Short summary

By directly analyzing the proximity of precipitation forecasts and observations, a precipitation forecast accuracy score (PAS) method was constructed. This method does not utilize traditional contingency table-based classification verification, can replace the threat score (TS), equitable threat score (ETS) and other skill score methods, and can be used to calculate the accuracy of numerical models or quantitative precipitation forecasts.

Abstract

With the development of refined numerical forecasts, problems such as score distortion due to the division of precipitation thresholds in both traditional and improved scoring methods for precipitation forecasts and the increasing subjective risk arising from the scale setting of the neighbourhood spatial verification method have become increasingly prominent. To address these issues, a general comprehensive evaluation method (GCEM) is developed for cross-scale precipitation forecasts by directly analyzing the proximity of precipitation forecasts and observations in this study. In addition to the core indicator of the precipitation accuracy score (PAS), the GCEM system also includes score indices for insufficient precipitation forecasts, excessive precipitation forecasts, precipitation forecast biases and clear/rainy forecasts. The PAS does not distinguish the magnitude of precipitation and does not delimit the area of influence; it constitutes a fair scoring formula with objective performance and can be suitable for evaluating rainfall events such as general and extreme precipitation. The PAS can be used to calculate the accuracy of numerical models or quantitative precipitation forecasts, enabling the quantitative evaluation of the comprehensive capability of various refined precipitation forecasting products. Based on the GCEM, comparative experiments between the PAS and threat score (TS) are conducted for two typical precipitation weather processes. The results show that relative to the TS, the PAS better aligns with subjective expectations, indicating that the PAS is more reasonable than the TS. In the case of an extreme precipitation event in Henan, China, two high-resolution models were evaluated using the PAS, TS, and fraction skill score (FSS), verifying the evaluation ability of PAS scoring for predicting extreme precipitation events. In addition, other indices of the GCEM are utilized to analyze the range and extent of both insufficient and excessive forecasts of precipitation, as well as the precipitation

45 forecasting ability for different weather processes. These indices not only provide overall scores
46 similar to those of the TS for individual cases but also support two-dimensional score distribution
47 plots, which can comprehensively reflect the performance and characteristics of precipitation
48 forecasts. Both theoretical and practical applications demonstrate that the GCEM exhibits distinct
49 advantages and potential promotion and application value compared to the various mainstream
50 precipitation forecast verification methods.

51

52 **1. Introduction**

53 Precipitation is one of the most important forecasting elements in weather forecasting (Bi et al.,
54 2016; Han et al., 2023). Short duration heavy rainfall often leads to flooding and geological disasters,
55 causing widespread and severe impacts (Zhong et al., 2022; Yang et al., 2023). Precipitation forecasts,
56 as focuses and challenges in meteorological department operations, have drawn widespread attention
57 from governments, societies and the public (Bi et al., 2016; Hao et al., 2023). Scientifically
58 evaluating precipitation forecasts helps people gain a clear understanding of the current precipitation
59 forecast levels and maintain appropriate psychological expectations for such forecasts. Moreover,
60 such evaluations assist forecasters in rationally analyzing the quality and characteristics of
61 quantitative precipitation forecast systems and aid researchers in understanding the level, strengths
62 and weaknesses of various types of forecasting systems, which in turn, offers valuable insights to
63 improve these systems (Zhong et al., 2022; Zhang et al., 2022; Liu et al., 2022b; Gofa et al., 2018).
64 However, there are several shortcomings in current precipitation verification approaches. For
65 instance, with traditional scoring methods, small errors in the location or timing of convective
66 features can lead to false alarms and missed events, and their utility is limited regarding diagnosing

67 model errors such as a displaced forecast feature or an incorrect mode of convective organization;
68 thus, traditional scoring methods often fail to reflect model performance improvements (Ahijevych et
69 al., 2009). For high-resolution precipitation forecasts, even if the spatial distribution and intensity of
70 precipitation are consistent with the observations, slight spatial and temporal deviations between
71 forecasts and observations may still result in a large false alarm ratio and missed alarm ratio, leading
72 to lower forecast scores (Zhao and Zhang, 2018). With the rapid development of seamless fine
73 quantitative precipitation forecasts, the need for objective and rational evaluations of the accuracy
74 and characteristics of precipitation forecasts has become increasingly important and urgent (Chen et
75 al., 2021).

