7 **Abstract**

8 As the major global CO₂ sink, the oceanic buffering capacity total alkalinity (TA) is of growing scientific interest. TA is mainly
9 generated by weathering, and further by various anaerobic metabolic processes. The Wadden Sea, located in the southern
10 North Sea is thought to be a source of TA for the carbonate system of the North Sea, but quantifications are scarce. Here, we
11 observed TA, dissolved inorganic carbon (DIC), and nutrients in the Dutch Wadden Sea in May 2019. We sampled transect
12 surface waters to detect spatial distributions and compared it with earlier data. A tidal cycle was sampled to further shed light
13 on TA generation and potential TA sources. We identified the Wadden Sea as a source of TA with an average TA generation
14 of 7.6 μmol kg⁻¹ h⁻¹ during ebb tide in the Ameland Inlet. TA was generated in the sediments and washed out with off running
15 water. A combination of anaerobic processes and CaCO₃ dissolution were potential sources of TA in the sediments. We assume
16 that seasonality and the associated nitrate availability in particular influence TA generation by denitrification, which we assume
17 is low in spring and summer.

18 **1 Introduction**

19 As the regulator of the ocean carbon dioxide (CO₂) sink, total alkalinity (TA) is of increasing scientific interest and investigated
20 worldwide in the Anthropocene (Abril and Frankignoulle, 2001;Bozec et al., 2005;Chen and Wang, 1999;Dickson,
21 1981;Middelburg et al., 2020;Norbistrath et al., 2022;2023;Renforth and Henderson, 2017;Thomas et al., 2004;2009;Sabine et
22 al., 2004). The Anthropocene describes the current era of our planet, when environmental changes, driven by humans, have
23 become identifiable in geological records (Zalasiewicz et al., 2010;Crutzen, 2002). Coastal regions, which are the direct
24 interface between most, if not all, compartments of the Earth system (i.e., terrestrial, aquatic, oceanic) and human societies,
25 appear particularly vulnerable to environmental and climate change (Glavovic et al., 2015). This holds true for the Wadden
26 Sea, the shallow, coastal sea along an approximately 500 km coastline of the Netherlands, Germany, and Denmark, in the
27 southern North Sea, which is declared as an UNESCO world natural heritage site since 2009. Most part of it is located between
28 the protecting barrier Islands and the Mainland, which makes it a unique and the world's largest uninterrupted stretch of tidal
29 flats with multiple tidal inlets (Fig. 1). Due to the topography, the Wadden Sea is a highly dynamic ecosystem with influences

30 from the mainland and the North Sea (Hoppema, 1993;Postma, 1954;Raaphorst and Veer, 1990). Driving forces of the
31 dynamics in the Wadden Sea are nutrient and organic matter (OM) imports by rivers, high suspended particulate matter (SPM)
32 imports by the North Sea (Van Beusekom et al., 2012;Postma, 1954), and oceanic driven wind, waves, and tidal currents, as
33 well as the counterclockwise circulation of the North Sea (Elias et al., 2012). Large tidal amplitude and currents in conjunction
34 with shallow water depths allow for vertical water column mixing and an exchange between the benthic and pelagic realms.
35 The high tidal currents also impact the biogeochemistry of the North Sea (Postma, 1954), as they cause a strong exchange of
36 water masses.

37 The North Sea and its carbon storage capacity is an important atmospheric CO₂ sink by exporting and storing the absorbed
38 CO₂ in the deep layers of the Atlantic Ocean (Schwichtenberg et al., 2020;Thomas et al., 2004;2009;Burt et al., 2016;Borges
39 et al., 2005;Hu and Cai, 2011;Brenner et al., 2016).

40 Next to chemical rock weathering (Suchet and Probst, 1993;Meybeck, 1987;Berner et al., 1983), TA, usually consisting of
41 bicarbonate and carbonate, is also generated in various stoichiometries by calcium carbonate (CaCO₃) dissolution and
42 anaerobic metabolic processes, such as denitrification, which is the reduction process of nitrate to dinitrogen gas in the nitrogen
43 cycle (Hu and Cai, 2011;Wolf-Gladrow et al., 2007;Chen and Wang, 1999;Brewer and Goldman, 1976).

44 Understanding of TA sources have recently become increasingly important due to increasing anthropogenic CO₂ emissions,
45 and the resulting demand for ocean based net-negative CO₂ emissions (e.g., Keith et al., 2006;Matthews and Caldeira,
46 2008;Zhang et al., 2022).

47 In previous studies, the Wadden Sea was estimated as a TA source of the North Sea with a loading between 39 Gmol yr⁻¹
48 (Schwichtenberg et al., 2020) and 73 Gmol yr⁻¹ (Thomas et al., 2009). Both studies suggested the entire Wadden Sea as one of
49 the most important TA sources of the carbon storage capacity of the North Sea. Burt et al. (2016) highlighted the importance
50 of coastal TA production for regulating the buffer system in the North Sea, whereby they suggest denitrification as the major
51 TA source. Due to the strong connection between the North Sea and the Wadden Sea, a better understanding of TA generation
52 in the latter one is required. Here, we focus on the Dutch Wadden Sea that has been well-studied during the past decades
53 (Hoppema, 1990, 1991, 1993;De Jonge et al., 1993;Elias et al., 2012;Ridderinkhof et al., 1990;Postma, 1954;Van Beusekom
54 et al., 2019;Schwichtenberg et al., 2017). In particular Hoppema (1990);(1993) observed the spatial and temporal variability
55 of TA, which we compare with our observed transect data to detect potential differences over the last 30 years. In addition, we
56 further shed light on potential TA sources in the Dutch Wadden Sea.

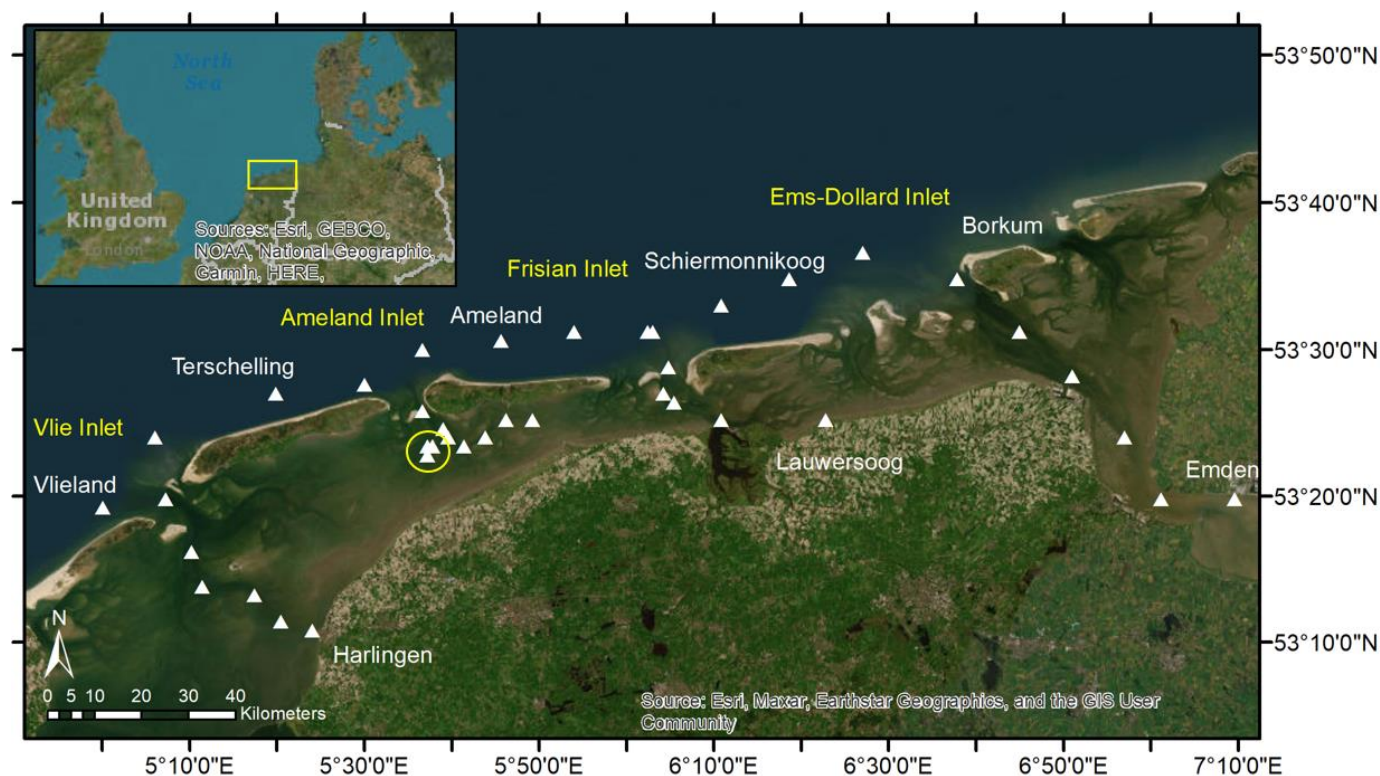

57 **2 Methods**

58 **2.1 Study site and sampling**

59 This study is based on samples collected on a research cruise (LP20190515) in the Dutch Wadden Sea (Frisian Islands) on RV
60 *Ludwig Prandtl* in May 2019 (Fig. 1). We collected water samples in the Wadden Sea starting at Harlingen, through the Vlie
61 Inlet around the islands Vlieland and Terschelling, through the Ameland Inlet to Ameland Island, from there on via the Frisian

62 Inlet to Lauwersoog, and around Schiermonnikoog Island via the Ems-Dollard Inlet to Emden. Nearly half-hourly, we
63 continuously collected discrete surface (1.2 m depth) water samples with a bypass from the onboard flow-through FerryBox
64 system (Petersen et al., 2011), which provided essential physical parameters such as salinity and temperature. In addition, we
65 sampled a tidal cycle from high tide to low tide and from low tide to high tide on each of two days as an anchor station in the
66 waterway at the western side of Ameland in the Ameland Inlet.

