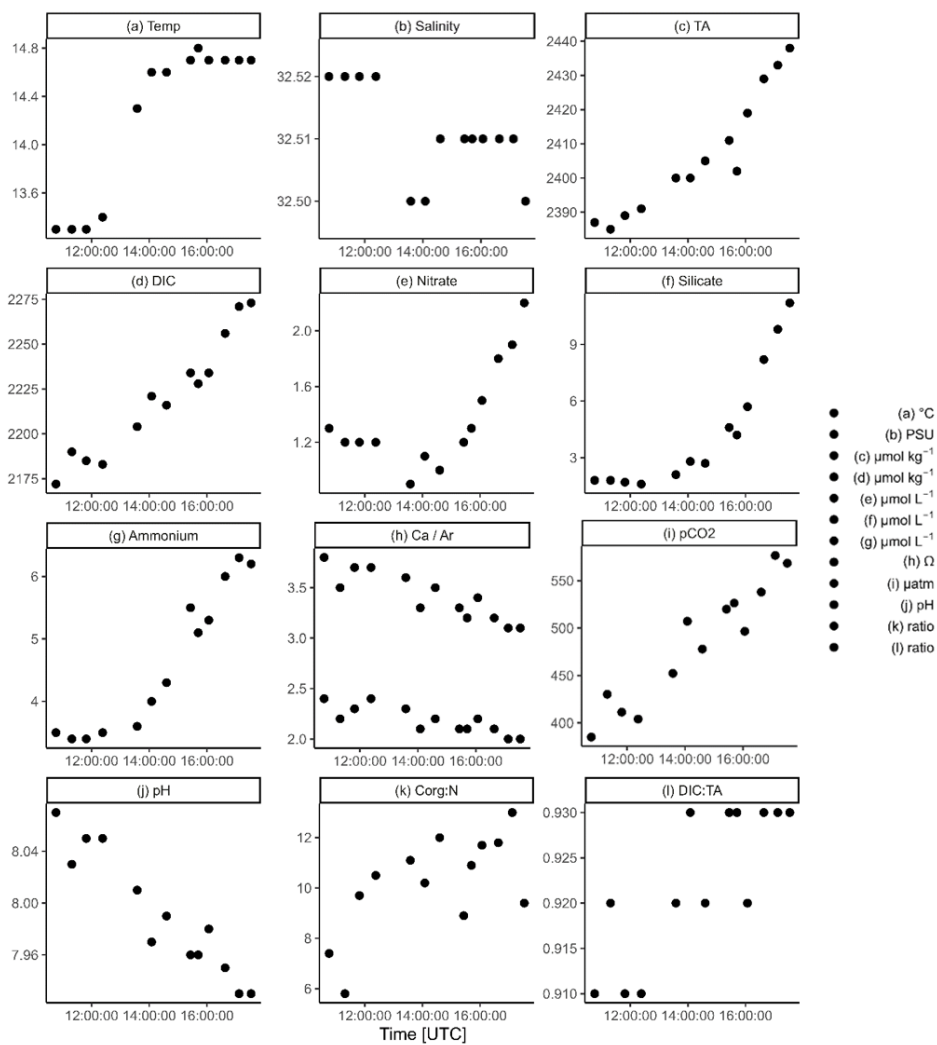

197 $\text{C}_{\text{org}}:\text{N}$ ratios of SPM increased during ebb tide (Fig. 4k). A minimum $\text{C}_{\text{org}}:\text{N}$ ratio of 5.6 was observed around high tide and
198 increased to a maximum of 13.0 during ebb tide. Simultaneously, the SPM concentration increased during ebb tide, from 12.8
199 mg SPM L^{-1} to a maximum of 82.4 mg SPM L^{-1} at the second last station (Table B1).

205 points) saturation states (Ω), i) $p\text{CO}_2$ (μatm), j) pH, k) $C_{\text{org}}:\text{N}$ ratio of SPM, and l) DIC:TA ratio. Note the different y-axes
206 and the +1 hour time difference between the local time and the UTC time.

207 3.3 TA generation

208 Tidal forcing leads to a bi-diurnal exchange between Wadden Sea and North Sea water. The tidal forcing also induces a strong
209 benthic-pelagic coupling (Huettel et al., 2003; Røy et al., 2008). Many studies support that the outflowing water exports
210 material from the sediment including remineralization products from organic matter (e.g., Billerbeck et al., 2006; Røy et al.,
211 2008). Here, we focus on the hypothesis that the sediments are a significant source of TA.

