Abstract. Hail remains a major threat to agriculture in Switzerland and beyond, and assessments of current and future hail risk are of paramount importance for decision-making in the insurance industry and the agricultural sector. However, relating observational information on hail with crop-specific damages is challenging. Here, we build and systematically assess an open-source model to predict hail damage footprints for field crops (wheat, maize, barley, rapeseed) and grapevine from the operational radar product Maximum Expected Severe Hail Size (MESHS, used as proxy for hail intensity) at different spatial resolutions. To this end, we combine the radar information with detailed geospatial information on agricultural land use and geo-referenced damage data from a crop insurer for 12 recent hail events in Switzerland. We find that for field crops, model skill gradually increases when the spatial resolution is reduced from 1 km-km down to 8 km. For even lower resolutions, the skill is diminished again. On the contrary, for grapevine, a lower model resolution tends to reduce skill, which is attributed to the different spatial distribution of field crops and grapevine in the landscape. It is shown that identifying a suitable MESHS thresholds to model damage footprints always involves trade-offs. For the lowest possible MESHS threshold (20 mm) the model predicts damage about two-times-too-often-twice as often as observed (high frequency bias and number of false alarms/false alarm ratio) but also has a high probability of detection (80%). The frequency bias decreases for larger thresholds and reaches an optimal value close to 1 for MESHS thresholds of 30-40 mm. However, this comes at the cost of a substantially lower probability of detection (around 50%) while overall model skill, as measured by the Heidke Skill Score (HSS), remains largely unchanged (0.41-0.44). We argue that, ultimately, the best threshold selection therefore depends on the user-need-and-the-relative costs of a false alarm or-versus a missed event. Finally, the frequency of false alarms can-be substantially-reduced-is substantially reduced and skill is improved (HSS=0.54) when only areas with high cropland density are considered. Results from this simple, open-source model show that modelling of hail damage footprints to crops from single-polarization radar in Switzerland is skillful-skillful and is best done at 8 km-km resolution for field crops and 1 km-km for grapevine. They further allow different users of such models to identify the suitable threshold for their application, taking into account associated trade-offs.

1 Introduction

Hail storms frequently cause severe damage to agriculture and infrastructure in various places across the globe (~~Allen et al., 2020; SwissRe,~~

25 ~~(Bell et al., 2020; Allen et al., 2020; Gobbo et al., 2021; Rana et al., 2022)~~. In fact, severe convective storms (which include hailstorms) are among the costliest perils worldwide (SwissRe, 2021). ~~Larger-scale catastrophes like tropical cyclones or earthquakes cause substantially more damage per event, but severe convective (hail-)storms occur comparatively more often.~~ Switzerland is a particularly ~~hail-prone country with an~~ hail-prone country with a nationwide average of 32 hail days during the convective season (April to September) and locally up to three ~~and or~~ more hail days in hot spot regions (Schroeer et al., 2022).
30 The number of hail days varies strongly from year to year. Summer 2021 was an example ~~for of~~ a record hail season ~~causing extreme damages-,~~ causing extreme damage in a series of intense and widespread thunderstorms (Kopp et al., 2022). The main crop insurer in Switzerland, Schweizer Hagel (SH), reported around 14⁺,000 damage claims and insured losses of around CHF 110 Million (approx. USD 117 million, Schweizer Hagel, 2021) for this year. Hail remains ~~currently~~ the costliest natural hazard for insured agricultural production in Switzerland and the events of summer 2021 demonstrated the need for reliable
35 assessments of hail risk for key stakeholders ~~such as, among others,~~ including insurers, governments, and farmers.

~~Here, we present a model to predict hail damage footprints to field crops and grapevine in Switzerland based on operational radar data and detailed information on agricultural land use. The model is verified with geo-referenced damage claims from SH. To make it accessible to stakeholders, the model is implemented in the open-source natural catastrophe modelling platform CLIMADA (Aznar-Siguan and Bresech, 2019).~~ Compared to other weather-related hazards, reliable data on hail remains scarce

40 due to the small scale of thunderstorms and accompanying hail streaks as well as the high costs to maintain observational networks at a large scale. Therefore, radar data is frequently used to obtain an estimate of hail on the ground because it is continuous in space and time (Kunz and Kugel, 2015; Puskeiler et al., 2016). Recently, the Swiss Federal Office of Meteorology and Climatology (MeteoSwiss) has compiled a comprehensive assessment of hail frequency and hail stone sizes for Switzerland based on 20 years of single-polarization radar data at ~~a~~ 1 km-km spatial resolution providing an important basis for
45 hail risk assessments (Schroeer et al., 2022; Trefalt et al., 2022). The climatology is based on two hail products that are computed operationally: The Maximum Expected Severe Hail Size (MESHS), which is different from the widely used maximum expected size of hail (MESH, Witt et al., 1998) and the Probability of Hail (POH; Betschart and Hering, 2012). Both are based on a height difference between the melting level and the height of a ~~certain-given~~ reflectivity level, a criterion introduced by Waldvogel et al. (1979). MESHS and POH are physically meaningful as they relate to the vertical extent of the thunderstorm updraft above the melting level, representing the hail growth zone. A larger vertical extent is associated with a higher likelihood of hail as well as an increase in the potential size of hailstones.

Single-polarization radar products such as MESHS and POH provide valuable estimates of the occurrence of hail on the ground as verified with, e.g., insurance claims (Holleman et al., 2000; Kunz and Kugel, 2015; Puskeiler et al., 2016; Nisi et al., 2016), reports of observers and media (Cică et al., 2015) and ~~crowd-sourced~~ crowdsourced hail reports (Barras et al., 2019). ~~More~~
55 ~~specifically, verification~~ Verification based on insurance claims generally ~~showed a high probability~~ shows high probabilities of detection [POD, fraction of damage events that is predicted, often around 0.8 or larger] but also relatively high false alarm ratios

[FAR, fraction of predictions without damage, up to 0.8] (~~Kunz and Kugel, 2015; Puskeiler et al., 2016; Nisi et al., 2016; Warren et al., 2020~~) (Kunz and Kugel, 2015; Puskeiler et al., 2016; Nisi et al., 2016; Warren et al., 2020; Schmid et al., 2024). However, these metrics usually strongly depend on the hail intensity threshold used to identify damaging hail, the objective selection of which is not always possible. For example, one can choose the threshold with the highest skill score (e.g. Puskeiler et al., 2016) or one can require that frequency of damage prediction equals the frequency of damage occurrence (i.e. a frequency bias of 1, Warren et al., 2020). Further, these verification studies usually rely on pragmatic choices ~~of regarding~~ the scale of spatial aggregation or the distance between damage claim and radar signal tolerated. ~~Often, a One~~ reason for this ~~was is~~ that insurance claims ~~were are often~~ only available at the ~~community-municipality~~ level, which ~~does not allow assessing the skill at the km-scale. But a~~ is typically much coarser than the resolution of the radar observations (~ 1 km). A strong dependence of the skill on the spatial scale can be expected, as lowering the spatial resolution (or increasing the tolerated distance ~~) yields a higher chance between damage claim and radar signal~~ increases the likelihood of overlap between radar ~~signal and damages~~ (Holleman et al., 2000; Schmid et al., 2023). ~~signals and damages~~ (Holleman et al., 2000; Schmid et al., 2024). The physical reasons for this are the horizontal drift of hail by wind (e.g. Schiesser, 1990) and limitations in the spatial accuracy of radar-based hail observations, which rely on storm-related proxies to infer hail sizes on the ground (Betschart and Hering, 2012). Also, information on the presence and density of ~~cropland-exposed assets~~ (e.g., buildings, cars, cropland) is essential for reliable skill metrics but has often not been incorporated in previous verification studies.

~~First Early~~ efforts to relate crop damage ~~of individual fields~~ to radar information (Omoto and Seino, 1978; Seino, 1980; Schiesser, 1990) or to hail pad measurements (Changnon, 1971; Morgan, 1976; Katz and Garcia, 1981) derived crop-specific damage functions based on data pairs of damaged fields and observed measures of hail intensity. Schiesser (1990) presented damage functions that link harvest loss at the field scale for individual crop types at various phenological stages to hail kinetic energy derived from single-polarization radar. ~~Directly applying such functions to radar measurements without without additional verification and taking into account cropland density will remain difficult to interpret.~~ Sánchez et al. (1996) developed a statistical model to estimate harvest loss for barley and wheat based on hail sizes observed by ~~hailpads~~ hail pads and meteorological observers in northwestern Spain. More recent efforts used satellite imagery to estimate crop damage after a hail event (Bentley et al., 2002; Singh et al., 2017; Prabhakar et al., 2019; Bell et al., 2020; Sosa et al., 2021)

Despite ~~these~~ past efforts to quantify hail damages to specific crops, ~~openly available models of this kind do currently, there is~~ (to our knowledge, ~~not exist anywhere~~) a lack of openly available models for assessing crop hail damages. Existing models have been developed in the insurance industry and are proprietary (AIR Worldwide, 2023). ~~Hence, to build openly available (operational) radar-based hail damage models for individual crops, more systematic and~~ Here, we present an open-source approaches-are-needed model to predict hail damage footprints to field crops and grapevine in Switzerland based on operational radar data and detailed information on agricultural land use. The model is verified with geo-referenced damage claims from SH. To make it accessible to stakeholders, the model is implemented in the open-source natural catastrophe modelling platform CLIMADA (CLIMate ADaptation) (Aznar-Siguan and Bresch, 2019)).

To extend the CLIMADA platform with a hail damage footprint detection module, in this study hail intensity measures from operational, single-polarization radar (MESHS and POH) are ~~coupled to~~ combined with detailed, crop-specific, geo-referenced

cropland information to build simple yes/no damage models for field crops (wheat, corn, barley, rapeseed) and grapevine at different spatial resolutions. The models are systematically verified based on detailed, crop-specific damage information from SH of twelve recent hail events in Switzerland.

95 More specifically, the following questions are addressed:

1. ~~Which~~-What spatial resolution is most suitable to model hail damage footprints for field crops and grapevine based on operational, single-polarization radar data in Switzerland?
2. Is it possible to objectively define the best ~~hail-intensity~~-MESHS and POH threshold(s) to model hail damage footprints?
3. How sensitive is the model performance to ~~cropland-density~~the minimum number of crop fields within a grid cell (cropland density)?