76 Precipitation forecast verification involves various methods, including traditional contingency
77 table-based classification verification and spatial verification methods. The traditional verification
78 method can be traced back to 1884, when Finley introduced a dichotomous contingency table for
79 tornado forecasts and evaluated these forecasts using the proportion correct scoring method (Finley,
80 1884). Subsequently, systematic attention was given to the evaluation of forecast classification
81 methods, and Finley's forecast verification method became a classic example of the discussion of
82 forecast scoring methods (Murphy, 1996). Gilbert (1984) proposed two scoring methods, namely, the
83 ratio of verification and the ratio of success in forecasting. The ratio of verification later became
84 known as the threat score (TS) (Palmer and Allen, 1949) or the critical success index (Donaldson et
85 al., 1975; Mason, 1989). The ratio of success is referred to as the Gilbert skill score (GSS) (Schaefer,
86 1990) or the equitable threat score (ETS) (Doswell et al., 1990; Gandin and Murphy, 1992). The TS
87 encourages correct event forecasts (hits) and accounts for the impacts on the false alarm and missed
88 alarm ratios, which can better guide forecasters or research and development personnel in making

89 reasonable subjective and objective predictions compared to relying solely on simple “accuracy”.
90 Meanwhile, the ETS eliminates the influence of random forecasts on the score, resulting in a fairer
91 skill score (Liu et al., 2022a).

92 In addition to the TS and ETS, the methods of traditional contingency table-based classification
93 verification include Peirce skill score (PSS) (Peirce, 1884; Hanssen and Kuipers, 1965; Murphy and
94 Daan, 1985; Flueck, 1987), Heidke skill score (HSS) (Doolittle, 1885; Doolittle, 1888; Heidke,
95 1926), probability of detection (POD), frequency bias (BIAS), accuracy (ACC), false alarm ratio
96 (FAR), missing ratio (MR), probability of false detection (POFD), etc. The PSS is a fair score index
97 that is equal to the hit rate minus the false detection probability; the HSS eliminates the influence of
98 random forecasts, and the results can reflect the forecast skill (Liu et al., 2022a). Many studies have
99 reviewed and compared these two scoring methods (Doswell et al., 1990; Schaefer, 1990; Marzban,
100 1998; Mason, 2003). In extreme weather event verification (including severe convective weather
101 such as short duration heavy rainfall), the traditional scoring methods (such as the TS and ETS) for
102 dichotomous events often yield scores of zero when the occurrence probability of the object being
103 verified is very low. Therefore, Stephenson proposed the extreme dependency score (EDS) for
104 evaluating extreme events. The EDS has the advantage that different forecast systems converge to
105 different values and has no explicit dependence on the bias of the prediction system (Stephenson et
106 al., 2008; Casati et al., 2008).

107 It has been more than a century since Gilbert proposed two scoring concepts, i.e., the ratio of
108 verification and the ratio of success in forecasting (later known as the TS and ETS). The TS and ETS
109 have been widely used for the performance evaluation of threshold-based event forecasts despite
110 their evident shortcomings (Stephenson et al., 2008). Today, in various forecast verification

111 applications, including high-resolution quantitative precipitation and extreme weather forecast
112 verification, the TS and ETS remain mainstream approaches (Tang et al., 2017; Wei et al., 2019;
113 Chen et al., 2021; Liu et al., 2023). With the continuous introduction of new scoring methods, several
114 problems in traditional verification have been solved. However, the advantageous position of the TS
115 remains unchallenged. Although the reasons for this are varied, its objectivity and practicality merit
116 attention.