212 For a first rough estimate of a maximum TA export during ebb tide, we used the mean observed TA increase ($\Delta\text{TA} / 2$) of 25.8
213 $\mu\text{mol TA kg}^{-1}$ during ebb tide (in the Ameland Inlet, part of the Borndiep tidal basin), a tidal prism of $478 \cdot 10^6 \text{ m}^3$ of the
214 Borndiep tidal basin, and a share of intertidal flats of 53 % (Louters and Gerritsen, 1994). Assuming that only the intertidal
215 sediments exchange TA, we estimated a TA export of 6.6 Mmol TA per tide to the North Sea. Assuming two ebb tides and a
216 lunar cycle of 24.8 hours this would result in a daily export of 12.7 Mmol TA.

217 The significant correlation of TA and silicate ($R^2 = 0.93$), and the insignificant relation between TA and salinity ($R^2 = 0.32$),
218 as well as silicate and salinity ($R^2 = 0.21$), suggest that TA originates from the tidal flats in this part of the Dutch Wadden Sea
219 and is not from admixture carried by river runoff. The significant correlation between TA and silicate both during ebb tide
220 point to the same source (Fig. 5b).

221 To further elucidate potential TA sources in the Dutch Wadden Sea, we correlated TA with DIC, silicate, nitrate, and
222 ammonium in the half tidal cycle from high tide to low tide, respectively (Fig. 5).