100

While most of the study focuses on MESHS, the same methodology is also applied to POH and results are compared.

The remainder of this paper is structured as follows. First, the three main datasets are introduced, and the model setup and verification method described (Sect. 2). Then, it is discussed how the model skill depends on spatial resolution (Sect. 3.1) and MESHS threshold (Sect. 3.2). Subsequently, the combined effect of threshold and resolution is ~~analyzed~~-analysed (Sect. 3.3).

105 The sensitivity of this combined effect ~~on-to~~ cropland density and the ~~selection-use~~ of POH as a hazard variable is then assessed in Sect. 3.4. Finally, the key results are discussed, including how the use of alternative verification approaches ~~would~~-might affect them (Sect. 3.5). The paper ends with a summary of the key conclusions in Sect. 4.

2 Data and Methods

2.1 Hail hazard data

110 In this study, single-polarization radar data products on a 1x1 ~~km~~-km regular grid are used to ~~characterize hail hazard~~quantify hail intensity. The Swiss radar network consists of 5 dual-polarization Doppler C-band radars ~~and is (black dots in Fig. 1) and has been~~ in place in this form since 2016 (Germann et al., 2016). The two products used here, the Maximum ~~expected severe hail size~~ Expected Severe Hail Size (MESHS), and the Probability of Hail (POH)~~are single-polarization radar products provided-, are computed operationally~~ by MeteoSwiss (Betschart and Hering, 2012; Trefalt et al., 2022; Germann et al., 115 2022)~~and are computed operationally. MESHS depends on-~~ The underlying reflectivity data are mapped to a regular 1x1 km grid using a pre-calculated projection table relating polar to Cartesian coordinates. Reflectivity is calibrated with multiple independent sources of information, including various types of weather echoes, ground clutter, signals from the sun, and others (Germann et al., 2015). Radar signal attenuation can lead to a bias in individual hail cells, but we expect this bias to be small compared to the known inherent uncertainty of hail detection from radar data, which is due to the indirect estimation of hail size. Note that direct hail size estimation is limited by resonance scattering effects in large hail stones (e.g. Kaltenboeck and Ryzhkov, 2013). MESHS describes the empirical relationship between the size of the largest hailstone and the difference between the top of the 50 dBZ echo and the freezing level height. It is computed from the so-called ~~"Treloar~~

120

~~nomogram~~—‘Treloar nomogram’ of Joe et al. (2004), which is based on Treloar (1998). MESHS ranges from a minimum value of 20 ~~mm~~mm and theoretically has no upper limit. Note that MESHS is designed to indicate the size of the largest hailstone within 1 ~~km~~km² and does not represent a spatial average. Although ~~MESHS~~it is not explicitly connected to actual hail size, positive relationships between ~~crowd-sourced hail sizes and MESHS~~MESHS and crowdsourced hail sizes have been reported by Barras et al. (2019). Here, daily (06 UTC ~~—~~06 UTC) maximum MESHS values are used to define a hail day (or hail event). We use 06 UTC (~~08am~~8 am local time) to define a hail day because it represents the minimum of the average daily hail activity (Schroeder et al., 2022). This minimizes the risk of splitting a ~~hail storm~~single hail event into two consecutive hail days.

POH is based on an empirical relationship between the likelihood of hail at the ground and, similar to MESHS, the height difference between the top of the 45 dBZ echo and the environmental freezing level. It was originally introduced by Waldvogel et al. (1979) and further developed by Witt et al. (1998) and Foote et al. (2005). The form of the relationship by Foote et al. (2005) ~~has been directly implemented by MeteoSwiss and is operational~~is used operationally by MeteoSwiss since 2008 (Trefalt et al., 2022). As for MESHS, daily (06 UTC ~~—~~06 UTC) maximum values are used.

To investigate how the model skill changes with reduced spatial resolution, the radar data (MESHS and POH) ~~is aggregated to~~are aggregated at 2, 4, 8, 16, and 32 ~~km regular grids~~km spatial resolution using the maximum ~~intensity~~value within each grid cell. The maximum is preferred over the mean because it largely conserves the value range of ~~the intensity variable~~MESHS and POH. Further, this approach is consistent with the assumption that the maximum intensity value determines the occurrence of damage.

2.2 Agricultural exposure data

Detailed geospatial information on agricultural ~~land use~~production was obtained from ~~Swiss cantonal data on agricultural land use (geodienste.ch) that was then merged to a Swiss-wide dataset~~official Swiss land use data (geodienste.ch). The data ~~used here are valid for~~are available only starting from 2021~~and not available for earlier years but will be updated annually after 2021.~~, which we use here as a reference. The original data contain polygons of each agricultural field and information on its type of use and cultivated crop. For this study, the data are aggregated to the number of fields and the total crop area within a 1x1 ~~km~~km grid for winter wheat, maize (incl. silage and forage maize), winter barley, rapeseed, and grapevine, based on the ~~centre~~center point of each field. Further, an aggregate category called field crops is defined that incorporates winter wheat, maize, winter barley and rapeseed. To model ~~yes/no~~hail damage footprints at the grid scale, ~~the exposure is turned~~these exposure data are converted into a binary field depending on the number of fields n within a grid cell

$$exposure = \begin{cases} 0 & n < n_{\text{thresh}} \\ 1 & n \geq n_{\text{thresh}} \end{cases} \quad (1)$$

If not specified otherwise, ~~n_{thresh}~~ n_{thresh} is set to 1. This means that a grid cell is ~~considered~~included as exposure if it contains at least one field of the considered crop type ~~—(shown for field crops and grapevine in Fig. 1).~~ Because it is expected that the probability of damage increases with ~~n_{thresh}~~ n_{thresh} , the sensitivity of the model skill to different choices of ~~n_{thresh}~~

155 n_{thresh} is examined in Sect. 3.4. Cropland density can be expressed ~~in as the~~ number of fields per ~~km~~km² (cropland number density, shown in Fig. A1) or, ~~as also since~~ the area of each field is known, as the fraction of land area covered by a specific crop (cropland area fraction). For ~~those grid cells containing at least one field at~~ $n_{\text{thresh}} = 1$ and 1 km-resolution km spatial resolution, the average cropland ~~number densities are~~ densities (in grid cells where the crops are present) are: 36.7 (grapevine), 9.7 (field crops), 4.6 (wheat), 4.3 (corn), 2.5 (barley), and 2.4 (rapeseed). The corresponding cropland area fractions are: 7.3% (grapevine), 14.4% (field crops), 5.7% (corn), 3.5% (barley), and 4.2% (rapeseed). The gridded cropland data (number of fields, total area) is provided open-source via the CLIMADA ~~data API~~ Application Programming Interface (API).

2.3 Model formulation

The model formulation evaluated here follows the risk framework of the IPCC (IPCC, 2022) implemented in CLIMADA (Aznar-Siguan and Bresch, 2019) and defines a hazard, exposure and ~~a vulnerability (or impact function)~~. ~~The an impact~~ function. The impact function describes the vulnerability of exposed assets to the hazard. Here, the exposure consists of a binary field and the hazard consist of the radar data (~~here shown for~~ MESHS). The impact function is defined by one threshold parameter s and represents a step function which is 0 below s and 1 above s .

$$f_{\text{imp}} = \begin{cases} 0 & \text{MESHS} < s \\ 1 & \text{MESHS} \geq s \end{cases} \quad (2)$$

The ~~damage footprint then is~~ impact, i.e. the damage footprint, is then computed as the product of exposure and impact function

$$\text{damage}_{\text{footprint}} \text{impact} = \text{exposure} \cdot f_{\text{imp}} \quad (3)$$

The resulting impact is a binary field ~~of~~ with 1 for grid cells where there is modeled damage and 0 where there is not.

2.4 Damage claims

To evaluate the skill of this model, damage information is obtained from ~~damage claims~~ claims data provided by the Swiss Hail insurance company (SH) for ten hail ~~days events~~ between 2017 and 2021. Damage information includes the event date, location, crop type and harvest loss as estimated by employees of SH in the field. Roughly a quarter of all claims indicated zero harvest loss and were removed. This resulted in a total of 26²,292 crop-specific damage claims used for this study, out of which 21% are winter wheat, 26.5% maize (~~incl. grain and silage maize~~), ~~34% grapevine~~, 10% rapeseed, 8.5% winter barley, and 34% grapevine. About 76 % of these claims contain explicit coordinates of the affected fields, while the remaining claims are only provided at the community municipality level. To still be able to consider them in our analysis, these remaining claims are randomly distributed on all farmland (wheat, maize, barley, rapeseed) or all vineyards (grapevine) of that community. This procedure was repeated 1000 times for wheat and grapevine to assess the uncertainty associated to this random placement. It was found that the 95% confidence interval for the skill metrics considered in this study at 1 km-km spatial resolution is below 1% for wheat and below 2% for grapevine. Therefore, the uncertainty introduced by the random placement is considered small.

185 Based on a careful comparison with radar data and the Swiss Severe Weather Database (sturmarchiv.ch), some damage claims related to nocturnal hailstorms were re-dated to the previous day to match the time window of the radar data (06 UTC ~~-06-06~~ UTC). This resulted in a total of 12 hail days (see Table 1), instead of the 10 hail days provided in the original data by SH. ~~Further, two hail events~~ Two of the hail events (8 July 2017 and 1 August 2017) occurred when at least one of the crops had already been completely or ~~to a large extent~~ largely harvested. These dates were identified ~~if no or very few damage claims to a~~ crop were registered, even if this crop type was present in a region where numerous damage claims are recorded by comparing the number of reporter damage claims for the various crops (no or only a few claims for a crop, but many claims for the other crops) (see fourth column in Table 1). ~~The obtained~~ These dates were further verified based on information on indicative starting dates for harvests (wheat: end of July, barley: end of June, rapeseed: mid-July, maize: October) (www.schweizerbauern.ch, 2023).