67
68 **Figure 1** Sampling site in the Dutch Wadden Sea. The sampling stations around the Frisian Islands in May 2019 are visualized
69 with the white triangles. The yellow circle highlights the anchor stations for the tidal cycle sampling in the Ameland Inlet on
70 two days. During the sampling day from low tide to high tide, we had two samples that we took slightly more western due to
71 drifting. The island and city names are shown in white, the inlets in yellow. The tidal flats and sedimentary structures are well
72 visible between the barrier islands and the mainland.

73 2.2 Sampling and analysis

74 2.2.1 Carbon species

75 For carbon measurements we sampled water with overflow into 300 mL BOD (biological oxygen demand) bottles and
76 preserved them with 300 μ L saturated mercury chloride (HgCl_2) to stop biological activity. Each BOD bottle was filled without

77 air bubbles and closed by using a ground-glass stopper coated in Apiezon® type M grease and a plastic cap. The samples were
78 stored in a cool dark environment until measurements in the lab.
79 The parallel analyses of TA and DIC were carried out by using the VINDTA 3C (Versatile Instrument for the Determination
80 of Total dissolved inorganic carbon and Alkalinity, MARIANDA - marine analytics and data), which measures TA by
81 potentiometric titration and DIC by coulometric titration with a measurement precision $< 2 \mu\text{mol kg}^{-1}$. (Shadwick et al., 2011).
82 To ensure a consistent calibration of both measurements, we used Certified Reference Material (CRM batch # 187) provided
83 by Andrew G. Dickson (Scripps Institution of Oceanography).
84 The calcite saturation state (Ω) and the pH were computed with the CO₂SYS program (Lewis and Wallace, 1998), using the
85 measured parameters TA, DIC, salinity, temperature, silicate and phosphate as input variables, together with the dissociation
86 constants from Mehrbach et al. (1973), as refit by Dickson and Millero (1987).

87 2.2.2 Nutrients

88 Water for nutrient samples was filtered through pre-combusted (4 h, 450 °C) GF/F filters to store them afterwards frozen in
89 three 15 mL Falcon tubes for triplicate measurements in the lab.
90 We measured the nutrients with a continuous flow automated nutrient analyzer (AA3, SEAL Analytical) and a standard
91 colorimetric technique (Hansen and Koroleff, 2007) for nitrate (NO_3^-), nitrite (NO_2^-), phosphate (PO_4^{3-}), and silicate (Si), and
92 a fluorometric method (K erouel and Aminot, 1997) for ammonium (NH_4^+) (Grasshoff et al., 2009).
93 In order to determine the total carbon (C), organic carbon (C_{org}) and nitrogen (N) concentrations in SPM and associated $\text{C}_{\text{org}}:\text{N}$
94 ratios, we used pre-combusted (4 h, 450 °C) GF/F filters, which we dried after sampling at 50 °C to remove all humidity and
95 stored frozen until measurement. For the C_{org} determination, filters were acidified with 1N HCl and dried overnight to remove
96 all inorganic carbon content. Filters were measured with a CHN-elemental analyzer (Eurovector EA 3000, HEKAtech GmbH)
97 in the Institute of Geology, University Hamburg, and calibrated against a certified acetanilide standard (IVA Analysentechnik,
98 Germany). The standard deviations were 0.05 % for carbon and 0.005 % for nitrogen.