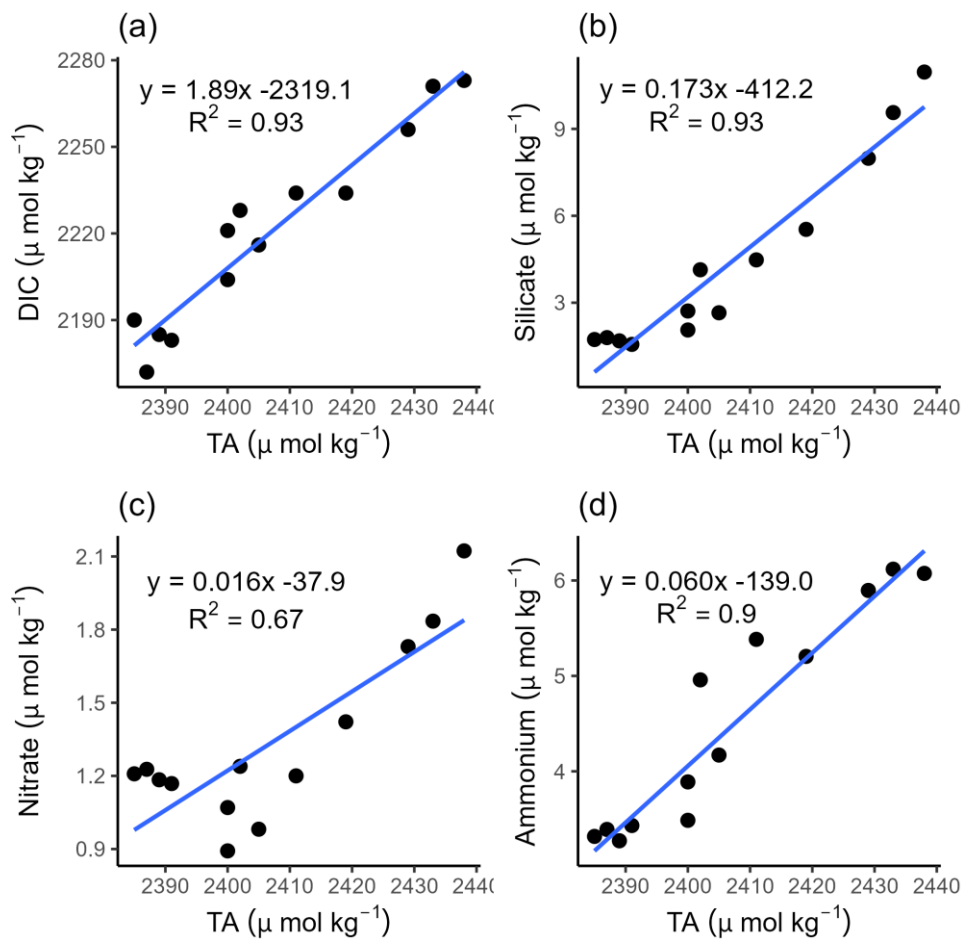

223 The correlation between TA and DIC is a measure between anaerobic and aerobic processes. Our data show a strong positive
224 correlation between DIC and TA ($R^2 = 0.93$) with TA concentrations being higher than DIC concentrations (Fig. 5a). We
225 observed a release excess of DIC compared to TA as indicated by the slope of 1.89 and by an increase in DIC ($\Delta\text{DIC} = 101.3$
226 $\mu\text{mol kg}^{-1}$) almost twice as high as TA ($\Delta\text{TA} = 51.6 \mu\text{mol kg}^{-1}$) (Fig. 5a). This excess DIC may be caused by strong CO_2
227 production due to high aerobic OM degradation, which can be supported by seawater being supersaturated in $p\text{CO}_2$ with respect
228 to the atmosphere (Fig. 4i, Table B1), or by uptake from the atmosphere due to water movement by tidal forcing. However,
229 given the heterotrophic nature of the Wadden Sea (e.g., van Beusekom et al., 2012), a CO_2 undersaturation is unlikely. The

230 TA increase can be fueled by various processes which we will discuss below. We detected a linear positive correlation of
231 increasing TA and silicate ($R^2 = 0.93$) during ebb tide, supporting pore water outflow (Fig. 5b) as pore water is the major Si
232 source during summer (van Bennekom et al., 1974). A stronger influence of the pore water with ongoing ebb tide is indicated
233 by increasing values. The positive correlation between nitrate and TA ($R^2 = 0.67$) (Fig. 5c) was less strong than the correlations
234 between TA and DIC, and TA and Si, which could be traced back to an effect of the first four samplings points that were
235 probably at the tipping point from high tide to low tide. In the remaining samples, the increasing nitrate and TA concentrations
236 suggest a stronger TA generation than nitrate production, balancing TA that may be consumed by nitrification (i.e., nitrate
237 production).

 240 tide in the Ameland Inlet.

241 4 Discussion

242 4.1 Spatial TA variability

243 Hoppema (1990) reported TA distributions in the westernmost part of the Dutch Wadden Sea around the barrier islands Texel,
244 Vlieland, and Terschelling. He focused on the tidal basins drained by the tidal inlets Marsdiep and Vlie located more to the
245 west than our sampling stations (not visible on the map). Hoppema (1990) did not observe a continuous increase of salinity in
246 the Wadden Sea from the fresh water source towards the North Sea and associated this to the influence of tidal differences and
247 an arbitrary sampling scheme. The presence (dominance) of North Sea water in the Dutch Wadden Sea and on the tidal flats
248 is supported by our transect data, which show relatively high salinities at coastal North Sea level. Brackish salinities were only
249 detected in the ~~large~~ Ems-Dollard Inlet, which receives fresh water from the river Ems, and close to Harlingen and Lauwersoog,
250 which have direct fresh water inflows by smaller rivers and streams. The absence of clear salinity gradients in the more eastern
251 part of the Dutch Wadden Sea investigated in our study suggest that most of the IJsselmeer discharge was exchanged with the
252 North Sea through the Marsdiep (e.g., Duran-Matute et al., 2014).

253

254 The spatial TA data by Hoppema (1990), show lower TA concentrations at stations with more fresh water influence and higher
255 TA concentrations in the tidal inlets. The data of this study also show high TA concentrations in the tidal inlets, suggesting
256 TA generation in sediments, which is possibly fueled by high imports of nutrients and OM (van Beusekom and De Jonge,
257 2002). The even higher TA concentrations at stations with lower salinities close to the mainland observed in this study also
258 show the influence from the catchment area on the coast, and possibly TA generation in the shallow sediments near the coast.
259 In May (1986), Hoppema (1990) found TA concentrations ranging between 2319 and 2444 $\mu\text{mol TA kg}^{-1}$ at salinities between
260 18.62 and 29.17. Our lowest observed TA concentration was 2332 $\mu\text{mol TA kg}^{-1}$ at a salinity of 32.14, and our highest TA
261 concentration was 2517 $\mu\text{mol TA kg}^{-1}$ at a salinity of 20.25 close to the coastal mainland. A comparison of both studies shows
262 that the general TA levels are in a similar range, but that the spatial gradients are opposite.