190

195 Finally, to allow damages to be compared directly to exposures and modelled damage footprints, damage claims were gridded to the same 1x1 ~~km~~-km grid as the exposure data. This gridded dataset indicates the number of damaged fields separately for each crop type as well as the aggregate ~~category field crops~~ field crops category (wheat, maize, barley, rapeseed). It is important to note that, in Switzerland, average insurance coverage is 69% for field crops and 43% for grapevine (SH, personal communication) indicating that, in our study, the total number of damaged fields is ~~likely~~ probably underestimated. This is

200 expected to negatively affect model skill, mainly via a larger number of false alarms.

Damage and exposure data are from different sources, and therefore it is checked whether damage actually occurs where exposure is identified. The fraction of claims that are in a ~~1x1 km~~-km grid cell without exposure is small (wheat: 3%, corn: 2%, barley: 7%, rapeseed 11%, field crops: 0.5%, grapevine: 0.4%) and reduces strongly for coarser resolutions. For the aggregate category field crops, the mismatch is significantly lower than for the individual crops. The more relevant number for

205 our study is the fraction of grid cells with damage that have zero exposure, because such grid cells would artificially reduce model skill. This fraction is larger but remains in the range of a few percent (wheat: 5%, corn: 4%, barley: 9%, rapeseed 13%, field crops: 1.5%, grapevine: 4%) ~~. This fraction and~~ also reduces for coarser resolutions, reaching almost zero at 8 ~~km~~-km for all field crops and about 2% for grapevine. Hence, a coarser resolution can efficiently reduce the mismatch between damage and exposure, in particular for field crops. Note that the exposure used here is in principle only valid for 2021. However, there are

210 only small differences in the mismatch between events in 2021 and events prior to 2021, indicating that this is not ~~the a~~ major source of ~~the mismatch~~ uncertainty. To avoid artificially reducing the skill of the model due to the (albeit small) mismatches, grid cells with damage but no exposure are excluded from the verification process. The gridded damage data (number of fields) is provided open-source via the CLIMADA data API.

2.5 Verification based on contingency table

215 To measure the model skill at different spatial resolutions and for different ~~hail intensity thresholds~~, MESHS or POH thresholds, we use a 2x2 contingency table ~~is used~~ computed based on the joint distribution of predictions and observations on all grid cells with non-zero exposure (Table 2, c.f. Wilks, 2019). According to the model formulation, grid points with nonzero exposure that coincide with a hail intensity larger than a threshold s are considered damage predictions ($a + b$ in Table 2). Grid points

with nonzero damages and nonzero exposure are considered damage observations ($a + c$ in Table 2). From the four numbers of the contingency table (a = hits, b = false alarms, c = misses, d = correct negatives) a range of scalar attributes and skill metrics are computed (Wilks, 2019):

$$\begin{aligned}
 \text{FAR} &= \frac{b}{a+b} & \text{POD} &= \frac{a}{a+c} \\
 \text{BFB} &= \frac{a+b}{a+c} = \frac{\text{POD}}{1-\text{FAR}} & \text{PC} &= \frac{a+d}{a+b+c+d} \\
 \text{CSI} &= \frac{a}{a+b+c} = \frac{1}{\frac{1}{1-\text{FAR}} + \frac{1}{\text{POD}} - 1} & \text{PC}_{\text{rand}} &= \frac{(a+b)(a+c) + (b+d)(c+d)}{(a+b+c+d)^2} \\
 \text{HSS} &= \frac{\text{PC} - \text{PC}_{\text{rand}}}{1 - \text{PC}_{\text{rand}}} = \frac{2(ad - bc)}{(a+c)(c+d) + (a+b)(b+d)}
 \end{aligned}$$

where FAR denotes the false alarm ratio (FAR=0 for a perfect model), POD the probability of detection or hit rate (POD=1 for a perfect model), B, FB the frequency bias (perfect model: 1, overforecast: >1, underforecast: <1), PC the proportion correct, also called accuracy (PC=1 for a perfect model), CSI the critical success index, also known as threat score (CSI=1 for a perfect model), and HSS the Heidke Skill Score. For a perfect model, FAR is 0 and all other metrics 1, with an FB>1 indicating overforecasting and FB<1 underforecasting. PC and CSI are both measures of forecast accuracy, but CSI has the advantage that it is a simple measure to account for the trade-off between high POD and low FAR (Roebber, 2009). However, PC has the advantage over CSI that it takes into account the ability of the model to correctly predict non-events (correct negatives, d in Table 2). The HSS is a classical forecast skill score on the basis of PC and quantifies the accuracy PC of the forecast compared to the PC of a random forecast, PC_{rand} (perfect model: HSS=1, no skill: HSS=0, Heidke, 1926). The overall model performance in this study is assessed based on the HSS. For comparison, the radar product used by Warren et al. (2020) to compile a hail climatology for Brisbane and Sydney, Australia, achieved a HSS of around prior studies achieved an HSS of radar-based hail detection around 0.3-0.5 (e.g. Kunz and Kugel, 2015; Ortega, 2018; Warren et al., 2020) with Warren et al. (2020) regarding their values around 0.5, which the authors regarded as ‘moderate skill’ as ‘moderate skill’.

3 Results

3.1 The effect of resolution on model skill

First, average model skill as measured by HSS across all events and its dependence on spatial resolution is investigated for each crop type individually for a MESHS threshold of $s=20$ mm-mm (Fig. 42). For wheat, maize, rapeseed and barley, model skill substantially increases with decreasing spatial resolution up to 8 km-km and reduces or remains constant for higher coarser resolutions. Aggregating them to one crop type (field crops) conserves this behaviour but increases overall skill. For grapevine, the behaviour is opposite: Skill reduces with coarser decreasing resolution up to 8 km-km and increases again thereafter. The increased skill when verifying hail damages on a larger scale is well known for neighbourhood-based ap-

proaches (~~Warren et al., 2020; Schwartz, 2017; Schmid et al., 2023~~)(Warren et al., 2020; Schwartz, 2017; Schmid et al., 2024), even if these approaches have substantial methodological differences to our resolution-based approach. It can essentially be explained by the reduced penalization of forecasts due to ~~e.g. spatial displacement of forecast and~~ spatial displacement from the observation [hereafter referred to as the scale effect]. However, the reduced skill with coarser resolution for grapevine cannot be explained with the scale effect.

To further explore this contrasting behaviour, the effect of ~~a coarser~~ resolution on model skill is considered for individual events for both wheat (Fig. 23) and grapevine (Fig. 3) ~~(4) with $s = 20$ mm~~mm. Focusing on wheat at ~~1 km~~km (Fig. 2a-e, d3a, c, e, g), high average POD and FAR (both around 0.8) are found, with considerable differences between events. We discuss three representative examples (a shifted forecast, an overforecast, and a good forecast) in more detail. An event with low skill (HSS=0.16, POD=0.47, FAR=0.89) occurred on 15 June 2019 over Western Switzerland (Fig. 23a). In this case, the observed damage footprint (grey and blue grid cells) is shifted to the east relative to the predicted damage footprint (red and blue grid cells), resulting in many misses and false alarms and few hits. Then, 28 June 2021 (Fig. 2b3c) was an extreme hail event with an exceptionally large spatial extent (Kopp et al., 2022) (HSS=0.21, POD=0.91, FAR=0.81). It is characterized by many false alarms, notably over North-Eastern Switzerland. This results in low skill, despite the high POD. With a large frequency bias (~~BFB~~=4.8) this forecast can be characterized as overforecast. Finally, the event on 12 July 2021 (Fig. 2e3e) has the best skill (HSS=0.51, POD=0.61, FAR=0.53). The main damage footprint over North-Eastern Switzerland was captured very well, but a number of misses at the edges of the damage footprint and scattered over the Swiss Plateau lead to a lower POD compared to the previous examples.

Reducing the resolution to ~~8 km affects metrics of the three representative examples~~km affects the verification statistics for the three cases differently (Fig. 2d-g3b, d, f, g). The shifted forecast (15 June 2019, Fig. 2d3b) greatly improves (HSS=0.42) due to a substantially higher POD (0.93) ~~and~~ a lower FAR (0.67). This is mainly because the coarser resolution compensates for the spatial shift of a few km, which turns misses and false alarms into hits. The overforecast (28 June 2021, Fig. 2e3d) also improves (HSS=0.38) but mostly because of a lower FAR (0.57) while POD remains unchanged. ~~Finally, the skill of the~~ The coarser resolution effectively eliminates the red ‘holes’ of false alarms that occur between the blue areas of hits. However, its impact on misses is limited, considering they were already minimal at the 1 km resolution. Similarly, the more cohesive damage footprint at 8 km, in comparison to 1 km, contributes to a reduced FAR (0.38) for the good forecast (12 July 2021, Fig. 2f3f). However, the overall skill remains largely unchanged ~~, as the benefit of a lower FAR (0.38) is compensated by a lower POD (0.55). Again the due to the increased significance of~~ individual scattered damage reports over the Swiss Plateau ~~contribute substantially to this relatively low POD (without them, the, resulting in a lower POD (0.55; without these reports,~~ POD would be 0.73). HSS increases for all 10 considered events if spatial resolution is reduced from 1 km to 8 km (Fig. 23g). However, there are substantial differences in the magnitude of the increase between events. The FAR reduces with lower resolution for all events and POD increases for 7 out of 10 events. POD does not increase for events where it is already very high (e.g., the overforecast) or where many misses are located far away from the ~~modeled-modelled~~ damage footprint (e.g., the good forecast). For grapevine, the story is different (Fig. 34), as illustrated ~~in the following~~ with the 15 June 2019 event. At ~~1 km~~km, the model predicts damage footprints for grapevine well (HSS=0.47; Fig. 34a, g). Reducing the resolution to ~~8 km~~km in this case increases

the FAR from 0.65 to 0.78 and reduces HSS to 0.30, despite a higher POD (Fig. 4b,g). A similar behaviour is observed for the 24 July 2021 event (Fig. 3e4e,f,g), while for the 28 June 2021 event, the skill remains unchanged (Fig. 3b,e4c,d,g). Considering all events, the following overall pattern emerges (Fig. 34g): Reducing the resolution reduces HSS or does at least not increase it significantly, despite a higher POD. This is in contrast to the behaviour for wheat. The difference mostly arises because FAR generally increases for grapevine but consistently reduces for wheat. A key difference between the two considered crops is that the damage footprints for grapevine are more heterogeneous and scattered than for wheat, due to the very localized distribution of grapevine in the landscape compared to the spatially more evenly spread distribution of wheat. Many false alarms appear in the regions with low density of grapevine while hits populate the regions with high grapevine density, notably at the shores of the Lake Geneva, Neuchâtel and Biel Lake Geneva and the Three-Lake-Region in Western Switzerland and the Lake Zurich in the North-East. Reducing the resolution mainly increases the fraction of these false alarms, leading to lower skill (Fig. 3d4e,f,g).