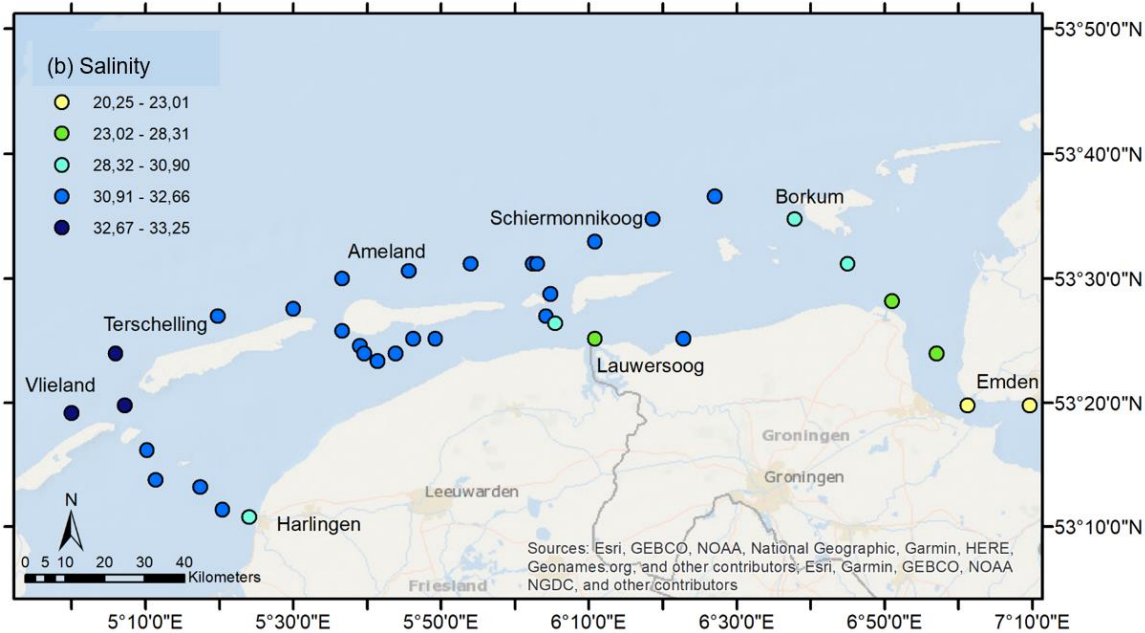

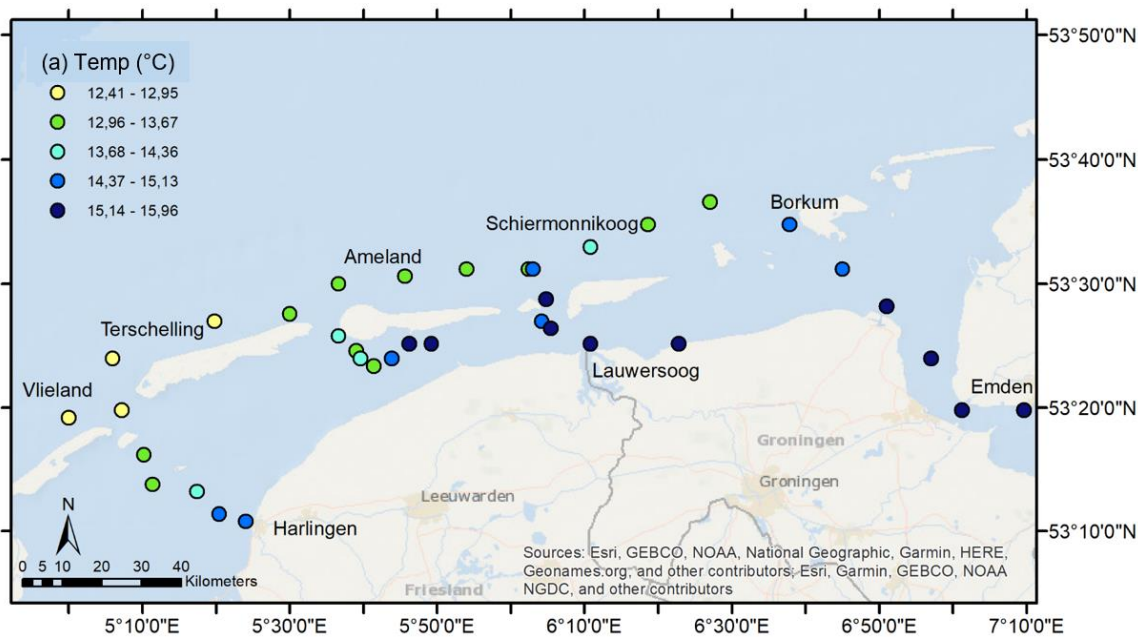

99 3 Results

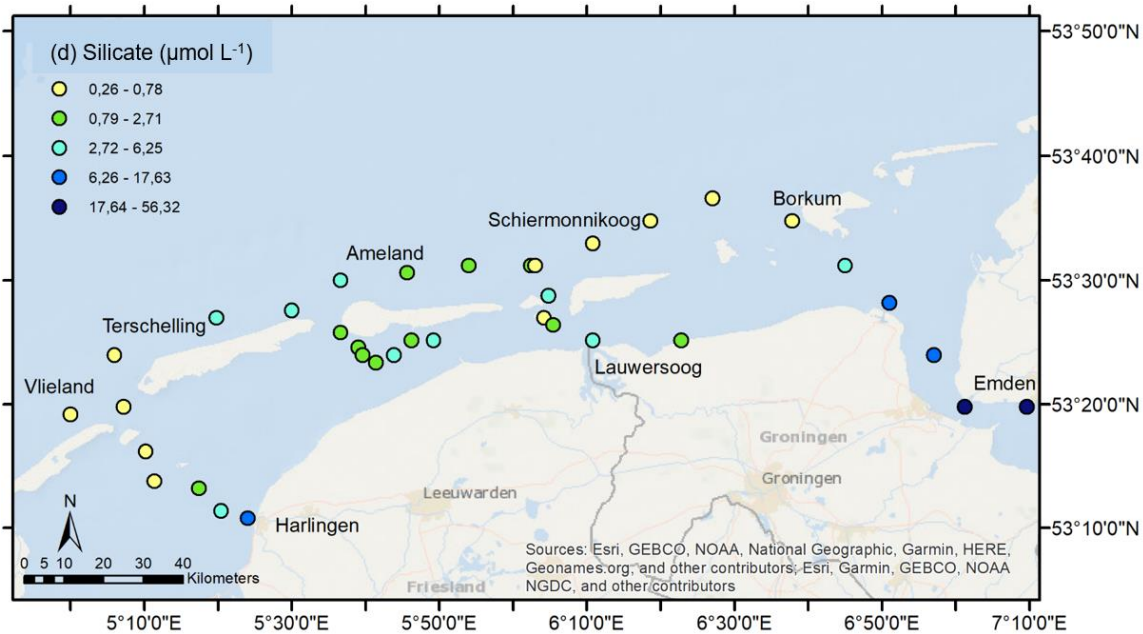

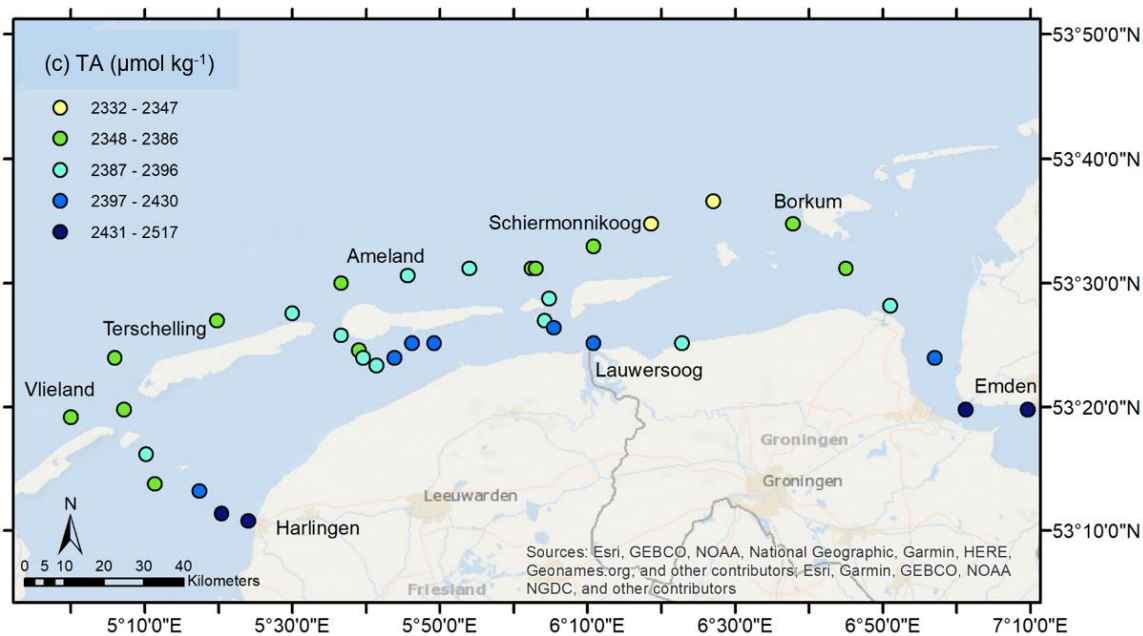

100 3.1 Spatial parameter distribution

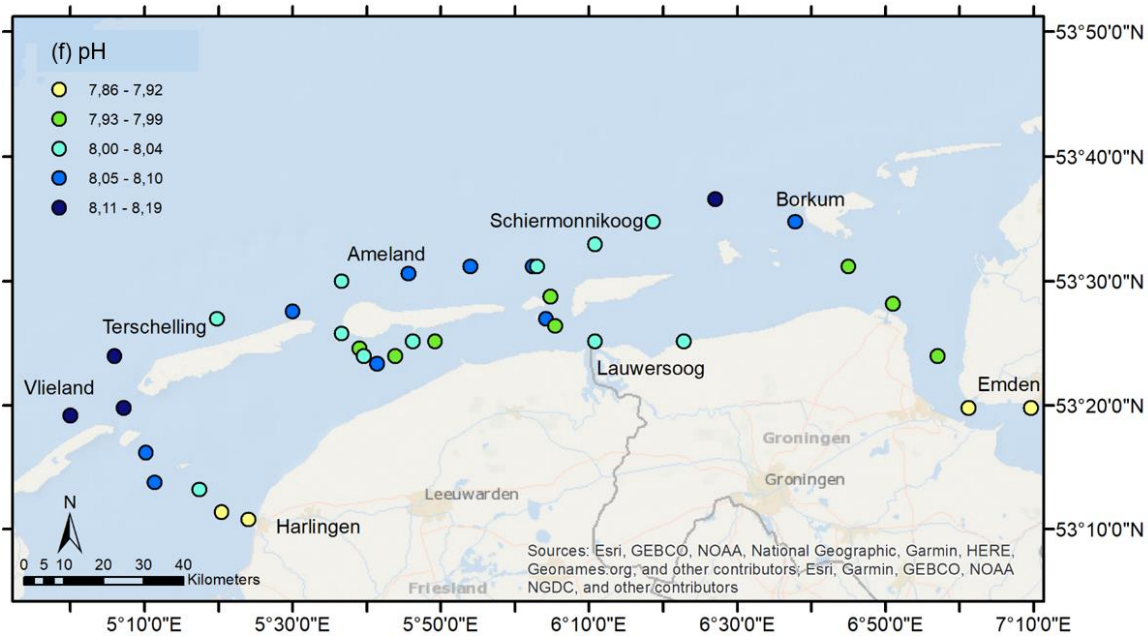

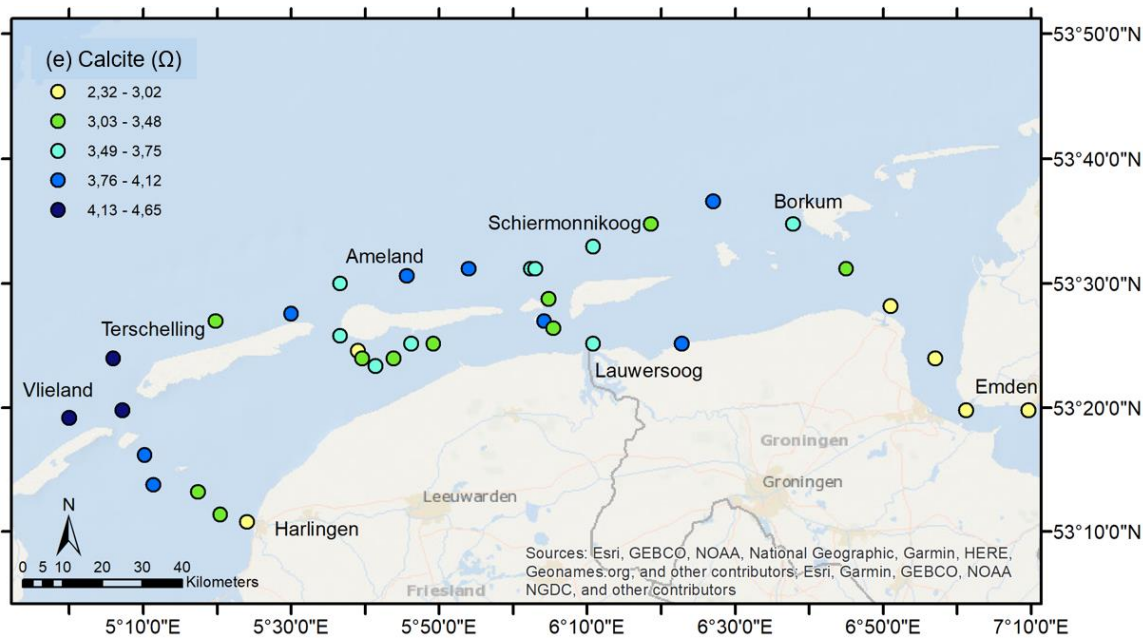

101 In order to investigate the spatial distribution of total alkalinity (TA) in the Dutch Wadden Sea and compare its general status
102 with the past, we observed the spatial distribution of TA and related parameters from the coastal mainland towards the open
103 ocean as surface water transect.
104 The temperatures varied between 12 and 16 °C with higher temperatures towards the coastal mainland (Fig. 2a). Salinity was
105 relatively stable with only minor differences varying from 28 to 33 (Fig. 2b). Lower salinities were only observed in the four
106 sampling stations in the Ems Estuary with the minimum value of 20.25 at the most upstream station.