117 The traditional TS categorizes precipitation according to thresholds and performs verification
118 using a dichotomous contingency table. The TS can be viewed as a measure of forecast accuracy that
119 excludes hit forecasts for “non-occurrence” precipitation events (referred to as no precipitation), and
120 its calculation formula is simple, objective and standardized. However, there are two main
121 limitations of the TS. First, precipitation is categorized by thresholds based on the contingency table,
122 which has limitations in terms of classification. The drawback of artificially dividing precipitation
123 into different threshold ranges is that it cannot guarantee that two adjacent precipitation values will
124 always fall within the same threshold range. Slightly different precipitation values are not within the
125 same threshold, which can lead to precipitation score distortion. The second limitation is related to
126 the so-called “double penalty” issue. With the development of high-resolution numerical weather
127 forecasting and the shortening of the spacing between model grid points, some meso- and small-scale
128 phenomena have been portrayed by models. However, it is difficult for high-resolution numerical
129 forecasts to match the characteristics of the observed meso- and small-scale forecasts, resulting in
130 traditional scoring methods often cannot reflect these improvements in terms of model performance.
131 Assuming a constant forecast area, when there is a small deviation in the timing and location of
132 events between a forecast and an observation, both “false alarms” and “missed alarms” will occur,

133 which is referred to as the “double penalty” phenomenon. This phenomenon leads to a score lower
134 than the subjectively expected result, making it difficult to obtain appropriate verification scores
135 when a forecast that “looks good” is not as good as one that “looks bad” (Ahijevych et al., 2009;
136 Wilks, 2006; Ebert, 2008; Chen et al., 2021). For low-probability events with limited sample size for
137 verification, such as torrential rain and short-term heavy rainfall, the “double penalty” issue becomes
138 more prominent. The TS and ETS for torrential rain are often at the unskilled end of the scoring
139 values (Chen et al., 2019). In recent years, new mainstream scoring methods have addressed most of
140 the abovementioned limitations but still have shortcomings. Such methods include the improved
141 gradient decreasing method, which still results in poor scores for good forecasts, and the
142 neighbourhood spatial verification method, which has too many subjective components and may
143 miss meso- and small-scale information.

144 To address the limitations of threshold-based precipitation classification, and improve the
145 verification effect, e.g., the gradient decreasing method (hereinafter referred to as the magnitude-
146 improved TS) is used to verify the accuracy of rainstorm forecasts (Yang et al., 2017), and
147 appropriate weights are assigned to close forecast values to avoid scores of zero (Table 1). However,
148 the magnitude-improved TS still has limitations. For example, if the observed 24-hour accumulated
149 precipitation is 50 mm, when forecast A is 48 mm and forecast B is 98 mm, forecast A is evidently
150 better than forecast B. According to the original TS, forecast B scores 1 point, while forecast A does
151 not score any points. For the magnitude-improved TS, forecast B scores 1 point, as it still falls within
152 the same magnitude category as the observed precipitation, while forecast A scores only 0.4 points,
153 which still fails to reflect the fact that forecast A is superior to forecast B (Table 2). By employing the
154 new scoring method, i.e., the precipitation accuracy score (PAS), which will be discussed later,

155 forecast A scores 0.998 points, while forecast B scores 0.398 points, confirming the rationality and
156 validity of this new method.

157 To address the “double penalty” issue, a common approach is to employ the neighbourhood
158 spatial verification method (also known as the fuzzy method), which has two specific processing
159 forms. The first approach is simple upscaling, which uses a certain method (such as value averaging,
160 maximum, value weighting) to select values within the scale range (Chen et al., 2019), adjusting the
161 high-resolution forecast and observation information to a larger scale to reduce the accidental
162 information of high-resolution data, and then using the traditional skill score (Yates et al., 2006;
163 Weygandt et al., 2004). The other form is the improved neighbourhood spatial verification method
164 proposed by Roberts and Lean (2008). By referring to the Murphy skill score, this method obtains
165 comprehensive evaluation information by comparing the occurrence frequency (probability) of
166 precipitation within different scale windows. If the forecasted occurrence frequency closely
167 approximates the observed occurrence frequency, the forecast is considered valuable (Zhao and
168 Zhang, 2018). From the perspective of the precipitation occurrence probability within the analysis
169 region, the precipitation occurrence probability for observations and forecasts is the ratio of the
170 precipitation area to the analyzed area of the region, which is referred to as the fraction skill score
171 (FSS). These two processing methods effectively solve the “double penalty” problem, but neither can
172 address the issue of excessive smoothness of the precipitation fields during the upscaling process
173 (Zhao and Zhang, 2018), which may result in the omission of some small- to meso-scale information
174 (Zepeda-Arce et al., 2000).