It is clear that the scale effect tends to reduce FAR with coarser resolution, irrespective of the crops' spatial distribution. To understand the behaviour for grapevine, an additional effect of a coarser resolution on FAR has to be considered: The chance of a false alarm also depends on cropland density [hereafter referred to as the density effect]. The main reason for this is the enormous variability of hail within a storm at the scales of a few hundred meters (Morgan and Towery, 1975) (Morgan and Towery, 1975; Ortega et al., 2009) combined with insured fractions of fields well below 100%. Hence, the average FAR at 1 km grid points with 1 field is higher (wheat: 82%, grapevine: 79%) than at grid points with 10 fields (wheat: 74%, grapevine: 60%). In conclusion, if cropland density strongly reduces with coarser resolution, FAR is affected depending on how cropland density changes will increase accordingly. For a crop that occurs everywhere in is widespread across the domain, average cropland density within a grid cell is independent of less dependent the resolution (even if density within individual 1 km grid cells varies). However, the more a crop occurs fragmented in distinct parts of the domain, the stronger cropland density decreases with coarser resolution. Hence, this density effect contributes to an increase of FAR. For wheat, the average cropland density within a grid cell decreases by slightly more than a factor of 2 from 4.6 fields per km² at 1 km to 1.9 fields per km² at 8 km resolution. For grapevine however, it decreases from 36.7 fields per km² to 4.2 fields per km² which is about a factor of 9 (note that the results are almost identical if cropland area fraction is used). The reason for these differences can also be expressed in terms of an areal inflation factor: Only every 9th. That is, the area covered by all exposure grid cells at a given spatial resolution divided by the area covered by all exposure grid cells at 1 km resolution. By this definition, the inflation factor is 1 at 1 km resolution and increases for coarser resolutions (Fig. km grid cell within a 8 km grid cell actually contains exposure (inflation factor of 9A2)). At all resolutions, these inflation factors are much larger for grapevine than for wheat (Fig. A2).

In conclusion, the scale effect dominates over the density effect for wheat and the density effect dominates over the scale effect for grapevine. Hence, to achieve a good skill when modelling hail damage footprints it is beneficial to reduce the resolution from the original 1 km to about 8 km for field crops while 1 km provides the best skill for grapevine.

3.2 The effect of MESHS threshold on model skill

Next, we aim to identify suitable MESHS threshold(s) to model hail damage footprints for field crops and grapevine. An often used method to determine an ideal hail intensity threshold is to evaluate a skill metric (e.g. HSS or CSI) as a function of threshold and determine the location of the maximum (see e.g. Puskeiler et al., 2016; Kunz and Kugel, 2015). However, for wheat and grapevine at 1 km-resolution, CSI and HSS do not exhibit a clear maximum. They remain largely unchanged up to 40 mm for field crops and 35 mm for grapevine, and decline at higher thresholds (Fig. 45). Note that the sample size for grapevine is substantially smaller, especially at large MESHS thresholds (grey bars in Fig. 45), leading to larger uncertainty of the exact skill values. Warren et al. (2020) suggest to additionally constrain the optimal threshold with the condition that B-FB is close to 1 to avoid overforecasting. Here, this would result in an optimal threshold even above 40 mm for wheat and 45 mm for grapevine. Conversely, a MESHS threshold of 30 mm for field crops would result in a frequency bias of 2, i.e. it results in twice as many forecasts than observations. Hence, selecting a threshold comes with a trade-off between (i) a high POD (blue line in Fig. 45) and (ii) a low FAR (red line in Fig. 4) and B-5) and FB closer to 1.

3.3 Combined effects of resolution and threshold on model skill

To provide an overview of the combined effects of resolution and threshold on model skill, the performance diagram is used (Fig. 5; Roebber, 2009; Wilks, 2019) (Fig. 6; Roebber, 2009; Wilks, 2019). The performance diagram shows the relationship between POD and 1-FAR for model set-ups based on (also known as the success ratio) for spatial resolutions of 1, 4, and 8 km spatial resolution and MESHS thresholds of 20, 30, and 40 mm. A perfect model is located in the top right of the diagram. For field crops (Fig. 6a) it becomes evident that, for all three resolutions, an increase of the threshold strongly reduces POD but also reduces FAR and B-FB (dashed diagonal lines), leaving its skill practically unchanged (shading, as measured by CSI; Fig. 5a, practically unchanged (shading)). Reducing the model resolution shifts the points in the diagram towards the top right, i.e. increases the skill by strongly reducing FAR, increasing POD and reducing B and increasing POD. Note that the more favourable skill measure, HSS, can not be shown in the performance diagram directly, as, unlike CSI, it also depends on the number of correct non-events, d. However, CSI behaves similar to HSS for resolutions below 8 km.

The diagram also reveals the key differences between grapevine and field crops (Fig. 56b). Consistent with the results from Sect. 3.1, the main difference is that, for grapevine, the FAR is not reduced with reduced coarser resolution but even slightly increased, for a given threshold (i.e., the "threshold-resolution threshold-resolution web" is squeezed together in the horizontal direction). This results in a tendency for lower skill despite the small increase in POD. An exception is the slight increase in CSI for the 40 mm threshold from 1 to 8 km resolution due to a substantial increase in POD and an almost unchanged FAR. This is because in this region of the phase space, CSI is more sensitive to changes in POD than changes in FAR.

3.4 Sensitivity to cropland density and hazard variable

NowHere, the sensitivities of the model performance to ~~first~~, cropland density (via n_{thresh}) and ~~second~~, to n_{thresh} and the selection of an alternative ~~hazard-variable-radar product~~ (POH) are discussed.

The sensitivity to cropland density is substantial. An increase in n_{thresh} leads to a decrease in FAR for all crops (Fig. 67), while POD remains largely unaffected (not shown). ~~Until n_{thresh} values of about 20 for field crops at (8 km-km resolution) and 10 for grapevine (at 1 km-km resolution), the FAR decreases strongly by about 10 percent points for field crops and about 20 percent points for grapevine, respectively.~~ Beyond these thresholds, the ~~FAR- n_{thresh}~~ curve tends to flatten out. Increasing n_{thresh} comes with the cost that the fraction of fields included is reduced (Fig. A3). Hence, an optimal value of n_{thresh} reduces FAR as much as possible but keeps the included fraction of fields or crop area high. Here, a pragmatic choice for all field crops at 8 km-resolution is $n_{thresh}=20$, which maintains 95% of ~~the number of~~ fields for rapeseed, 96% for barley, 98% for wheat and maize, and 99% for ~~the combined~~ field crops (Fig. 67a). Note that, for certain crops, even higher n_{thresh} are justified (e.g. wheat, maize, field crops, see Fig. A3a). For the aggregate crop class field crops, ~~even a $n_{thresh}=100$ (or larger) is justified, as it still preserves 96% of fields.~~ however, the associated reduction in FAR is rather modest (approx. 5 percentage points). Very similar numbers result when crop area is considered instead of field number. For grapevine at 1 km-km resolution, a suitable choice is $n_{thresh}=10$, which reduces FAR by almost 0.2 and still preserves 95% of the number of vineyards (Figs. 67b and A3b). However, it conserves only 86% of vineyard area, which would also justify a lower threshold.

The effect of $n_{thresh}=20$ for field crops on model performance is illustrated in the using a performance diagram (Fig. 78a). For all resolutions, the ~~"threshold-resolution-web"~~ shifts to the right in the diagram compared to the original $n_{thresh}=1$. Hence, FAR is substantially reduced and POD remains nearly constant, leading to a higher skill. Note, however, that the choice of the optimal n_{thresh} heavily depends on the chosen spatial resolution. In other words, an $n_{thresh}=20$ preserves 99% of field crops at 8 km resolution but less than 30% at 1 km resolution.

Finally, the sensitivity of the model performance to the selection of POH instead of MESHS is tested (Fig. 78b). The identical analyses as for MESHS are performed for POH for model is tested for POH thresholds of 70, 85, and 100% and, at spatial resolutions of 1, 4, and 8 km-resolution and n_{thresh} km, and with $n_{thresh}=1$. Compared to MESHS, the ~~"threshold-resolution-web"~~ is shifted towards the top left in the performance diagram. This indicates higher POD but also a higher FAR, and lower overall skill. These results are consistent with previous studies (Nisi et al., 2016; Schmid et al., 2023)(Nisi et al., 2016; Schmid et al., 2024). Further, the highest possible threshold (100%) still exhibits substantial frequency biases a large frequency bias (>1.5), limiting POH-based models to applications where overforecasting is not a problem. Hence, MESHS is better suited to model hail damage footprints for most applications.

3.5 Discussion

In this section, the key results are discussed in more detail, including how they would be affected by the use of different verification approaches. The optimal resolution was found to differ for field crops (8 kmkm) and grapevine (1 kmkm). It was argued that two competing effects play a role: First, the scale effect tends to increase skill for coarser resolutions, because larger distances of forecast and damage observation are tolerated (Warren et al., 2020; Schwartz, 2017; Schmid et al., 2023)

between forecast and observed damage are tolerated (Warren et al., 2020; Schwartz, 2017; Schmid et al., 2024). Second, the fact that the area covered by the exposure grid cells is artificially inflated with coarser resolution leads to lower cropland densities and hence, higher chances of false alarms, which reduces skill (density effect). The effect of a changing cropland density is particularly relevant, because hail storms are very localized phenomena with a high within-storm spatial variability (Morgan and Towery, 1975) (Morgan and Towery, 1975; Ortega et al., 2009). The density effect strongly depends on the spatial distribution of crops: It is larger for crops that are scattered unevenly (like grapevine) and smaller for crops that area occur more homogeneously distributed across the domain (like wheat and other field crops). Hence, reducing the spatial resolution is only beneficial for crops that are sufficiently evenly distributed in the landscape. We acknowledge that it remains open what ‘sufficiently’ is-means in this context. The dependence of cropland density on spatial resolution has also been acknowledged by (Griffith et al., 2000) discussed by Griffith et al. (2000). In fact, it is a property that can be found for aggregation of any spatially heterogeneously distributed feature. For example, Baker et al. (2007) found that the density of drainage channels per unit area strongly reduced with coarser resolution.