107 Spatial transect TA concentrations ranged from 2332 $\mu\text{mol kg}^{-1}$ to 2517 $\mu\text{mol kg}^{-1}$. We observed lower concentrations on the
108 oceanic, i.e., North Sea side of the Frisian Islands with somewhat higher concentrations around Ameland (Fig. 2c). In contrast
109 to the oceanic side, the concentrations were higher with values $> 2380 \mu\text{mol TA kg}^{-1}$ in the Wadden Sea. Only in the Ems
110 Estuary, the concentrations were even higher, with values up to 2517 $\mu\text{mol TA kg}^{-1}$ at the most upstream station. We saw
111 higher TA values in the Wadden Sea than in the open ocean, supporting the assumption of TA being generated in this tidal flat
112 area. We also observed highest TA concentrations at the coastal mainland that decreased towards the North Sea.
113 In silicate (Si), we observed a similar pattern as in TA, with higher concentrations in the Wadden Sea and lower ones towards
114 the ocean (Fig. 2d). Highest concentrations were observed at the coastal mainland and in the Ems Estuary. Silicate
115 concentrations were between 0.26 and 56.32 $\mu\text{mol L}^{-1}$.
116 The calcite saturation state (Ω) was supersaturated in the entire observed study site (Fig. 2e). We observed values from 2.32
117 to 4.65. Highest values were observed at the oceanic side of the barrier islands in the North Sea. Lowest values were observed
118 near Harlingen and in the Ems Estuary.
119 Similar to the calcite saturation state (Ω), we observed higher pH values in the North Sea and lower values in the Wadden Sea
120 and near the coastal mainland (Fig. 2f). The pH values ranged from 7.86 to 8.19. Lowest values were observed near Harlingen
121 and in the Ems Estuary.
122 The nitrate (NO_3^-) concentrations were similar in a low range ($< 3 \mu\text{mol NO}_3^- \text{L}^{-1}$) in the entire transect, with higher
123 concentrations ($< 6 \mu\text{mol NO}_3^- \text{L}^{-1}$) at only a few stations close to land, and maximum concentrations ($< 38 \mu\text{mol NO}_3^- \text{L}^{-1}$) in
124 the Ems Estuary (Fig. 2g).
125 Concentrations of DIC ranged from 2097 $\mu\text{mol kg}^{-1}$ to 2430 $\mu\text{mol kg}^{-1}$ (Fig. 2h). DIC values were similar to TA values, with
126 higher concentrations near the coastal mainland and in the Ems Estuary, and decreasing concentrations toward the North Sea,
127 where we observed lowest DIC concentrations.
128

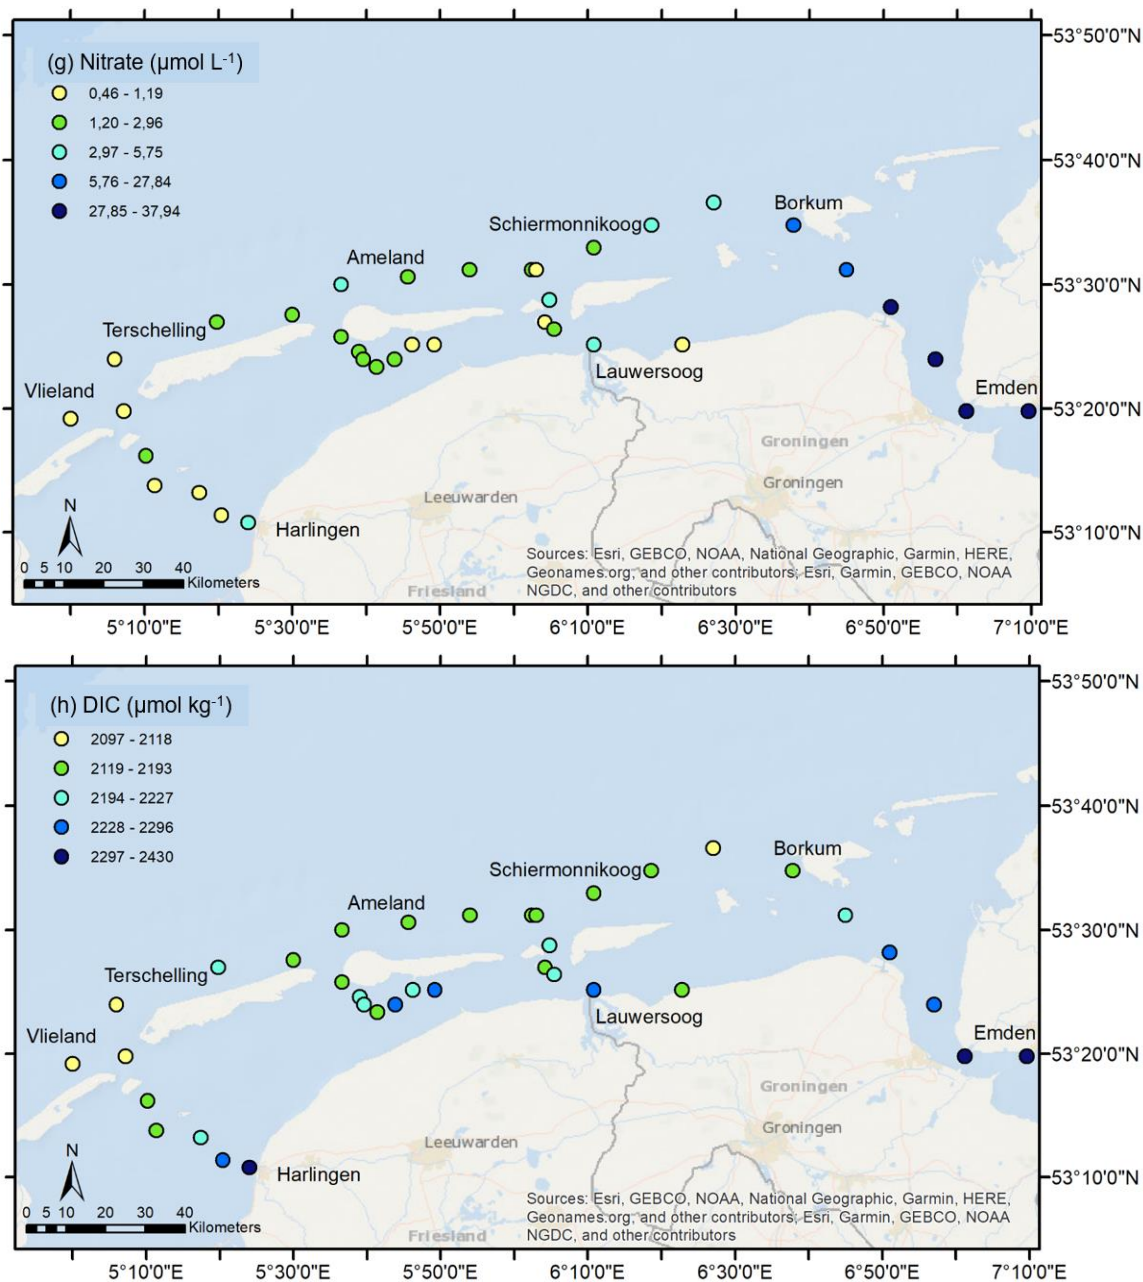

Figure 2 Spatial distribution of various parameters. Latitudinal and longitudinal distribution of a) temperature ($^{\circ}\text{C}$), b) salinity, c) total alkalinity (TA; $\mu\text{mol kg}^{-1}$), d) silicate (Si; $\mu\text{mol L}^{-1}$), e) calcite saturation state (Ω), f) pH, g) nitrate (NO_3^- ; $\mu\text{mol L}^{-1}$), and h) dissolved inorganic carbon (DIC; $\mu\text{mol kg}^{-1}$) from surface water samples in May 2019.

The strong impact from the Ems Estuary is visible in all parameters with higher values in the outer estuary and its adjacent zones, or with lower values in case of pH and the calcite saturation state. Furthermore, we observed higher values around

143 Ameland Island than in the western part on our transect starting from Harlingen towards the Vlie Inlet. In particular at the
144 oceanic side from the Vlie Inlet, the impact of the North Sea is visible through lower temperatures and higher salinities. The
145 North Sea impact is also visible in the mixing between TA and salinity (Fig. 3). We only observed a relatively linear mixing
146 behavior in the transect through the Ems-Dollard Inlet and Vlie Inlet (Fig. 3). There, we observed decreasing TA concentrations
147 with increasing salinities from the mainland towards the ocean (Fig. 3). Therefore, we identified the Dutch Wadden Sea as
148 being a source of TA. We detected higher TA concentrations than the TA concentration computed for the salinity end-member
149 in the Ems-Dollard Inlet in the oceanic, i.e., North Sea side of Ameland (Ameland NS), in the Wadden Sea side of Ameland
150 (Ameland WS), and in the Vlie Inlet, indicating towards additional TA sources. The Ameland NS and Ameland WS data
151 clearly indicated non-conservative behavior with increasing TA concentrations and constant salinities.

152
153 **Figure 3** Total alkalinity - salinity mixing. Mixing between total alkalinity (TA) and salinity in the oceanic side of Ameland
154 and the Frisian Inlet (Ameland NS), in the Wadden Sea site of Ameland (Ameland WS), around Schiermonnikoog and in the
155 Ems-Dollard Inlet, and in the Vlie Inlet.

156 3.2 Tidal cycle

157 In order to estimate TA generation in the Dutch Wadden Sea, to shed light on potential TA sources, and to estimate the potential
158 TA amount that is exported to the North Sea, we observed a tidal cycle at an anchor station in the Ameland Inlet on two days
159 with the observation of flood tide and ebb tide, respectively. Here, our focus is on ebb tide data that we used to identify pattern
160 in the various parameters in off running water (Table 1).

161 During ebb tide, TA ranged from high tide with $2387 \mu\text{mol TA kg}^{-1}$ to low tide with $2438 \mu\text{mol TA kg}^{-1}$ (Fig. 4a). We identified
162 an increase of $51.6 \mu\text{mol TA kg}^{-1}$ (ΔTA) over a duration of 6.8 h during ebb tide, resulting in a TA increase of $7.6 \mu\text{mol TA}$
163 $\text{kg}^{-1} \text{h}^{-1}$ at the sampling location.

164 DIC concentrations were similar to TA with minimum values at high tide ($2172 \mu\text{mol DIC kg}^{-1}$) and highest values (2273
165 $\mu\text{mol DIC kg}^{-1}$) at low tide. During ebb tide, we observed an increase of $101.3 \mu\text{mol DIC kg}^{-1}$ (ΔDIC) resulting in a DIC
166 increase of $14.9 \mu\text{mol DIC kg}^{-1} \text{h}^{-1}$ (Fig. 4b). DIC increased almost twice as much as TA.