263 A conservative mixing between TA and salinity is only visible in the Ems-Dollard Inlet and the Vlie Inlet (Fig. 3). While the
264 conservative mixing in the Ems-Dollard Inlet is more dominated by the fresh water discharge from the Ems River, the
265 conservative mixing in the Vlie Inlet is more dominated by North Sea water passing through this deep inlet and allowing more
266 North Sea water to be transported towards the coast. After the Marsdiep Inlet, the Vlie Inlet has the highest average tidal prism
267 and is the second largest inlet in the Dutch Wadden Sea (Elias et al., 2012). Similar to our findings, Hoppema (1990) noted a
268 linear mixing of TA and salinity in the Vlie Inlet, and suspected a lower fresh water contribution there as well, which is in
269 accordance with model data (Duran-Matute et al., 2014).

270 In the Ems-Dollard Inlet, conservative mixing was observed, indicating minor contributions from other sources. In a previous
271 study, Norbistrath et al. (2023) observed very high TA concentrations and TA generation in the upper tidal river of the highly
272 turbid Ems Estuary, which may explain the high levels of TA in the Ems-Dollard Inlet (at low salinities) observed in this study.

273 Hoppema (1990) also observed a range of TA concentrations in the Dutch Wadden Sea and related these to different sinks and
274 sources. TA sinks can be calcium carbonate (CaCO_3) precipitation, or extraction of seawater carbonate by mollusks (e.g., Chen
275 and Wang, 1999; Hoppema, 1990). Variable fresh water inflows can either serve as a sink or a source (e.g., Chen and Wang,
276 1999; Hoppema, 1990). Other TA sources can be CaCO_3 dissolution, anaerobic metabolic processes in the sediment, or erosion
277 of TA enhancing sediments (e.g., Hoppema, 1990; Chen and Wang, 1999).

278 Except for the Ems-Dollard Inlet and close to Harlingen, we observed mainly marine salinities (> 30) but higher TA values in
279 the Dutch Wadden Sea than in the North Sea. We therefore exclude possible TA sinks and focus only on TA sources. According
280 to Hoppema (1990), the main causes for TA variations in the Dutch Wadden Sea were fresh water inflows and sources in the
281 sediment. In our study, fresh water inflows with high TA concentrations were only observed in the Ems-Dollard Inlet, but not
282 around the islands and the tidal flats. For a further TA source identification in the Dutch Wadden Sea, we investigated the TA
283 variability during ebb tide in a tidal channel close to Ameland.

284 **4.2 Determination of TA generation**

285 Burt et al. (2016) and Schwichtenberg et al. (2020) indicated TA generation in the Wadden Sea as an important source for the
286 North Sea's carbon storage capacity. Here, we want to further identify TA generation and potential TA sources.

287 In a study from the late 1980s, Hoppema (1993) observed a tidal cycle in the Marsdiep in May and September. Focusing on
288 TA, DIC, and oxygen, he also observed increasing TA values during ebb tide and assumed the tidal flats and discharging rivers
289 and canals as TA sources. Comparing our present TA data and the historical TA data, there is not a large difference in the
290 range of values observed during a tidal cycle. However, a further in-depth interpretation and comparison of both TA data sets
291 is limited by the low number of data, leading us to focus on TA generation during our cruise.

292 We made a very rough first estimate of the daily TA export. By using a 3D ecosystem model, Schwichtenberg et al. (2020)
293 estimated an annual export of 10 to 14 Gmol TA yr^{-1} for the entire Dutch Wadden Sea. Given that the Borndiep tidal basin
294 covers about 14% of the Dutch Wadden Sea and assuming no seasonal dynamics, our estimate of 12.7 Mmol d^{-1} compares
295 well with the annual averaged model estimate of 4.6 Mmol TA d^{-1} , but the overestimation suggests that seasonal dynamics
296 may be involved. Since our TA export based only on a half tidal observation, the inclusion of it into the model used by
297 Schwichtenberg et al. (2020) would be unreliable (pers. comm. J. Pätzsch, 2022). To test whether the observed TA generation
298 matches their suggested TA export, observational data of at least each season are required to run the model and gain a
299 representative result (pers. comm. J. Pätzsch, 2022).