Considering the MESHS threshold, the identified trade-off between high-POD-and-either achieving a high POD or a low FAR or-a-B-and-an-FB close to 1 eventually signifies that the optimal threshold depends on user needs and the relative costs of a false alarm and-versus a missed event. For example, if an insurance company wants to use this model to verify damage claims, it will prioritize a low threshold with a high POD. On the other hand, if scientists or governments use this model to communicate the damaged crop area after a hail event, they may want to avoid a systematic overestimation of the damage extent and chose a higher threshold. To incorporate the costs of false alarms and missed events in decision-making-decision-making with this model, user-tailored cost-loss-cost-loss models would have to be developed (de Elía, 2022). It is important to note that the best threshold for end users is not necessarily the one with the highest skill, but depends on their specific cost functions (Manzato, 2007).

The strongly reduced FAR with larger minimum number of fields within a grid cell ($n_{thresh}n_{thresh}$) is again related to the large within-storm spatial variability of hail. The lower the cropland density, the higher the chances that a hail event does not lead to damage-, i.e., a false alarm occurs despite the presence of hail. Hence, hail damage footprints can be better modeled modelled within the main crop production areas. These results are comparable to Tian et al. (2018) who found that the FAR of satellite-based detection of rainfall occurrence reduces with increased rain gauge density.

Finally, it is noted that other equally-valid-verification procedures exist than the ones used in this study. Two alternatives and their effect on our results are briefly discussed. First, Ebert and Milne (2022) suggest the use of the Pierce Skill Score (PSS, Peirce, 1884) as alternative to HSS for rare and severe events. PSS-One of their arguments in favour of PSS is that it is the only skill measure taking into account that, for rare and severe events, misses tend to be more problematic than false alarms. For more details on this discussion, the reader is referred to Ebert (2008). PSS favours a high POD and hence, in our case, a MESHS threshold of 20 ~~mm~~mm. Because of its high POD, a POH-based based model therefore outperforms a MESHS-based model when evaluated using PSS instead of HSS. PSS of the MESHS-based model for field crops remains nearly constant with coarser resolution until 8 ~~km~~km but reduces for even coarser resolutions, which corroborates the meaningfulness of the selection of an 8 ~~km~~km resolution.

Second, the use of fuzzy forecast verification has been proposed as alternative to point-based techniques to verify precipitation forecasts (Ebert, 2008). An often used fuzzy verification metric is the fractions skill score (FSS), which measures the fractional coverage of events in windows of different length scale around observations and forecasts (Roberts and Lean, 2008). It ~~allows identifying-can be used to identify~~ the scale at which a forecast should be believed. Using ~~a n_{thresh}~~ $n_{thresh}=20$, ~~the 1, 2, and~~ 420 ~~4 km~~-we find that models ~~are skillful for field crops are skilful~~ ($FSS > 0.5$) beyond a scale of 4 ~~km~~-km and for MESHS thresholds between 20-30 ~~mm~~mm. In general, the skill increases with larger scales and lower model resolutions. However, the 8 ~~km~~-km model does not ~~further-increase FSS-compared-to~~ ~~have a larger FSS than~~ the 4 ~~km~~-km model. This perspective confirms that ~~modeling-modelling~~ hail damage footprints is not ~~skillful-skilful~~ at the 1 ~~km~~-km scale but suggests that a 4 ~~km~~-km resolution could also be a suitable choice. Considering grapevine (~~n_{thresh}~~ $n_{thresh}=10$), the lowest scale at which ~~skillful-skilful~~ prediction 425 is possible is 6 ~~km~~-km at a threshold of 20 ~~mm~~mm. The FSS confirms that the skill does not improve with coarser spatial resolution, except for very large scales beyond 64 ~~km~~km.

4 Conclusions

This study presents an open-source model implemented in ~~CLIMADA-to-predict~~ the ~~open-source natural catastrophe modelling platform CLIMADA (Aznar-Siguan and Bresch, 2019) to predict~~ hail damage footprints (occurrence of hail damage~~yes/no~~) 430 for individual crops after the passage of a hailstorm based on the operational single-polarization meteorological radar product MESHS and detailed agricultural land use data. Damage information from a crop insurer was used to quantify the skill of the model with different skill metrics. The main goal was to assess the model performance for different choices of spatial resolution (aggregation), MESHS threshold, and threshold of the number of fields used to define the exposure (cropland density). For field crops (wheat, maize, rapeseed, barley) the model ~~performance~~ improves substantially when coarsening spatial res- 435 olution ~~gradually-from 1 km-km to 8 km~~km, mainly because it relaxes the requirement for exact spatial overlap of ~~modeled modelled~~ and observed damage footprints (scale effect). Beyond 8 ~~km~~,~~-the km~~, model skill tends to reduce again. On the contrary, for grapevine, coarser resolution tends to lower ~~the~~ model skill. We conclude that this difference between field crops and grapevine is mainly related to the different spatial distribution of these crops in the landscape [scattered for grapevine vs. more ~~evenly-homogeneous~~ for field crops], which determines how strongly cropland density reduces with coarser resolution. 440 A lower cropland density leads to a higher chance of a false alarm (density effect). For wheat, the scale effect dominates, while for grapevine the density effect dominates.

Increasing the ~~hail-intensity-MESHS~~ threshold from 20 ~~mm~~-mm to 40 ~~mm~~-mm strongly decreases the probability of ~~damage~~ detection (POD) ~~for hail damage~~ but also reduces false alarm ratio (FAR) and frequency bias (~~FB~~). The overall skill (HSS) ~~remains-largely-unaffected-is only moderately affected~~ by the threshold selection, due to the trade-off between POD and FAR 445 that has to be aligned with user needs and their specific cost functions.

Model performance can be substantially improved at all resolutions by selecting a higher minimum cropland density (~~n_{thresh}~~ n_{thresh}) for the exposure definition, mainly due to a reduction in FAR. Considering an alternative radar-based hail product (POH) reveals higher POD, higher FAR and lower skill compared to MESHS, confirming previous studies (~~Nisi et al., 2016; Schmid et al., 2023~~)

(Nisi et al., 2016; Schmid et al., 2024).

450 Finally, ~~suitable model setups (resolution, threshold s , minimum exposure density n_{thresh}) can be identified to model damage footprints to field crops and grapevine. Some of the most suitable setups~~ the key skill metrics of selected representative model setups for the best resolution (8 km for field crops ~~and grapevine are presented~~, 1 km for grapevine) are shown in Table 3 ~~including associated skill metrics~~. For all crops, MESHS thresholds of 20 and 30 ~~mm outperform MESHS thresholds~~ mm outperform a MESHS threshold of 40 ~~mm in particular for higher n_{thresh}~~ mm, in particularly for higher n_{thresh} . In general, a

455 larger n_{thresh} will yield results closer to the “true” skill of MESHS, i.e., the skill it would have given a gapless hail detection network on the ground, but comes at the cost of reduced number of data points for verification. The best performing setups (HSS~0.53) for field crops are achieved at 8 ~~km~~ km resolution and reach a POD of about 0.8 combined with a FAR of about 0.5 (for MESHS > 20 ~~mm~~ mm) or a POD around 0.7 combined with an FAR of about 0.4 (for MESHS > 30 ~~mm~~ mm). For grapevine, the best performance (HSS~0.48) is achieved at 1 ~~km~~ km and reaches either POD of around 0.7 and a FAR of

460 0.6 (for MESHS > 20 ~~mm~~ mm) or POD and FAR of around 0.55 (for MESHS > 30 ~~mm~~ mm).). We note again that the suitable threshold depends on the purpose for which the model is used. For climatological purposes, it is important that the frequency bias is close to 1. While thresholds of 20–30 mm strongly overpredict damage occurrence (FB>1), a threshold of 40 mm underpredicts it (FB<1). The MESHS threshold with FB closest to 1 is 34 mm for both field crops at 8 km and grapevine at 1 km and is hence recommended to derive accurate climatological frequencies of crop hail damage occurrence.

465 These results are comparable to previous verification efforts of MESHS (Nisi et al., 2016) or the original Waldvogel et al. (1979) criterion (Puskeiler et al., 2016), ~~as well as MESH (Cintineo et al., 2012; Skripniková and Řezáčová, 2014; Kunz and Kugel, 2015; Warren~~ , although methodological verification approaches substantially differ from ours. Traditionally, verification of radar-based hail detection has focused on the dependence of the skill on the hail intensity threshold. Our work highlights that it is crucial to also consider the dependence on spatial scale and the density of cropland or, more generally, the observation network.

470 ~~This simple damage yes/no model~~ The model presented here provides a first step towards the (operational) modelling of hail ~~damages~~ damage as well as hail risk assessments for crops in Switzerland. It is important to note that larger damage datasets would substantially increase the robustness of the results due to the large event-to-event variability. Gridded exposure and damage information are provided open-source via the CLIMADA data API to facilitate their use for operational purposes as well as the further development and validation of (hail) damage models for crops in Switzerland.

475 *Code and data availability.* The code (Python 3.9) to produce the figures in this manuscript and run the model is available at https://github.com/CLIMADA-projec/climada_papers. Gridded exposure, damage and hazard information is available via the CLIMADA data API <https://climada.ethz.ch/data-types/>. CLIMADA is an open-source and -access software (<https://doi.org/10.5281/zenodo.7691855>) and can be used with any user-provided portfolio under the General Public Licence gpl-3.0.