175 The neighbourhood spatial verification method considers values that are spatially and
176 temporally adjacent between forecasts and observations during the matching process, thus relaxing

177 the strict requirements for spatiotemporal matching (Ebert, 2008; Casati et al., 2008). However, since
178 the determination of the neighbourhood range is a rather subjective process, it hinders the
179 standardization of verification scores and lacks comparability, which may negatively affect objective
180 quantitative verification. Numerous experiments have shown that there is an obvious improvement in
181 the scoring values after adopting the neighbourhood spatial verification method (Chen et al., 2019),
182 particularly for forecasts of large-magnitude precipitation. Nevertheless, the purpose of scoring is not
183 to achieve a monotonous increase in scoring values but rather to follow the principle of objectivity as
184 much as possible. Errors are errors and cannot be solved by simply lowering the standard. Instead,
185 reasonable and fair criteria should be utilized to reflect the true extent of errors.

186 Currently, numerical weather forecasts and intelligent gridded forecasts have been developed to
187 output high-resolution precipitation products, while precipitation observations, whether in the form
188 of gridded or station data, are already high-resolution. Staying at the dichotomous classification level
189 for precipitation verification not only wastes existing data resources but also fails to meet the
190 evaluation requirements of refined forecasts. Therefore, to adapt to the development of refined
191 forecasts, a new scoring method is needed. In light of this, a comprehensive verification index for
192 precipitation forecasts is designed, and the following five aspects are considered. (1) The impact of
193 categorical events on rainstorm forecasts should be reduced. In particular, high-resolution forecasts
194 can refer to continuous variables for scoring methods. Especially for the evaluation of
195 high-resolution precipitation forecasts, the scoring method of continuous variables can be borrowed
196 for reference. (2) The design of the scoring method should aim to minimize subjective factors such as
197 the artificial range division and condition settings, ensuring scoring objectivity and comparability. (3)
198 The designed scoring performance indices should possess ideal attributes such as fairness,

199 independent of climatological probability, suitability for extreme events, and boundedness as much
200 as possible. (4) The devised scoring method should be easy to promote, concise and efficient, with
201 clear concepts and scientific rationality. (5) Different comprehensive verification indices for
202 precipitation forecasts should reflect the forecasting performance and characteristics of
203 high-resolution quantitative precipitation products from various perspectives.

204 In this study, on the basis of analyzing the limitations of traditional verification methods as well
205 as improved methods, a new general comprehensive evaluation method (GCEM) for cross-scale
206 precipitation prediction is proposed. This method is applied and verified through practical examples.
207 The remainder of this paper is organized as follows. Section 2 provides an overview of various
208 scoring indices and their attributes in the GCEM and introduces the optimization processing method
209 for the PAS index in the application. Through ideal experiments, the characteristics of the scoring
210 methods are analyzed based on the score curves described in Section 3. Section 4 presents
211 comparative experiments, including the new scoring method, the traditional scoring method and the
212 neighbourhood spatial verification method based on typical cases. Finally, a summary and discussion
213 are presented in Section 5.

214 **2 Cross-scale general comprehensive evaluation method**

215 **2.1 Overview of the general comprehensive evaluation method**

216 To address the issues of “distorted scores due to the division of precipitation thresholds and
217 increased subjective risks brought about by the setting of the neighbourhood spatial verification
218 method” in traditional and improved precipitation scoring methods, this study refers to the
219 verification method for heavy rainfall forecasts based on predictability (Chen et al., 2019) and
220 combines the advantages of relative and absolute errors. A GCEM is constructed by directly

221 analyzing the proximity of forecasted precipitation to observed precipitation. It primarily includes
 222 the PAS, and the expression of its core scoring function is as follows:

$$223 \quad \text{PAS} = \begin{cases} \sin\left(\frac{\pi}{2} \cdot \frac{x}{u}\right), & 0 \leq x < u \\ e^{-\left(\frac{x-u}{u}\right)^2}, & 0 < u \leq x \end{cases} \quad (1)$$