300 **4.3 TA source attribution**

301 **4.3.1 Local sediment outwash**

302 In order to gain further insight into potential sources of TA, we compared our TA and nutrient data. The main focus was on
303 dissolved silicate (Si) as van Bennekom et al. (1974) showed that this nutrient is depleted in the Wadden Sea during the spring

304 diatom blooms and further showed that pore water is the main source of dissolved Si during summer. It is important to note
305 that winter concentrations in the Rhine (main contributor to the IJsselmeer) have not changed much since the 1970s and
306 showing maximum concentrations of about $125 \mu\text{mol Si L}^{-1}$ in winter and clear seasonal dynamics due to uptake by diatoms
307 (unpublished results based on data provided by Pättsch (2024); available through [https://wiki.cen.uni-](https://wiki.cen.uni-hamburg.de/ifm/ECOHAM/DATA_RIVER)
308 [hamburg.de/ifm/ECOHAM/DATA_RIVER](https://wiki.cen.uni-hamburg.de/ifm/ECOHAM/DATA_RIVER)). We identified a silicate increase of $1.4 \mu\text{mol Si L}^{-1} \text{ h}^{-1}$ during ebb tide. Due to
309 the absence of large estuaries nearby and salinity consistently being above 32 at our tidal sampling station ~~near around~~ the
310 island of Ameland, we exclude fresh water runoff as a major silicate source and indicate TA sources within the Wadden Sea.
311 Submarine groundwater discharge (SGD) was identified as a source for nutrient fluxes in tidal flat ecosystems in previous
312 studies (e.g., Billerbeck et al., 2006; Røy et al., 2008; Santos et al., 2021; Waska and Kim, 2011; Wu et al., 2013). Since we
313 observed relatively constant marine salinities, we suspect that deep pore water flow (e.g., Røy et al., 2008) enriched with
314 nutrients act as a source for our observed increasing TA and nutrients parameters. TA generation in tidal flats was also observed
315 by Faber et al. (2014), who focused on a large macro tidal embayment in southern Australia. They also found increasing TA
316 values during ebb tide, associated the TA increase with a higher fraction of pore water, and determined the tidal cycle as the
317 controlling force for pore water exchange. Their findings and the observed silicate outwash support our assumption that TA is
318 generated in the sediments of the tidal flats and is washed out during ebb tide. In addition, we exclude lateral advected signals
319 from more western regions as the Vlie Inlet, since the TA concentrations in the surface transect samples in the Vlie Inlet
320 (except of the two samples close to the coastal mainland near Harlingen) were in the same range as the other observed TA
321 concentrations and were smaller than the increasing TA concentrations during ebb tide. Both increases in TA and silicate are
322 tidal signals, and we identify TA generation in the sediments of the tidal flats here as the major local TA source.

323 4.3.2 TA generating processes

324 The ~~deduced observed~~-TA generation of $7.6 \mu\text{mol TA kg}^{-1} \text{ h}^{-1}$ and the silicate increase of $1.4 \mu\text{mol Si L}^{-1} \text{ h}^{-1}$ indicated an
325 excess of TA ~~compared to silicate~~ (also Fig. 5b). ~~Considering a supposed A given~~ TA:Si ratio of 2:1 (Marx et al. 2017), ~~the~~
326 ~~observed $1.4 \mu\text{mol Si L}^{-1} \text{ h}^{-1}$~~ -would ~~then~~ account for a TA generation of $2.8 \mu\text{mol TA kg}^{-1} \text{ h}^{-1}$. High Si concentrations in tidal
327 flat pore water (Rutgers van der Loeff, 1974) and in situ production of Si from dissolving diatom frustules are the most probable
328 sources of the Si (e.g., van Bennekom et al., 1974). Since we observed more TA generated than silicate being washed out,
329 other biogeochemical processes must be responsible for the TA generation in the sediments of the tidal flats in the Dutch
330 Wadden Sea.

331

332 We exclude CaCO_3 dissolution as TA source in the ~~overlying water column~~, since the Ω values were ~~clearly~~-supersaturated
333 with $\Omega > 1$ (Fig. 4h*i*, Table B1). The continuous calcite supersaturation nicely indicated the inflow and dominance of North
334 Sea water during the flood, with Ω values similar to previously observed North Sea values ($\Omega \sim 3.5$ to 4) (Charalampopoulou
335 et al., 2011; Carter et al., 2014). In pore water, carbonate undersaturation and associated CaCO_3 dissolution can only be driven

336 metabolically, due to CO₂ production by OM remineralization, or due to the reoxidation of compounds reduced previously by
337 anaerobic processes (Brenner et al., 2016; Jahnke et al., 1994).