Author contributions. All co-authors provided valuable comments and suggestions during in-depth discussions in the development of this study. Beyond that, specific contributions are: **RP**: Conceptualization of the study, methodology, software, data curation, visualizations, paper writing, review and editing. **TS**: methodology, software, data curation, paper review and editing. **LV**: paper review and editing. **PC**: conceptualization, paper review

Competing interests. The authors declare no competing interest.

Acknowledgements. The authors thank the Swiss hail insurance company (SH) for providing damage data for this study. In particular, we thank Guendalina Barloggio from SH for the helpful communication and discussions during the process. Further, we thank Hansueli Lusti and Hans Feyen from SH for valuable inputs and discussions. Finally, we thank colleagues from MeteoSwiss and the whole scClim team (<https://scclim.ethz.ch/>) for the many inputs and discussions. This study was funded by the Swiss National Science Foundation (SNSF) Sinergia grant CRSII5_201792.

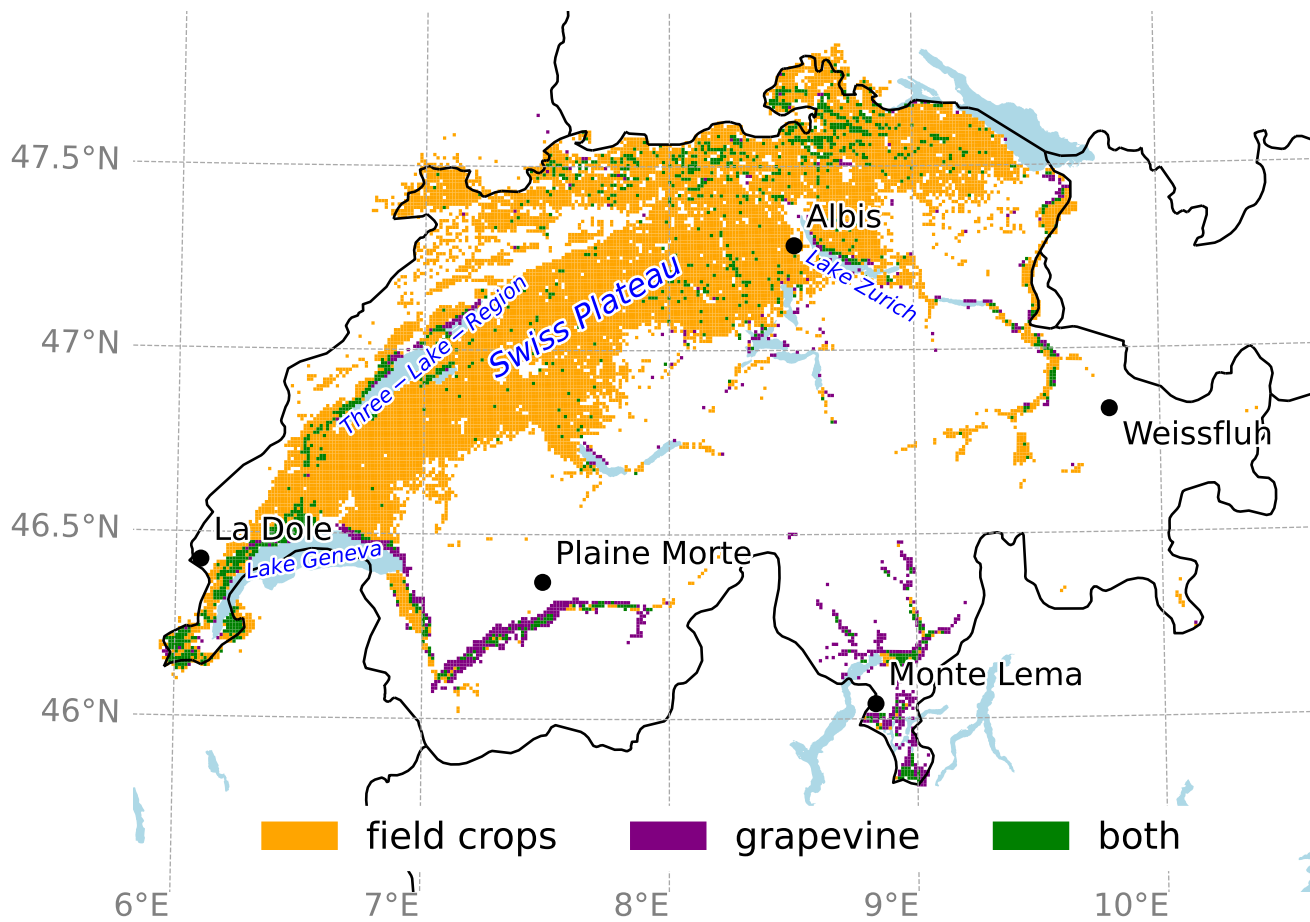

Figure 1. Study region showing exposed field crops (orange), grapevine (purple), and both of the two categories (green), at 1km resolution with at least 1 field per km², and the five radar locations (black dots). Regions / Lakes appearing in the discussion of the results are named in blue.

Figure 2. Skill (HSS) of the prediction of hail damage footprints with MESHS (20 ~~mm~~-mm threshold) for wheat (blue), maize (orange), rapeseed (green), barley (red) and grapevine (grey dotted) as well as an aggregate class field crops (black dashed, includes wheat, maize, rapeseed, barley) as a function of spatial resolution.

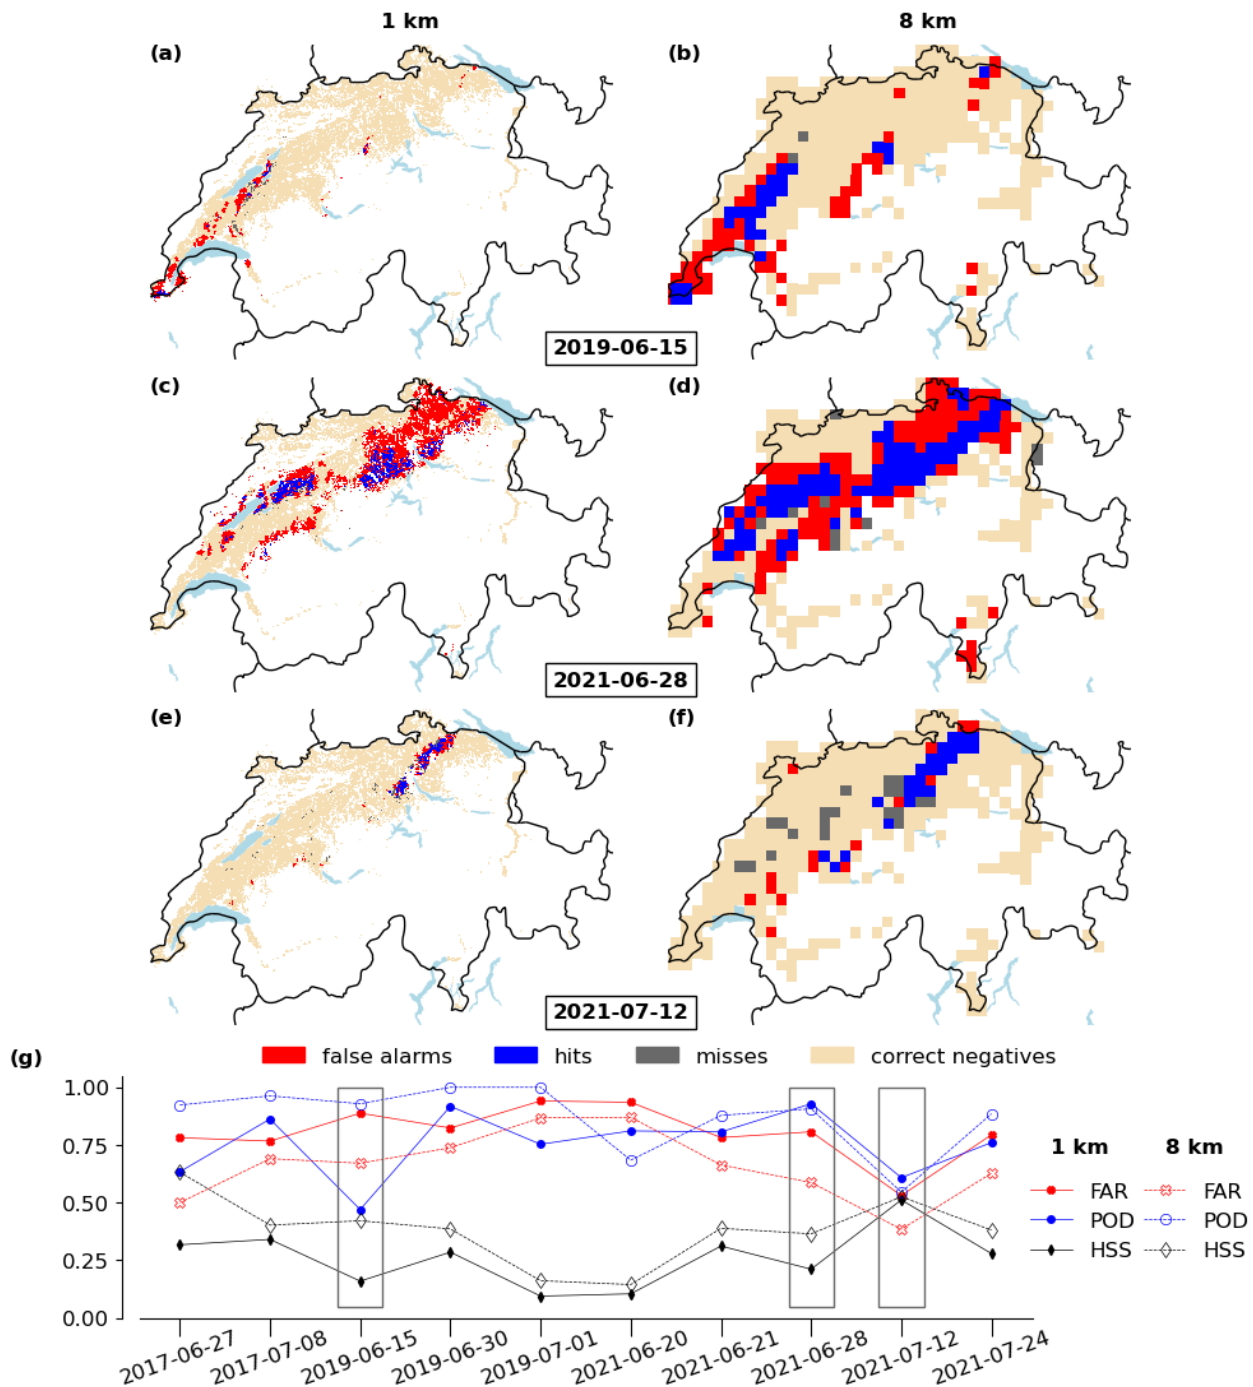

Figure 3. (a-e) 1x1 km and (d-f) 8x8 km grid cells classified as false alarms (red), hits (blue), and misses (grey) for damages to wheat based on MESHS > 20 mm. Dates shown are (a,b) 15 June 2019, (c,e) 28 June 2021, and (e,f) 12 July 2021. Unshaded cells indicate grid cells without exposure. (g) FAR, POD, HK, and HSS for all 10 recorded events and for (filled symbols) 1 km spatial resolution and (empty symbols) 8 km spatial resolution. Black boxes in panel (g) indicate the events shown in panels (a-f).