167 In silicate, we detected a similar pattern with low values ($1.8 \mu\text{mol Si L}^{-1}$) at high tide and increasing concentrations during
168 ebb tide to a maximum of $11.2 \mu\text{mol L}^{-1}$. The silicate increase (ΔSi) of $9.4 \mu\text{mol Si L}^{-1}$ resulted in a silicate increase of 1.4
169 $\mu\text{mol L}^{-1} \text{h}^{-1}$ during ebb tide (Fig. 4c).

170 The salinity observations allow us to exclude conservative mixing for dilution, since the salinity was constant between 32.50
171 and 32.52 (Fig. 4d). We observed values in the range of saline waters similar to water of the North Sea.

172 The calcite saturation state (Ω) had a maximum value (3.8) at high tide and decreased to 3.1 during ebb tide (Fig. 4e). The
173 maximum at high tide indicated the influence of the North Sea that reduced with off running water.

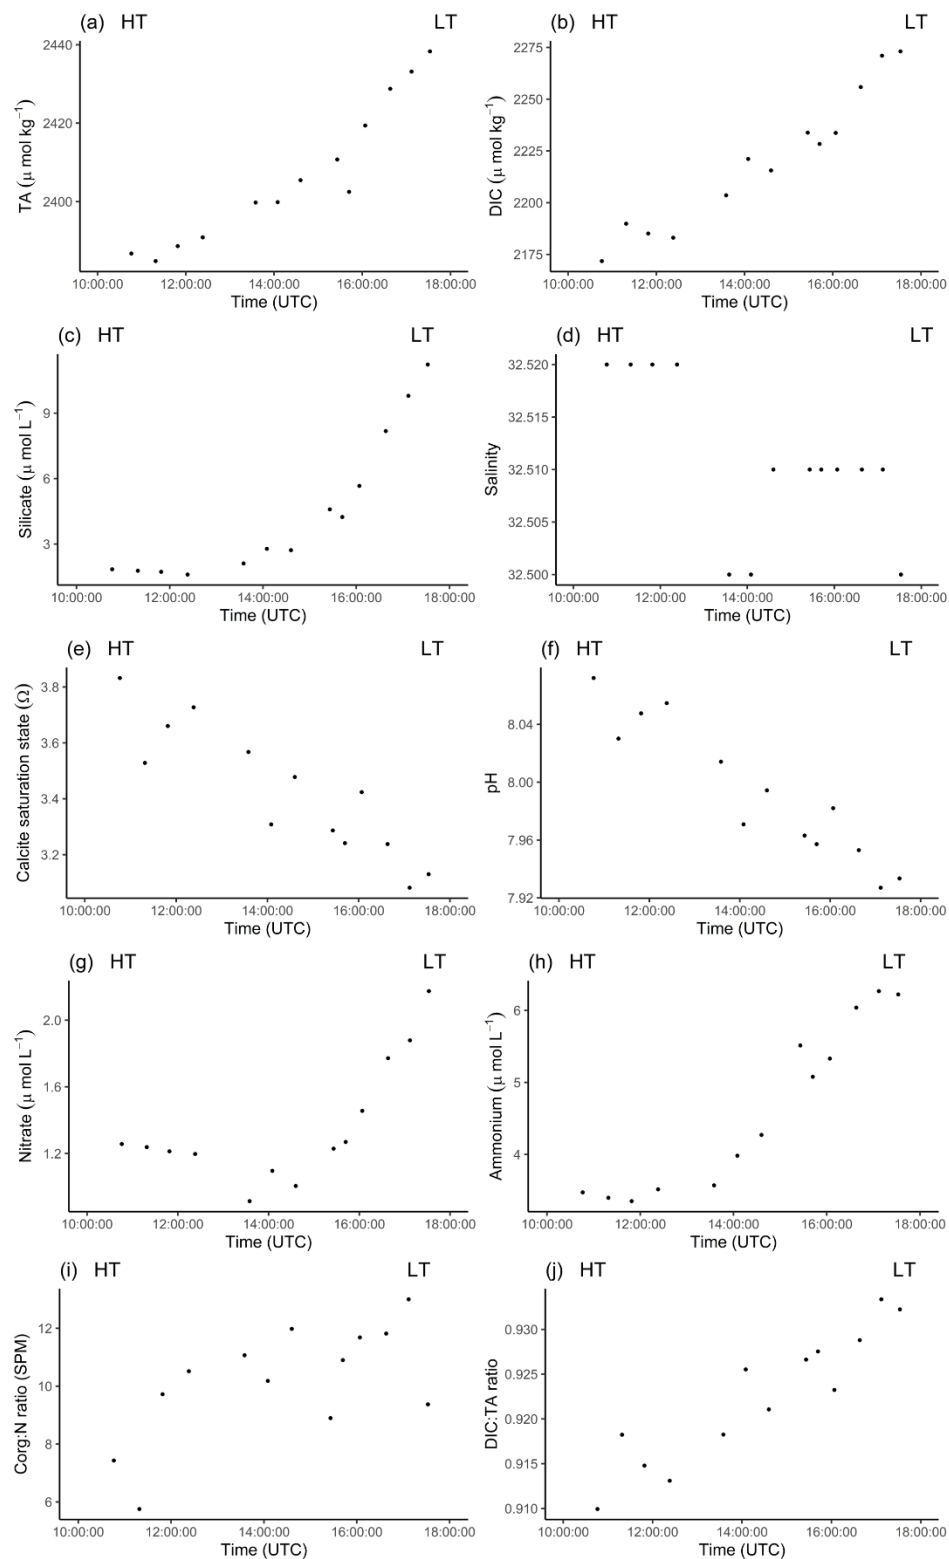

174 Similar to omega, the pH had maximum values (8.07) at high tide and decreased to a minimum of 7.93 during ebb tide (Fig.
175 4f). We observed decreasing pH with off running water.

176 Nitrate concentrations approached seawater with a minimum observed nitrate concentration of $1.26 \mu\text{mol NO}_3^- \text{L}^{-1}$ and a
177 maximum concentration of $2.17 \mu\text{mol NO}_3^- \text{L}^{-1}$ (Fig. 4g). During ebb tide, nitrate slightly increased by $0.92 \mu\text{mol NO}_3^- \text{L}^{-1}$
178 (ΔNO_3^-), resulting in a nitrate increase of $0.13 \mu\text{mol NO}_3^- \text{L}^{-1} \text{h}^{-1}$.

179 Ammonium increased from $3.47 \mu\text{mol NH}_4^+ \text{L}^{-1}$ to $6.22 \mu\text{mol NH}_4^+ \text{L}^{-1}$ during ebb tide (Fig. 4h). We observed an ammonium
180 increase (ΔNH_4^+) of $2.74 \mu\text{mol NH}_4^+ \text{L}^{-1}$ resulting in an increase of $0.4 \mu\text{mol NH}_4^+ \text{L}^{-1} \text{h}^{-1}$.

181 $\text{C}_{\text{org}}:\text{N}$ ratios of SPM increased during ebb tide (Fig. 4i). We observed a minimum $\text{C}_{\text{org}}:\text{N}$ ratio of 5.6 around high tide that
182 increased to a maximum of 13.0 during ebb tide. Simultaneously, the SPM concentration increased during ebb tide, from 12.8
183 mg L^{-1} to a maximum of 82.4mg L^{-1} at the second last station (Table 1).

184

186 **Figure 4** Tidal cycle. Temporal distribution of a) total alkalinity (TA), b) dissolved inorganic carbon (DIC), c) silicate, d)
 187 salinity, e) calcite saturation state (Ω), f) pH, g) nitrate, h) ammonium, i) $C_{org}:N$ ratio of SPM from high tide to low tide.
 188 Note the different y-axes.

189

190 **Table 1** Tidal cycle sample parameter during ebb tide. Sample no. 545 is the first sample at high tide and sample no. 557 is
 191 the last sample at ebb tide on May 21st 2019. Shown are rounded up values of the various parameters per sample.

Sample No.	Temp [°C]	Sal	TA [$\mu\text{mol kg}^{-1}$]	DIC [$\mu\text{mol kg}^{-1}$]	Si [$\mu\text{mol L}^{-1}$]	NO_3^- [$\mu\text{mol L}^{-1}$]	NO_2^- [$\mu\text{mol L}^{-1}$]	NH_4^+ [$\mu\text{mol L}^{-1}$]

192 3.3 TA generation

193 The Dutch Wadden Sea is exposed to strong tidal forcing by the North Sea leading to a bi-diurnal exchange of water. The
194 strong tidal forcing highlights the benthic-pelagic coupling and let us assume that the outflowing water exports material from
195 the sediment. In order to support our assumption, we further investigated potential TA sources.

196 For a first rough estimate of a maximum TA export during ebb tide, we used the observed TA increase (ΔTA) of $51.6 \mu\text{mol}$
197 kg^{-1} during ebb tide observed at an anchor station in the Ameland Inlet, and the tidal prism of $478 \cdot 10^6 \text{ m}^3$ the Ameland Inlet
198 (Louters and Gerritsen, 1994). With this estimate, we arrived at a rough TA export on the order of 23.9 mol TA during ebb
199 tide from the Ameland Inlet into the North Sea. With an observed tidal duration of 6.8 h , the estimated TA export of 23.9 mol
200 would result in a TA export of 3.5 mol h^{-1} .