224 where PAS represents the scoring value, x is the forecasted precipitation (mm), and u is the observed
 225 precipitation (mm). The PAS falls between 0 and 1, where a higher score indicates a better
 226 precipitation forecast effect. When $\text{PAS} = 1$, it signifies a perfect forecast, indicating that the
 227 forecasted and observed precipitation match entirely. For Eq. (1), given the observation value $u > 0$
 228 mm, when the forecasted precipitation is 0 mm, then $\text{PAS} = 0$, indicating that the model has no
 229 forecast skill. When the forecasted precipitation amount is sufficiently large, $\text{PAS} \rightarrow 0$, indicating no
 230 forecast skill as well (Fig. 1). Additionally, considering the large fluctuation characteristics of the
 231 function curve when the observed precipitation is less than 10 mm, Eq. (1) was smoothed and
 232 optimized (see Section 2.2 for details).

233 The GCEM system also includes the following indices:

234 (1) Insufficient precipitation index (IPI), whose core scoring function expression is as follows:

$$235 \quad \text{IPI} = \sin\left(\frac{\pi}{2} \cdot \frac{x}{u}\right) - 1, \quad 0 \leq x < u \quad (2)$$

236 where IPI represents the scoring value, reflecting the degree of underestimation in precipitation
 237 forecasts when the forecasted value is less than the observed value. The IPI falls within $[-1, 0)$,
 238 where a value closer to 0 indicates a lower degree of underestimation.

239 (2) Excessive precipitation index (EPI), whose core scoring function expression is as follows:

$$240 \quad \text{EPI} = 1 - e^{-\left(\frac{x-u}{u}\right)^2}, \quad 0 < u < x \quad (3)$$

241 where EPI represents the scoring value, reflecting the degree of overestimation in precipitation
 242 forecasts when the forecasted value exceeds the observed value. The EPI falls within (0, 1), where a
 243 value closer to 0 indicates a lower degree of overestimation.

244 (3) Insufficient and excessive precipitation index (IEPI), whose core scoring function
 245 expression is as follows:

$$246 \quad \text{IEPI} = \begin{cases} \sin\left(\frac{\pi}{2} \cdot \frac{x}{u}\right) - 1, & 0 \leq x < u \\ 1 - e^{-\left(\frac{x-u}{u}\right)^2}, & 0 < u \leq x \end{cases} \quad (4)$$

247 where IEPI represents the scoring value, reflecting the degree of deviation of the forecasted
 248 precipitation from the observed precipitation. The IEPI falls within [-1, 1), where a value closer to 0
 249 indicates a lower degree of forecast deviation. An IEPI less (more) than 0 indicates an insufficient
 250 (excessive) forecast, and an IEPI equal to 0 represents an unbiased forecast.

251 Additional explanation: Eqs. (2-4) are a series of theoretical indicator formulas derived from Eq.
 252 (1), therefore Eqs. (2-4) are referred as the core calculation formulas for the IPI, EPI, and IEPI,
 253 respectively. In practical applications, the optimized solution will be used (see Section 2.2) to
 254 calculate the IPI, EPI, and IEPI for the situations of $u \geq 0.1$ mm or $x \geq 0.1$ mm.

255 (4) The PAS clear/rainy forecast accuracy score (PASC), whose scoring function expression is
 256 as follows.

$$257 \quad \text{PASC} = \begin{cases} 1 & 0 \leq u < 0.1 \text{ and } 0 \leq x < 0.1 \\ \text{PAS}_{|u \times 0.1} & u \geq 0.1 \text{ or } x \geq 0.1 \end{cases} \quad (5)$$

258 where PASC represents the PAS scoring value for clear/rainy forecasts. “ $0 \leq u < 0.1$ and $0 \leq x <$
 259 0.1 ” denotes the correctly forecasted non-precipitation event with PASC=1. $\text{PAS}_{|u \times 0.1}$ denotes the
 260 overall PAS for precipitation forecasts under specific conditions where the observed precipitation $u \geq$
 261 0.1 mm or the forecasted precipitation $x \geq 0.1$ mm.