Figure 4. (a-e) 1x1 km and (d-f) 8x8 km grid cells classified as false alarms (red), hits (blue), and misses (grey) As Fig. 3 but for damages to grapevine on and (a,b) 15 June 2019, (b,c,d) 28 June 2021, and (e,e,f) 12 July 2021 based on MESHs > 20 mm. and (d,g) FAR, POD, HK, and HSS for all 12 recorded events and for (filled symbols) 1 km spatial resolution and (empty symbols) 8 km spatial resolution. Black Grey hatched boxes in panel (d,g) indicate the events shown in panels (a-f) and grey hatched boxes show events where the modeled with a modelled damage footprint is smaller than 80km below 80km².

Figure 5. POD (blue), FAR (red), HSS (black dotted), and CSI (black dashed) as a function of MESHS threshold for (a) field crops and (b) grapevine. Vertical green bars show thresholds with frequency biases (FB) of approximately 1 and 2 and grey bars show the total number of hail damage predictions at each threshold, as indicated by the vertical axis on the right. The total number of predictions summed over all thresholds is indicated at the top of each panel.

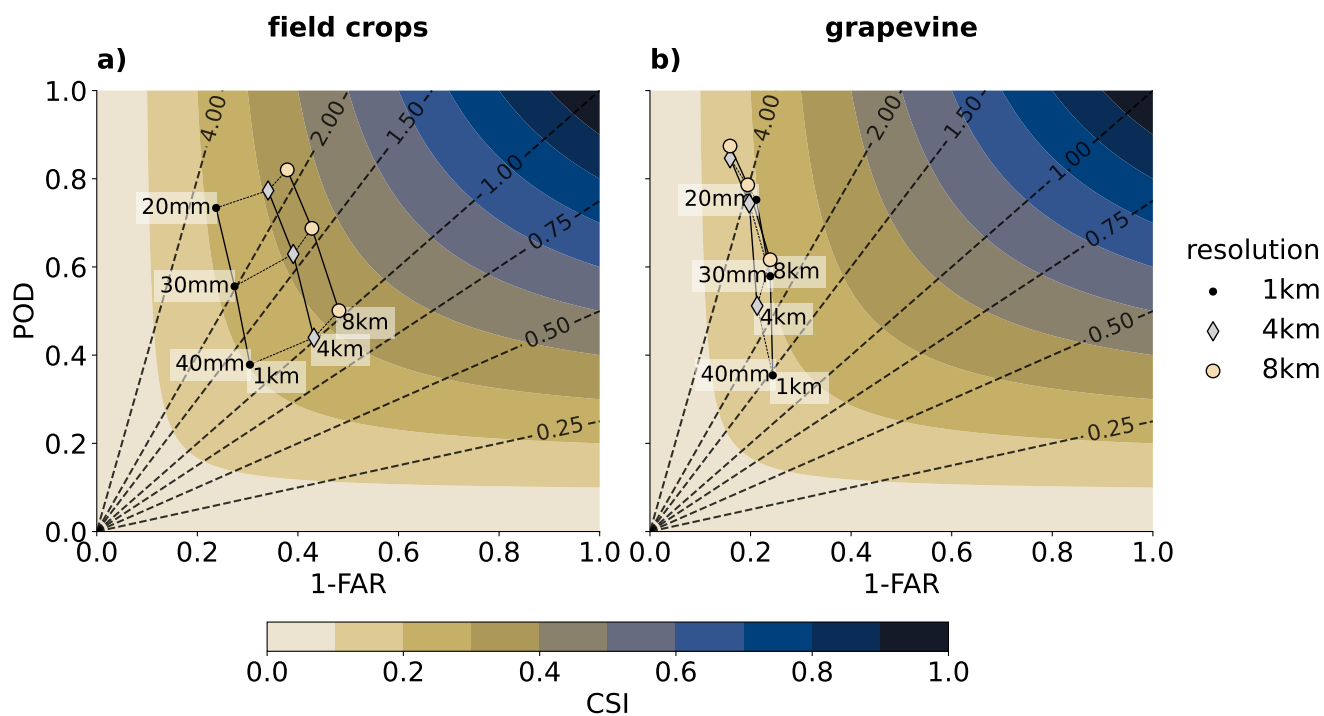

Figure 6. Performance diagrams showing POD vs. 1-FAR and CSI (shading), and frequency bias (dashed lines) for (a) field crops and (b) grapevine for MESH thresholds of 20, 30 and 40 mm and spatial resolutions of 1, 4, and 8 km. Dashed diagonal lines denote the frequency bias B .