338

339 Other potential sources of TA generation in the sediments can be further narrowed down by a more detailed interpretation of
340 changes ~~both~~ in DIC (Δ DIC) and TA (Δ TA) during ebb tide, and their combination with various nutrient ratios. The correlation
341 of DIC and TA reveals an ~~increase in DIC (Δ DIC) almost twice as high as in TA (Δ TA) excess of released DIC compared to~~
342 ~~TA~~ (Fig. 5a), as indicated by the slope of 1.89, ~~while we observed an increase in DIC (Δ DIC) almost twice as high as in TA~~
343 ~~(Δ TA)~~. The high Δ DIC points to high aerobic OM degradation and remineralization, resulting in high CO₂ production, ~~which~~
344 ~~is also indicated by seawater being supersaturated in pCO₂~~. High aerobic OM degradation was also previously observed in the
345 heterotrophic Wadden Sea (e.g., De Beer et al., 2005; van Beusekom et al., 1999), assuming an OM degradation and
346 remineralization occurring in the water and sediment in about equal parts (van Beusekom et al., 1999). High OM degradation
347 is indicated by the increasing C_{org}:N ratios of SPM during ebb tide (Fig. 4k, Table B1). Because we observed constant coastal
348 North Sea salinities, we rule out fresh water runoff and terrestrial signals as source for the increasing C_{org}:N ratios of SPM.
349 We assume that fresh OM is rapidly degraded in the water column, and the older OM settles on and in the sediment where the
350 degradation continues and where it is resuspended at the low prevailing water levels during ebb. Therefore, we assume that
351 the increase of SPM concentrations and their C_{org}:N ratios is an indicator for older and more refractory OM. The increase in
352 TA concentrations point to anaerobic processes, CaCO₃ dissolution, or a combination thereof as TA sources occurring in the
353 sediments.

354

355 For an upper bound estimate of sedimentary CaCO₃ dissolution as source of TA, we considered a Δ DIC: Δ TA ratio of 1:2.
356 Considering this ratio and the observed Δ TA of 51.6 μ mol TA kg⁻¹, CaCO₃ dissolution would lead to a ~~potential~~- Δ DIC of 25.8
357 μ mol DIC kg⁻¹. The remaining ~~potential~~-75.5 μ mol DIC kg⁻¹ (101.3 – 25.8 μ mol DIC kg⁻¹) of the observed ~~(Δ DIC in this study)~~
358 could then be produced by OM degradation and remineralization, and would, using the ~~theoretical~~ expected Redfield ratio of
359 C:N (6.6) ~~for fresh OM~~ (Hickel, 1984), correspond to an estimated ~~potential~~-dissolved inorganic nitrogen (DIN) production of
360 11.4 μ mol DIN kg⁻¹. However, this estimated ~~potential~~-DIN production (11.4 μ mol DIN kg⁻¹) of OM degradation and
361 remineralization exceeds the observed increase of Δ DIN (3.97 μ mol DIN L⁻¹; Table B1, sum of NO₃⁻, NO₂⁻ and NH₄⁺) during
362 ebb tide. Based on this estimation and the assumption that all DIN produced is released and thus lost, TA is probably produced
363 by CaCO₃ dissolution and anaerobic metabolic processes other than denitrification in the sediment. In addition to that, and
364 with an N-focused perspective, the DIN loss also hints to the occurrence of other processes that consume nitrogen species but
365 have no net effect on TA, such as anammox and coupled nitrification-denitrification (Hu and Cai, 2011; Middelburg et al.,
366 2020). The suggested DIN loss can be supported by considering the marine DIN:Si ratio, which is supposed to be about 1:1
367 (Brzezinski, 1985). We observed DIN:Si ratios decreasing from 2.7 to 0.8 during ebb tide, showing that both parameter
368 concentrations increased, whereby DIN concentrations increased less than silicate concentrations. The silicate excess with
369 respect to DIN at the end of ebb tide supports the DIN loss.