201 For a further source location of the generated TA, we checked various correlations and relations.

202 Based on the correlation of TA and silicate, and the relation between both and salinity, we were able to determine whether TA
203 originates in the Wadden Sea or is carried by river runoff. Both, TA and silicate increased almost proportionally during ebb
204 tide, pointing to the same origin (Fig. 5b). The similar pattern of TA over salinity and silicate over salinity suggested non-
205 conservative behavior of both, and rules out any sources due to fresh water dilution and river runoff (Table 1).

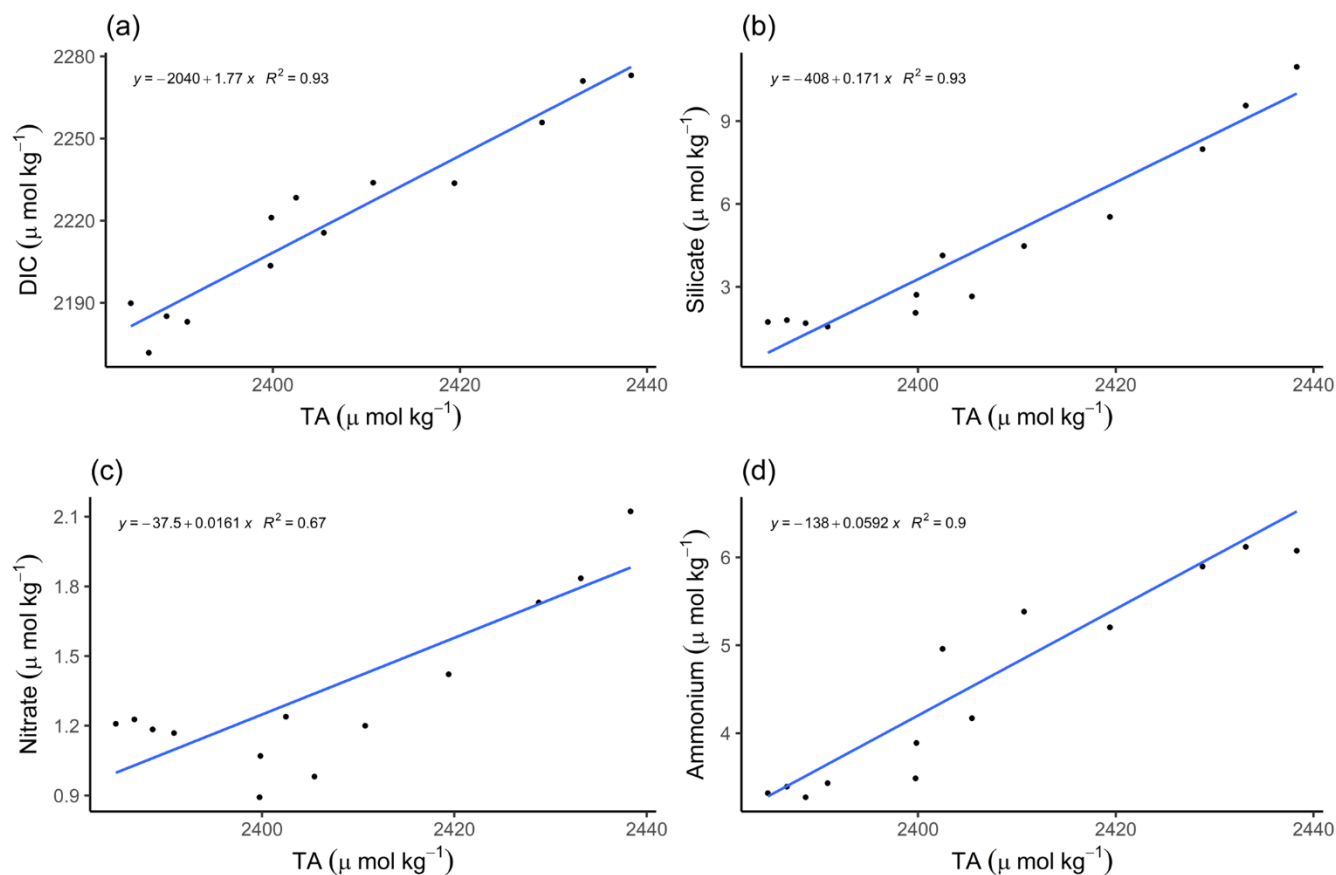

206

207 In order to further shed light on potential TA sources in the Dutch Wadden Sea, we correlated TA with various parameters
208 during ebb tide, i.e., from high tide to low tide. Thereby, the first four samples on the left plot side of the plots in Fig. 5 show
209 values probably at the tipping point of high tide and we recommend neglecting these samples in the interpretation of ebb tide
210 samples. The observation of samples collected during ebb tide allowed us to examine potential sources of TA generation.

211 First, we tested the correlation between TA and DIC that reveals the ratio between anaerobic and aerobic processes. We
212 identified a strong positive correlation between DIC and TA with TA concentrations $>$ DIC concentrations (Fig. 5a). However,
213 even when TA concentrations were higher than DIC concentrations, the slope of 1.77 indicated DIC release excess with an
214 increase in DIC ($\Delta \text{DIC} = 101.3 \mu\text{mol kg}^{-1}$) almost twice as high as TA ($\Delta \text{TA} = 51.6 \mu\text{mol kg}^{-1}$) (Fig. 5a). This may be caused
215 by strong CO_2 production due to high aerobic OM degradation, or uptake from the atmosphere by enhanced water movement.
216 The TA increase can be fueled by various processes which we will discuss at later stage.

217 We detected an almost linear positive correlation of increasing TA and silicate during ebb tide, supporting the out washing
218 process from the pore-water (Fig. 5b). We identified a stronger influence of the pore-water with ongoing ebb tide.

219 The positive correlation between nitrate and TA was lower than both previous correlations with a $R^2 = 0.67$ (Fig. 5c), which
220 could be traced back on an effect of the first four samplings as mentioned above. In the remaining samples, we observed
221 increasing nitrate and TA concentrations, suggesting a stronger effect of TA generation than nitrate production.

222

224 during ebb tide in the Ameland Inlet.

225 4 Discussion

226 4.1 Spatial TA variability

227 In the past, Hoppema (1990) reported TA distributions in the most western Wadden Sea around the barrier islands Texel,
228 Vlieland, and Terschelling. He focused on the tidal basins drained by the tidal inlets Marsdiep and Vlie located more western
229 than our sampling stations.

230 Hoppema (1990) did not observe an increase of salinity in the Wadden Sea from the fresh water source towards the ocean and
231 associated this to the influence of tidal differences. In most parts of the Wadden Sea we also did not observe an increasing
232 salinity with distance from the coast but a constant marine salinity. Increasing salinity with distance from the coast was only
233 detected in the large Ems Estuary with high discharges of fresh water, and close to Harlingen and Lauwersoog, which directly
234 have fresh water inflows by smaller rivers. Beside this, the Wadden Sea is clearly dominated by coastal North Sea water with

235 relatively high salinities. The occurrence of marine water in the entire Wadden Sea and on the tidal flats is supported by our
236 transect data that revealed relatively high salinities at coastal North Sea level in the entire Wadden Sea.

237 While the spatial TA data by Hoppema (1990), showed lower TA concentrations at stations with more fresh water influence
238 and higher TA concentrations in the tidal inlets, we observed high TA concentrations at stations with fresh water influence
239 and lower TA concentrations in the tidal inlets. This result suggests TA generation in sediments, which is fueled by high
240 imports of nutrients and OM (Van Beusekom and De Jonge, 2002). In May, Hoppema's (1990) data showed TA concentrations
241 ranging between 2319 and 2444 $\mu\text{mol kg}^{-1}$ at salinities between 18.62 and 29.17, while our lowest observed TA concentration
242 was 2332 $\mu\text{mol kg}^{-1}$ at a salinity of 32.14, and our highest TA concentration was 2517 $\mu\text{mol kg}^{-1}$ at a salinity of 20.25. In
243 addition to the spatial differences, the general level of TA was only slightly higher in our data than in the data from the early
244 1990s.

245 A conservative mixing between TA and salinity is only visible in the Ems-Dollard Inlet and the Vlie Inlet (Fig. 3). For the Vlie
246 Inlet, this can be explained by the fact that more water masses from the North Sea pass through the deeper inlets and transport
247 more seawater towards the coast. The Vlie Inlet is the one with the highest average tidal prism and the second largest inlet
248 after the Marsdiep Inlet in the Dutch Wadden Sea (Elias et al., 2012). Similar to our findings, Hoppema (1990) noted a linear
249 mixing of TA and salinity in the Vlie Inlet during his time, and suspected a lower fresh water content there as well.

250 For the Ems-Dollard Inlet, the Ems River discharges more fresh water and therefore dominates the mixing. In a previous study,
251 Norbistrath et al. (2023) observed very high TA concentrations and TA generation in the tidal river of the highly turbid Ems
252 Estuary, which may explain the high levels of TA in the estuary (at low salinities) that we observed in this study.

253
254 Compared to the past, our initial TA values in the Vlie Inlet sampled in May were somewhat higher than in Hoppema (1990),
255 where he sampled in June and August. His TA values measured in the Marsdiep Inlet in May were in a similar range to ours,
256 but the inlet is located more western with a higher impact from the North Sea and the IJsselmeer.

257 Hoppema (1990) also identified varying TA concentrations within the Dutch Wadden Sea and related these to different sinks
258 and sources. TA sinks can be calcium carbonate (CaCO_3) precipitation, or extraction of seawater carbonate by mollusks (Chen
259 and Wang, 1999;Hoppema, 1990). Variable fresh water inflows can either serve as a sink or a source (Chen and Wang,
260 1999;Hoppema, 1990). Other sources can be CaCO_3 dissolution, anaerobic metabolic processes in the sediment, or erosion of
261 TA enhancing sediments (Hoppema, 1990;Chen and Wang, 1999).