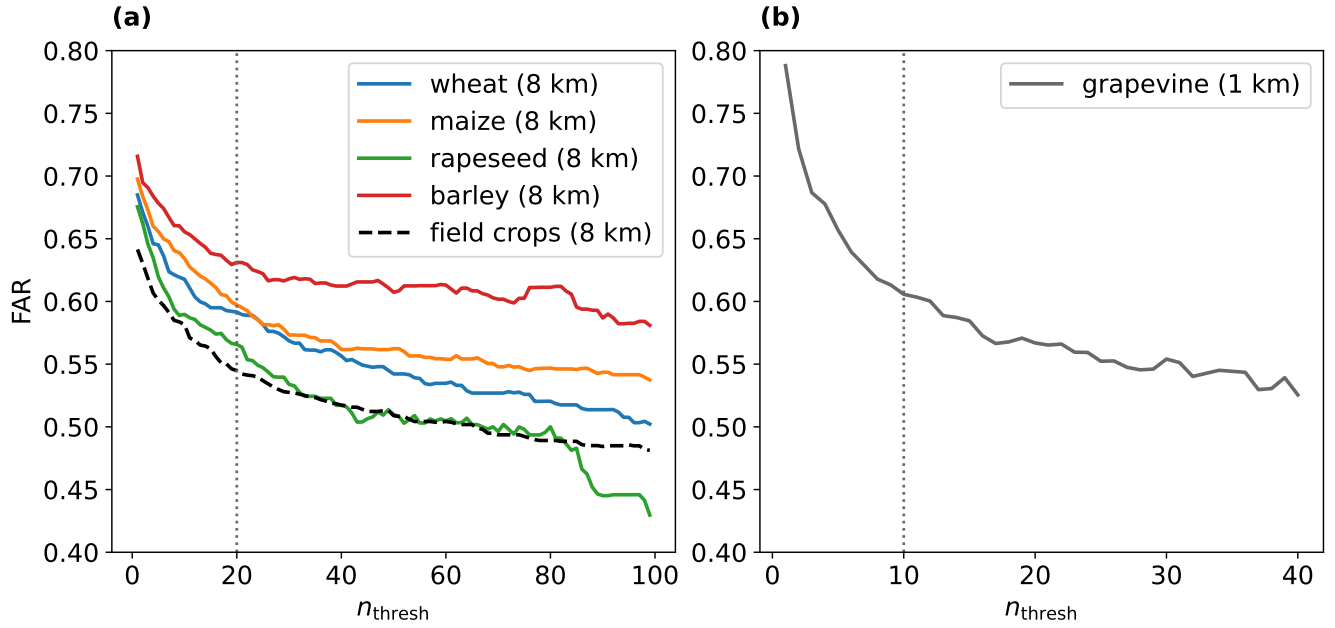

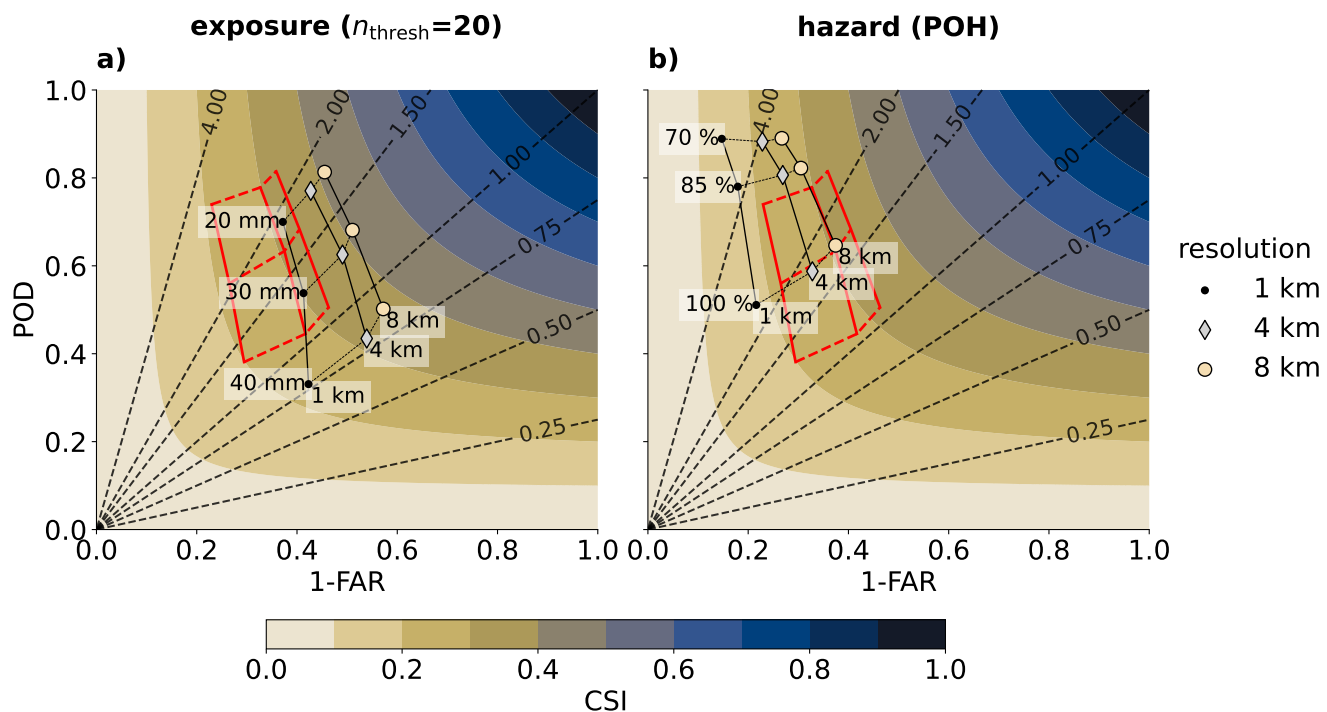

Figure 7. Change of the in FAR as a function of n_{thresh} (n_{thresh} (number of fields per grid cell) for (a) wheat (blue), maize (orange), rapeseed (green), barley (red), and field crops (black, dashed) at 8 km-km resolution and for (b) grapevine at 1 km-km resolution. The vertical bars denote pragmatic choices of n_{thresh} that avoid too-high limit FAR but still includes retain a large fractions (>95%) of the total exposed crop area / number of fields.

Performance diagrams for field crops for (a) alternative exposure, with an $n_{\text{thresh}}=20$ and (b) an alternative hazard (POH, 70, 85, and 100% thresholds). The values indicated with the red shape are shown for reference and are identical with the values shown in Figure 5a (MESHS, $n_{\text{thresh}}=1$):

Figure 8. Performance diagrams for field crops for (a) alternative exposure, with $n_{\text{thresh}}=20$ and (b) an alternative radar product (POH at thresholds of 70, 85, and 100%). The values indicated with the red shape correspond tho those shown in Figure 6a (MESHS, $n_{\text{thresh}}=1$).

Table 1. Overview of the 12 investigated hail ~~day~~events.

date	number of claims	damaged crops	harvested crops	comment
27 June 2017	2192	wheat, maize, barley, rapeseed, grapevine	-	
08 <u>8</u> July 2017	2824	wheat, maize, barley, rapeseed, grapevine, apples	barley	
01 <u>1</u> August 2017	1267	wheat, maize, rapeseed, grapevine, apples	wheat, barley, rapeseed	nocturnal hailstorm
15 June 2019	2185	wheat, maize, barley, rapeseed, grapevine, apples	-	
30 June 2019	632	wheat, maize, barley, rapeseed, grapevine	-	nocturnal hailstorm
01 <u>1</u> July 2019	549	wheat, maize, barley, rapeseed, grapevine, apples	-	
20 June 2021	558	wheat, maize, barley, rapeseed, grapevine, apples	-	
21 June 2021	2228	wheat, maize, barley, rapeseed, grapevine, apples	-	
28 June 2021	7383	wheat, maize, barley, rapeseed, grapevine, apples	-	
12 July 2021	2109	wheat, maize, barley, rapeseed, grapevine, apples	-	nocturnal hailstorm
13 July 2021	96	maize, grapevine	-	weak hail event
24 July 2021	4269	wheat, maize, barley, rapeseed, grapevine, apples	-	

Table 2. 2x2 contingency table

		observation	
		<i>yes</i>	<i>no</i>
prediction	<i>yes</i>	a (hits)	b (false alarms)
	<i>no</i>	c (misses)	d (correct negatives)

Table 3. Most suitable model setups (resolution, MESHS threshold s , cropland number density threshold n_{thresh}) for field crops (aggregate crop class including wheat, maize, rapeseed, and barley) and grapevine with the associated skill metrics, including the probability of detection (POD), the false alarm ratio (FAR), the Heidke Skill Score (HSS), and the frequency bias (FB).

crop type	parameters			skill metrics			
	resolution (km)	s (mm)	n_{thresh} <u>n_{thresh}</u>	POD	FAR	HSS	<u>FB</u>

field crops	8	40	20	0.50	0.41 <u>0.43</u>	0.47	<u>0.88</u>
field crops	8	40	1	0.50	0.52 <u>0.54</u>	0.43 <u>0.42</u>	<u>1.09</u>
grapevine	1	20	10	0.71 <u>0.70</u>	0.60 <u>0.61</u>	0.48*	<u>1.78</u>
grapevine	1	20	1	0.75	0.79	0.30	<u>3.54</u>
grapevine	1	30	10	0.55 <u>0.54</u>	0.56	0.46 <u>0.47</u>	<u>1.23</u>
grapevine	1	30	1	0.57	0.76	0.32	<u>2.41</u>
<u>grapevine</u>	<u>1</u>	<u>34</u>	<u>10</u>	<u>0.44</u>	<u>0.55</u>	<u>0.42</u>	<u>0.99</u> **

* highest skill for this crop type. ** frequency bias closest to 1 for this crop type. Note that $n_{\text{thresh}}=100$ is only a sensible choice for the aggregate field crops class due to its high cropland density. For individual crop types, lower values like $n_{\text{thresh}}=20$ are to be preferred.

Figure A1. Cropland number density at 1km spatial resolution for (a) wheat, (b) maize, (c) rapeseed, (d) barley, (e) field crops, and (f) grapevine.

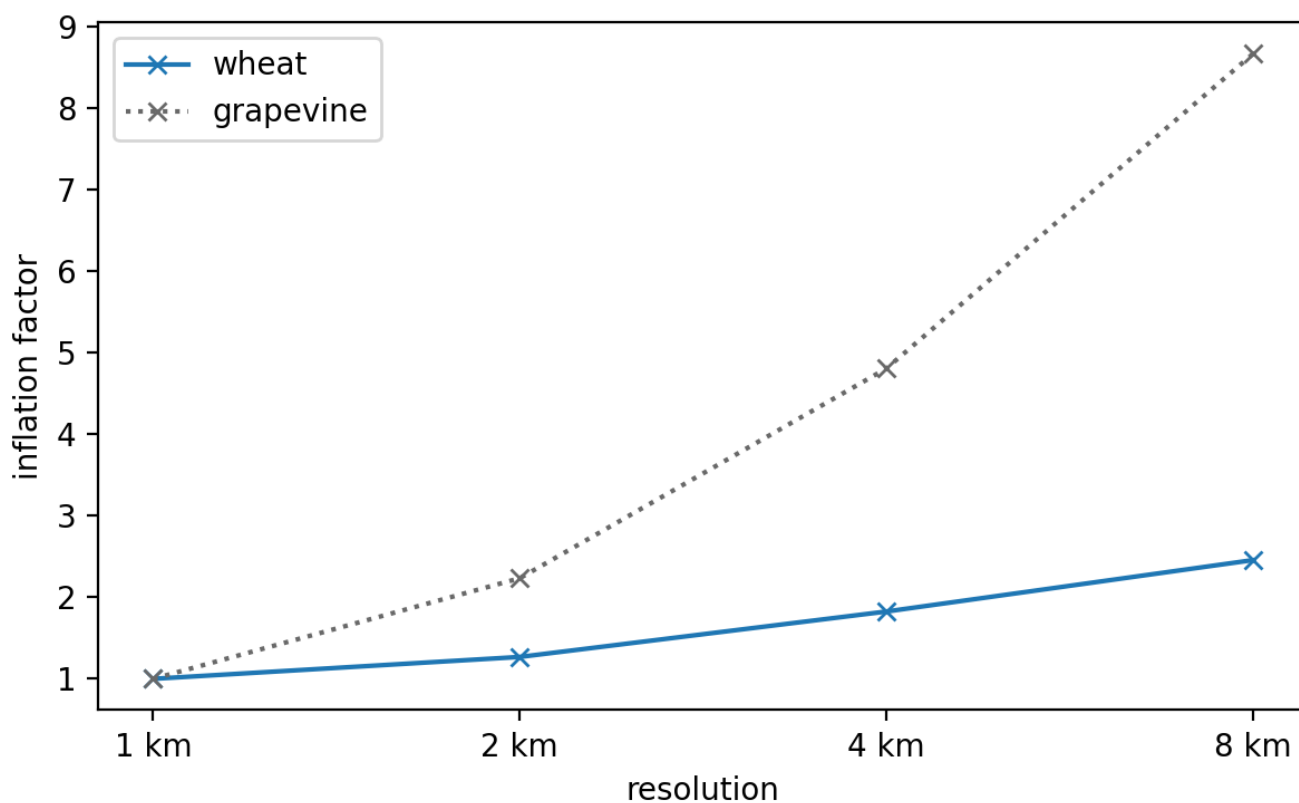

Figure A2. ~~Relative change of the Total~~ area covered by all exposure grid ~~points (inflation factor) as cells at~~ a ~~function of given~~ spatial resolution ~~relative to divided by the~~ area covered by all exposure grid cells at 1 km-km resolution (inflation factor) for wheat (blue) and grapevine (grey, dashed).

Figure A3. Change of the fraction of total number of fields included in the exposure as a function of n_{thresh} for (a) wheat (blue), maize (orange), rapeseed (green), barley (red), and field crops (black, dashed) at 8 km resolution and for (b) grapevine at 1 km resolution. In (b) the fraction of cropland area is also shown (dashed) because it deviates substantially from the fraction of fields for grapevine, but not crops shown in panel (a). The vertical bars denote the pragmatic choices of n_{thresh} (panel (a): 20, panel (b): 10) that avoid too high FAR but still includes a large fraction (>95%) of total exposed crop area / number of fields (see Fig. 67).