Formatiert: Schriftart: Kursiv

Formatiert: Tiefgestellt

370 Denitrification, the anaerobic irreversible reduction of NO_3^- to N_2 that generates 0.9 mole TA by using 1 mole NO_3^- as electron
371 acceptor (Chen and Wang, 1999) is a net TA source. Denitrification depends on the supply of nitrate, which seasonally varies
372 (van der Zee and Chou, 2005 and references therein). Generally, nitrate is depleted in summer due to high photosynthetic
373 activity and occurs in higher concentrations in winter (Kieskamp et al., 1991; Jensen et al., 1996; van der Zee and Chou, 2005).
374 This seasonality leads to denitrification rates also being lower in summer and higher in winter (Kieskamp et al., 1991; Jensen
375 et al., 1996). In previous studies, Faber et al. (2014) identified denitrification as a minor source of TA due to low denitrification
376 rates, and also Kieskamp et al. (1991) observed low denitrification rates in the Wadden Sea, with low nitrate concentrations
377 ($< 2.5 \mu\text{mol L}^{-1}$) in the ~~overlying water column~~. We observed nitrate concentrations ($< 2.17 \mu\text{mol L}^{-1}$) lower than the
378 concentration sufficient for denitrification assumed by Kieskamp et al. (1991). Therefore, we do not exclude denitrification,
379 but suspect it as a minor source of TA in the Dutch Wadden Sea at least in spring and summer due to the seasonal lack of
380 nitrate. Thomas et al. (2009) detected TA seasonality in the southern bight of the North Sea, which is also influenced by the
381 TA generation in the Wadden Sea. ~~We support their findings of lowered TA generation by denitrification in late spring and~~
382 ~~early summer.~~ In addition, the ~~calculated estimated potential DIN production excess~~ compared to the observed DIN not only
383 hints to other N consuming processes that have no effect on TA, but also suggests that allochthonous nitrate would be needed
384 to fuel the TA increase by denitrification. ~~In addition, the albeit low availability of nitrate indicates to predominantly aerobic~~
385 ~~metabolic activity in the overlying water and upper sediment layers during the time of our observations, which is in line with~~
386 ~~earlier studies reporting an enhanced relevance of anaerobic activity later in summer (Luff and Moll, 2004; Thomas et al.,~~
387 ~~2009).~~

388
389 The simultaneous increase of ammonium and TA (Fig. 4c, 4d, 5d) is important to notice, because under oxic conditions the
390 occurrence of ammonium is coupled with nitrification, a process that consumes ammonium and also TA (Chen and Wang,
391 1999). However, under anoxic conditions, such as in deeper sediment layers, ammonium cannot be reoxidized, accumulates,
392 and is washed out during ebb tide. Since we observed low nitrate concentrations and rule out terrestrial nitrate inputs here, the
393 increase in ammonium and TA implies the occurrence of other anaerobic processes of the redox system, such as sulfate and
394 iron reduction, to generate TA in the deeper, anoxic sediment layers in the Dutch Wadden Sea.

395 Sulfate reduction followed by iron reduction and the formation and burial of pyrite are net sources of TA, since TA
396 consumption by reoxidation is excluded when buried in sediments (Berner et al., 1970; Faber et al., 2014). Whether ~~and to what~~
397 ~~extent~~ these processes contribute to TA generation in the deeper sediments of the Dutch Wadden Sea cannot be further
398 identified without the necessary data. However, sulfate reduction was also mentioned as source of TA by Thomas et al. (2009).
399 ~~And t~~ The temporary slight appearance of noticeable sulfuric odor could be another indirect indicator for the occurrence of
400 sulfate reduction. In previous studies of tidal flats in the German Wadden Sea, Beck et al. (2008a); (2008b) observed increasing
401 TA concentrations with depth and identified sulfate reduction as the most important process for anaerobic OM remineralization
402 in pore water cores.

403

404 A strict comparison of the more northern (north of the Elbe Estuary) and the more western (Texel – Elbe Estuary) parts of the
405 Wadden Sea is difficult because the areas vary in terms of OM import and eutrophication effects (van Beusekom et al., 2019),
406 sediment composition, and extent between the barrier islands and the mainland, all of which influence the occurrence and
407 interaction of biogeochemical processes (Schwichtenberg et al., 2020). The area characteristics of the northern and western
408 Wadden Sea differ especially in terms of OM turnover being lower in the norther Wadden Sea. A previous study by Brasse et
409 al. (1999) identified high TA and DIC concentrations in the sediment of the North Frisian Wadden Sea and identified CaCO_3
410 dissolution and sulfate reduction as major TA sources, which is consistent with our findings.