262 Since we almost observed only marine salinities (> 30), and higher TA values in the Wadden Sea than in the North Sea, which
263 is in contrast to Hoppema (1990), we exclude TA sinks and only focus on TA sources here. According to Hoppema (1990),
264 the main causes for TA variations in the Dutch Wadden Sea were fresh water inflows and sources in the sediment. In our study,
265 fresh water inflows with high TA concentrations were only observed in the Ems Estuary and Ems-Dollard Inlet. For a further
266 TA source identification in the Dutch Wadden Sea, we observed the TA variability within a tidal cycle.

267 **4.2 Determination of TA generation**

268 Since Hoppema (1990) identified variations in the Wadden Sea's TA occurrence and distribution, and Burt et al. (2016) and
269 Schwichtenberg et al. (2020) assumed TA generation in the Wadden Sea as an important source for the North Sea's carbon
270 storage capacity, we want to further shed light on the TA generation and potential sources.

271 In a study from the early 1990s, Hoppema (1993) observed a tidal cycle in the Marsdiep in May and September, while he
272 focused on TA, DIC, and oxygen. In his study, salinity values between 21 and 26, which were lower than ours (> 32), were
273 observed. Hoppema (1993) also observed increasing TA values during ebb tide and assumed the tidal flats and discharging
274 rivers and canals as sources of TA.

275 We detected no large differences between our data and the TA values during a tidal cycle observed by Hoppema (1993).
276 However, an in-depth interpretation and comparison exceed the capacity of the data.

277 Since we observed a generation of $7.6 \mu\text{mol TA kg}^{-1} \text{ h}^{-1}$ during ebb tide, we also support the assumption of the Wadden Sea
278 being a TA source for the North Sea.

279 With the tidal prism of the Ameland Inlet by Louters and Gerritsen (1994), we estimated a first rough potential maximum TA
280 export from the Wadden Sea into the North Sea on the order of 23.9 mol TA during ebb tide (3.5 mol h^{-1}) at least between
281 spring and summer. This amount is just a maximum estimate, because some water in the main tide ways and channels have no
282 direct contact to the areas of the tidal flats. Since we only have one value of one tidal observation, an inclusion into the model
283 used by Schwichtenberg et al. (2020) would be unreliable (personal communication J. Pätsch, 2022). Schwichtenberg et al.
284 (2020) assumed an export of 10 to 14 Gmol TA yr^{-1} for the entire Dutch Wadden Sea. Whether our TA generation would
285 match their suggested TA export, more observational data are required. At least, observational data of each season are
286 mandatory to run the model and gain a representative result (personal communication J. Pätsch, 2022), which we suggest as
287 future work.

288 **4.3 TA source attribution**

289 **4.3.1 Local sediment outwash**

290 In order to gain further insight into potential sources of TA, we included nutrients in our investigation. The main focus was on
291 silicate that we used as a natural tracer since it is not directly provided anthropogenically and allowed us to determine the
292 silicate source (Van Der Zee and Chou, 2005). In the silicate concentrations, we identified a silicate increase of $1.4 \mu\text{mol Si}$
293 $\text{L}^{-1} \text{ h}^{-1}$ during ebb tide. Silicate originates from dissolution of diatoms and sediment outwash in the Wadden Sea (Van
294 Bennekom et al., 1974; Van Der Zee and Chou, 2005).

295 Here, we relate the silicate increase to outwash from sediments, because it markedly increased during ebb tide. This assumption
296 can be supported by Van Bennekom et al. (1974), who suggested silicate diffusion from interstitial water in the sediment as
297 potential source, since very high silicate concentrations were found in deeper sediment layers (Rutgers van der Loeff, 1974).

298 Due to the absence of large estuaries nearby and a salinity consistently above 32, we exclude fresh water runoff as a silicate

299 source here. This can be supported by the relation between silicate and salinity in which we observed a non-conservative
300 behavior (Table 1). Since TA behave also non-conservative relative to salinity (Table 1), the occurrence of TA sources in the
301 tidal flats of the Wadden Sea other than river runoff is supported.

302 Submarine groundwater discharge (SGD) was identified as a source for nutrient fluxes in tidal flat ecosystems in previous
303 studies (e.g., Santos et al., 2021; Waska and Kim, 2011; Wu et al., 2013). Waska and Kim (2011) identified strong SGD
304 contributing up to 50 to 70 % of the nutrient fluxes that fuel primary production in a tidal embayment (Hampyeong Bay) in
305 southwest Korea. In May, they observed low salinities indicating fresh water. However, in September they observed constant
306 marine salinities referring them to be exclusively composed of recirculating seawater. Since we only observed marine salinities
307 here, we suspect that recirculating marine groundwater enriched with nutrients could also act as a source for our observed
308 parameters.

309 TA generation in tidal flats was also observed by Faber et al. (2014), who focused on a large macro tidal embayment in southern
310 Australia. They also found increasing TA values during ebb tide. Because they used ^{222}Rn (radon-222) as a conservative tracer
311 to detect pore-water exchange, they were able to associate the TA increase with a higher fraction of pore-water, which
312 contained higher TA concentrations, and determined the tidal cycle as the controlling force for pore-water exchange. With this
313 explanation and the indicated silicate outwash, our assumption that TA is generated in the sediments of the tidal flats in the
314 Dutch Wadden Sea and is washed out during ebb tide is supported. The increase in TA and silicate is clearly a tidal signal. In
315 addition, since the observed marine TA concentrations in the Vlie Inlet, except of the two samples near Harlingen, were in the
316 same range as the other observed TA concentrations and were below the increasing TA concentrations during ebb tide, we
317 exclude lateral advected signals. We clearly identify TA generation here as local sources in the sediments of the tidal flats.

318 4.3.2 TA generating processes

319 The observed TA generation of $7.6 \mu\text{mol TA kg}^{-1} \text{h}^{-1}$ and the silicate increase of $1.4 \mu\text{mol Si L}^{-1} \text{h}^{-1}$ indicated an excess of TA
320 under consideration of a TA:silicate ratio of 2:1 (Marx et al. 2017), and under the condition of silicate being bound in minerals,
321 which would then account for a TA generation of $2.8 \mu\text{mol TA kg}^{-1} \text{h}^{-1}$. However, when silicate occurred dissolved in water it
322 does not contribute to TA generation (Meister et al., 2022). A TA excess related to silicate was also observed in the correlation
323 between TA and silicate (Fig. 5b). Since we observed more TA generated than silicate being washed out, other biogeochemical
324 processes must be responsible for the TA generation in the sediments of the tidal flats in the Dutch Wadden Sea.

325 With the observed omega values, we exclude CaCO_3 dissolution as TA source in the overlying water, since the omega values
326 were clearly supersaturated with $\Omega > 1$ (Fig. 4e). The continuous calcite supersaturation nicely indicated the inflow and
327 dominance of North Sea water during the flood, with omega values similar to previously observed North Sea values ($\Omega \sim 3.5$
328 to 4) (Charalampopoulou et al., 2011; Carter et al., 2014). However, because of the Ω supersaturation of the overlying water
329 and a lack of pore-water data, we were unable to determine if TA generation by CaCO_3 dissolution occurs in deeper sediment
330 layers. There, CaCO_3 dissolution can only be driven metabolically, when CO_2 is produced during OM remineralization or

331 reduced compounds that were previously produced during anaerobic processes are oxidized and lead to undersaturation with
332 respect to carbonates (Brenner et al., 2016; Jahnke et al., 1994).

333 By a more detailed interpretation of Δ DIC, Δ TA, and various nutrient ratios, we tried to further narrow down the potential
334 sources of TA generation in the sediments and used an upper bound estimate for CaCO_3 dissolution.

335 The correlation of DIC and TA reveals an excess of released DIC compared to TA (Fig. 5a), as indicated by the slope of 1.77,
336 while we observed an increase in DIC (Δ DIC) almost twice as high as in TA (Δ TA). The high Δ DIC points to high aerobic
337 OM degradation and remineralization, resulting in high CO_2 export. High aerobic OM degradation was also previously
338 observed in the Wadden Sea (e.g., De Beer et al., 2005), assuming an OM degradation and remineralization occurring in the
339 water and sediment in about equal parts (Van Beusekom et al., 1999). High OM degradation is also indicated by the increasing
340 $\text{C}_{\text{org}}:\text{N}$ ratios of SPM during ebb tide (Table 1). Because we observed constant coastal North Sea salinities, we rule out fresh
341 water runoff and terrestrial signals as source for the increasing $\text{C}_{\text{org}}:\text{N}$ ratios of SPM. We assume that fresh OM is rapidly
342 degraded, and the older OM settle on and in the sediment where the degradation continuous and where it is resuspended by
343 the water exchange with outflowing water. Therefore, we assume that the increase of SPM concentrations and their $\text{C}_{\text{org}}:\text{N}$
344 ratios is an indicator for older and more refractory OM.

345 The increase in TA concentrations point to anaerobic processes, CaCO_3 dissolution, or a combination thereof as TA source
346 occurring in the sediments.