411 **5 Conclusion**

412 The Dutch Wadden Sea is a unique and highly dynamic ecosystem. We observed higher TA values in the Dutch Wadden Sea
413 than in the North Sea and identified the Dutch Wadden Sea as a TA source for the North Sea's carbonate system. Compared
414 to previous studies (Hoppema, 1990, 1993), the TA values we observed were in a similar range, with high TA values in the
415 tidal basins. Beside the need for seasonal observations, future work should also focus on regional and seasonal impacts of fresh
416 water inflows of TA on the TA status in the Dutch Wadden Sea.

417 By observing salinity and using dissolved silicate as a tracer, we excluded fresh water and river runoff as significant TA sources
418 on the tidal flats, and instead, deduced local outwash from the sediments as sources of TA. Considering various stoichiometries,
419 we suggest that CaCO_3 dissolution generates TA in the more upper oxic sediment layers, and anaerobic, metabolic processes
420 such as denitrification, sulfate and iron reduction are potential TA sources in the deeper anoxic sediment layers. However, in
421 spring and early summer, denitrification seems to play a minor role in generating TA in the sediments of the Dutch Wadden
422 Sea due to seasonality and associated limited nitrate availability.

438 **Table B2** Half tidal cycle sample parameter during high tide. Sample no. 564 is the first sample at low tide and sample no.
439 578 is the last sample at high tide on 23 May 2019 (53.39°N & 5.63°E, 5.62°E*). Shown are rounded-up values of temperature
440 (Temp), salinity (Sal), total alkalinity (TA), dissolved inorganic carbon (DIC), silicate (Si), nitrate (NO₃⁻), nitrite (NO₂⁻),
441 ammonium (NH₄⁺), phosphate (PO₄³⁻), dissolved inorganic nitrogen (DIN), the amount of carbon (C) and organic carbon (C_{org})
442 of SPM, the amount of nitrogen (N) of SPM, the calcite (Ca) and aragonite (Ar) saturation states, the pH, and the seawater
443 partial pressure of CO₂ (pCO₂) per sample.

445

446 **Table B3** Transect parameter of cruise LP20190515 on RV *Ludwig Prandt* in the Dutch Wadden Sea in May 2019. Shown
447 are values of latitude (Lat), longitude (Lon), temperature (Temp), salinity (Sal), total alkalinity (TA), dissolved inorganic
448 carbon (DIC), silicate (Si), nitrate (NO₃⁻), the calcite (Ca) and aragonite (Ar) saturation states, and pH per sample. Our salinity
449 and temperature data were ~~complemented by~~ compared to data of three Rijkswaterstraat stations, which were close to our
450 stations. There, Dantziggat* (53°24'4.093", 5°43'37.132") showed temperatures of 11.4 and 14.9 °C and salinities of 31.9 and
451 31.2 on 10 and 27 May 2019, respectively, Terschelling 10** (53°27'37.318", 5°5'58.129") showed temperatures of 11.4 and
452 12.9 °C and salinities of 32.8 and 33.4 on 15 and 28 May 2019, respectively, and Vlietstroom*** (53°18'48.054", 5°9'35.655")
453 showed a temperature of 11.8 °C and a salinity of 31.1 on 14 May 2019.

454

455 **Data availability**

456 The data of this study are presented in the [appendices of this article](#) ~~or are available upon request from the corresponding~~
457 ~~author.~~

458 Author Contributions

459 MN wrote the manuscript, did the carbon sampling and sample measurement, analyzed and evaluated the data, and led the
460 study. JvB led the research cruise. JvB and HT contributed with editorial and scientific recommendations. MN prepared the
461 manuscript with contribution from all co-authors.

462 Competing interests

463 The contact author has declared that none of the authors has any competing interests.

464 Acknowledgement

465 We thank the crew from RV *Ludwig Prandtl* for their support during the cruise. We thank Leon Schmidt for the nutrient
466 sampling and measurements, ~~and~~ Marc Metzke for the C/N measurements, and Yoana Voynova and her department for the
467 FerryBox preparation. We further thank the Editor and two anonymous reviewers for their constructive comments, which
468 greatly improved this manuscript.

469 Financial support

470 This research has been funded by the German Academic Exchange Service (DAAD, project: MOPGA-GRI, grant no.
471 57429828), which received funds from the German Federal Ministry of Education and Research (BMBF).