347 For the upper bound estimate, we assumed CaCO_3 dissolution in the sediments with the DIC:TA ratio of 1:2 as source of TA.
348 Considering this ratio and the observed Δ TA of $51.6 \mu\text{mol TA kg}^{-1}$, a potential Δ DIC of $25.8 \mu\text{mol DIC kg}^{-1}$ of the observed
349 Δ TA would be produced by CaCO_3 dissolution. The remaining potential $75.5 \mu\text{mol DIC kg}^{-1}$ ($101.3 - 25.8 \mu\text{mol DIC kg}^{-1}$) of
350 the observed (Δ DIC) could then be produced by OM degradation and remineralization, and would, using the expected Redfield
351 ratio of C:N (6.6), correspond to an estimated potential dissolved inorganic nitrogen (DIN) production of $11.4 \mu\text{mol kg}^{-1}$. This
352 estimated potential DIN production ($11.4 \mu\text{mol kg}^{-1}$) of OM degradation and remineralization exceeded the observed increase
353 of Δ DIN ($3.97 \mu\text{mol L}^{-1}$; Table 1, sum of NO_3^- , NO_2^- and NH_4^+) during ebb tide. With this estimation and the assumption that
354 all DIN produced is released and thus lost, TA is probably produced by CaCO_3 dissolution and anaerobic metabolic processes
355 other than denitrification in the sediment. In addition to that, and with a N-focused perspective, the DIN loss also hints to the
356 occurrence of other processes that consume nitrogen species but have no net effect on TA, such as anammox and coupled
357 nitrification-denitrification (Hu and Cai, 2011; Middelburg et al., 2020). The suggested DIN loss can be supported by
358 considering the marine DIN:Si ratio, which is supposed to be 1:1 (Brzezinski, 1985). We observed DIN:Si ratios decreasing
359 from 2.7 to 0.8 from high tide to low tide. The decreasing ratios show that both parameter concentrations increased during ebb
360 tide, whereby DIN concentrations increased lower than silicate concentrations. We observed a silicate excess with respect to
361 DIN at the end of ebb tide, supporting the DIN loss.

362 Denitrification, the anaerobic irreversible reduction of NO_3^- to N_2 that generates 0.9 mole TA by using 1 mole NO_3^- as electron
363 acceptor (Chen and Wang, 1999) is a net TA source. Denitrification depends on the supply of nitrate, which seasonally varies
364 (Van Der Zee and Chou, 2005 and references therein). Generally, nitrate is depleted in summer due to high turnover rates and

365 occurs in higher concentrations in winter (Kieskamp et al., 1991;Jensen et al., 1996;Van Der Zee and Chou, 2005). This
366 seasonality lead to denitrification rates also being lower in summer and higher in winter (Kieskamp et al., 1991;Jensen et al.,
367 1996). In previous studies, Faber et al. (2014) identified denitrification as a minor source for TA due to low denitrification
368 rates, and also Kieskamp et al. (1991) observed low denitrification rates in the Wadden Sea, with low nitrate concentrations
369 ($< 2.5 \mu\text{mol L}^{-1}$) in the overlying water. Because we observed nitrate concentrations ($< 2.17 \mu\text{mol L}^{-1}$) lower than the
370 concentration sufficient for denitrification assumed by Kieskamp et al. (1991), we do not exclude denitrification, but suspect
371 it as a minor source for TA in the Dutch Wadden Sea at least in spring and summer due to the seasonal lack of nitrate. Thomas
372 et al. (2009) detected TA seasonality in the southern bight of the North Sea, which is also influenced by the TA generation in
373 the Wadden Sea. We support their findings of lowered TA generation by denitrification in late spring and early summer. In
374 addition, the calculated potential DIN excess compared to the observed DIN not only hints to other N consuming processes
375 that have no effect on TA, but also suggests that allochthonous nitrate would be needed to fuel the TA increase by
376 denitrification. In addition, the albeit low availability of nitrate indicates to predominantly aerobic metabolic activity during
377 the time of our observations, which is in line with earlier studies reporting an enhanced relevance of anaerobic activity later in
378 summer (Luff and Moll, 2004;Thomas et al., 2009).

379 Another source of TA in sediments is aerobic OM respiration with the associated formation of ammonium while consuming
380 H^+ (Blackburn and Henriksen, 1983;Berner et al., 1970;Brenner et al., 2016). The observed increasing ammonium (Fig. 4g)
381 could be associated with aerobic OM degradation resulting in ammonium formation, i.e., ammonium increase in the upper
382 oxygenated sediment layers, which would increase DIC by the production of CO_2 , and increase TA by the consumption of H^+
383 (Fig.5) (Brenner et al., 2016). In sediments, then the production of one mole ammonium (from ammonia) would generate one
384 mole TA (Berner et al., 1970;Meister et al., 2022). In contrast, in the water column, the aerobic respiration of OM produce
385 CO_2 and increase DIC, also visible in decreasing pH values (Fig. 4f), but consume TA and would not produce ammonium
386 (Chen and Wang, 1999). Therefore, aerobic OM respiration in the water column could only explain the higher increase in DIC
387 than in TA, but not the simultaneous increase in TA and ammonium (Fig. 5). Based on this, we assume that OM respiration
388 associated with TA generation occurs in the sediment, leading to TA and DIC generation and also to ammonium production,
389 which are then washed out during ebb tide. The produced ammonium is then also accessible for nitrification that produces
390 nitrate. A slightly increased nitrate concentration in the most upper sediment layers was observed by Beck et al. (2008a) in the
391 German Wadden Sea. This observation, a potential nitrate reservoir, nitrate production due to OM degradation and nitrification
392 occurring in the upper oxygenated sediment layers (Martin and Sayles, 1996), or a mix thereof could explain the low increasing
393 nitrate concentrations during ebb tide. However, as we rule out terrestrial nitrate imports as nitrate source here, the
394 simultaneous increase of TA and nitrate is noticeable for us, because nitrification consumes TA (Brenner et al., 2016). Here,
395 we assume that potential nitrification has a minor effect on TA, because we observed only low nitrate concentrations and a
396 really low increase of nitrate compared to the increase of ammonium and TA during ebb tide. The low nitrate concentrations
397 resulting in reduced availability of bound oxygen, i.e., electron acceptors, promote the occurrence of other anaerobic processes

398 of the redox system, such as sulfate and iron reduction, to generate TA in the deeper, anoxic sediment layers in the Dutch
399 Wadden Sea.

400 Sulfate reduction followed by iron reduction and the formation and burial of pyrite are net sources of TA, since TA
401 consumption by reoxidation is excluded when buried in sediments (Berner et al., 1970;Faber et al., 2014). Whether these
402 processes contribute to TA generation in the deeper sediments of the Dutch Wadden Sea cannot be further identified without
403 the necessary data. However, sulfate reduction was also mentioned as source of TA by Thomas et al. (2009). The temporary
404 slight appearance of noticeable sulfuric odor could be another indirect indicator for the occurrence of sulfate reduction. In
405 previous studies of tidal flats in the German Wadden Sea, Beck et al. (2008a);(2008b) observed increasing TA concentrations
406 with depth and identified sulfate reduction as the most important process for anaerobic OM remineralization in pore-water
407 cores. Sulfate reduction releases 1.14 mole TA with the oxidation of one mole carbon of POC , and iron reduction releases
408 8.14 mole TA with the oxidation of one mole carbon of POC, indicating that both processes are large sources of TA generation
409 (Brenner et al., 2016), but cannot be further interpreted without the necessary data.

410 A strict comparison of the northern and the western parts of the Wadden Sea cannot be fully recommended because the areas
411 vary in terms of OM import and eutrophication effects (Van Beusekom et al., 2019), sediment composition, and extent between
412 the barrier islands and the mainland, all of which influence the occurrence and interaction of biogeochemical processes
413 (Schwichtenberg et al., 2020). Although, the area characteristics of northern and western Wadden Sea differ, a previous study
414 by Brasse et al. (1999) identified high TA and DIC concentrations in the sediment of the North Frisian Wadden Sea and
415 identified CaCO₃ dissolution and sulfate reduction as major TA sources, which appear consistent with our findings.

416 **5 Conclusion**

417 The Dutch Wadden Sea is a unique and highly dynamic ecosystem. While observing the spatial TA distribution and TA
418 generation in the Dutch Wadden Sea, we detected higher TA values than in the North Sea, and identified the Dutch Wadden
419 Sea clearly as a TA source of the North Sea's carbonate system. Compared to the TA values of the previous studies by
420 Hoppema (1990);(1993), the TA values we observed were in a similar range, but while he observed lower TA values near the
421 coast, we found higher ones there. However, more data from various seasons would be needed for a better comparison between
422 then and now, and for a more precise status of TA.

423 By observing salinity and using silicate as a tracer, we excluded fresh water dilution and river runoff as TA sources and instead
424 identified outwash from tidal flat sediments as sources of TA. Aerobic, metabolic processes such as CaCO₃ dissolution and
425 ammonium formation seem to dominate TA generation in the upper oxic sediment layers and the overlying water, while
426 anaerobic, metabolic processes such as denitrification, sulfate and iron reduction are potential TA sources in the deeper anoxic
427 sediment layers. However, in spring and early summer, denitrification seems to play a minor role in generating TA in the
428 sediments of the Dutch Wadden Sea due to seasonality and associated limited nitrate availability.

429 **Data availability**

430 The data of this study are either presented in the article or are available upon request from the corresponding author.

431 **Author Contributions**

432 MN wrote the manuscript, did the carbon sampling and sample measurement, analyzed and evaluated the data, and led the
433 study. JvB led the research cruise. JvB and HT contributed with editorial and scientific recommendations. MN prepared the
434 manuscript with contribution from all co-authors.

435 **Competing interests**

436 The contact author has declared that none of the authors has any competing interests.

437 **Acknowledgement**

438 We thank the crew from RV *Ludwig Prandtl* for their support during the cruise. We thank Leon Schmidt for the nutrient
439 sampling and measurements.

440 **Financial support**

441 This research has been funded by the German Academic Exchange Service (DAAD, project: MOPGA-GRI, grant no.
442 57429828), which received funds from the German Federal Ministry of Education and Research (BMBF).