262 The discussion below pertains to the characteristics of the PAS scoring method. As an ideal
263 performance indicator, the PAS has the attributes of boundedness, fairness, sensitivity disparity,
264 suitability for extreme events and moderate symmetry.

265 (1) Boundedness. The PAS scoring values range between 0 and 1. A PAS score of 1 represents
266 an ideal forecast, while a score of 0 indicates that there is observed precipitation but no forecasted
267 precipitation or that the forecasted precipitation is sufficiently large. The scoring range is consistent
268 with that of traditional TS, making it easy to compare and evaluate the scoring methods and suitable
269 for practical forecast verification applications.

270 (2) Fairness. The PAS scoring method constitutes a scoring formula in an objective form
271 without a subjective boundary definition. Precipitation forecasts are verified without magnitude or
272 delimitation of the area of influence, and the closer to the observed situation the forecast is, the
273 higher the score, which is fair.

274 (3) Sensitivity disparity. According to the Chinese national standard GB/T 28592—2012
275 “Grade of precipitation” on the classification of precipitation grades, the public is more sensitive to
276 low-grade precipitation forecasts. As rainfall intensity increases, the public's sensitivity gradually
277 decreases; that is, the public has a higher tolerance for errors in response to heavier rainfall forecasts.
278 In other words, large errors in the forecasts of heavy rainfall events may be considered equivalent to
279 smaller errors in weaker rainfall events in terms of forecast scoring. As shown in Fig. 1, the
280 intersection point on the PAS scoring curves for the observed precipitation amounts of 25 mm and
281 100 mm corresponds to a forecasted amount of 42.4 mm. That is, the forecast errors are 17.4 mm and
282 57.6 mm for the observed 24-hour accumulated precipitation amounts of 25 mm and 100 mm,
283 respectively, while the scores are both 0.62. From the perspective of forecast service effectiveness,

284 this aligns with general public perception.

285 (4) Suitability for extreme events. From the PAS scoring curves for forecasts corresponding to
286 different observed precipitation amounts ($u = 10, 25, 50$ and 100 mm) (Fig. 1), it is evident that the
287 PAS scoring method performs well in evaluating precipitation event forecasts at the level of
288 torrential rain and above. For example, when the observed precipitation is 100 mm, with forecasted
289 amounts of 59 mm and 147.2 mm, the PASs are both 0.8 , whereas the TSs are 0 and 1 , and the
290 improved TSs are 0.8 and 1 , respectively. This result indicates that the PAS is suitable for scoring
291 heavy rainfall events, meeting the general applicability requirements as a scoring method that does
292 not degrade due to extreme events.

293 (5) Moderate symmetry. In Eq. (1), let the observed precipitation is the independent variable u ,
294 and the forecasted precipitation is the parameter x . Similarly, for different magnitudes of forecasted
295 precipitation (parameter $x = 10, 25, 50$ and 100 mm) and observed precipitation (variable u) ranging
296 from 0 to 300 mm, the corresponding scores are shown in Fig. 2. The scores also vary with the
297 degree of proximity between forecasts and observations. Figures 1 and 2 exhibit similar trends but
298 are not identical, illustrating that the PAS possesses moderate symmetry.

299 **2.2 PAS verification for precipitation forecasts**

300 From the properties of the core verification function of the PAS, it is noted that when the
301 observed precipitation $u < 10$ mm, there is a large gradient in the PAS curve. A slight change in the
302 forecasted value (x) can result in a large fluctuation in the PAS. To account for this characteristic,
303 based on a comprehensive analysis in combination with the sensitivity of forecasters and the public
304 to small-scale precipitation, a smoothing optimization scheme is applied to the PAS curve for
305 accumulated precipitation below 10 mm. Similarly, the IPI, EPI, IEPI and PASC curves are

306 appropriately smoothed and optimized according to their respective definitions.

307 Assumptions:

308 (1) $PAS = 0.6PAS|_{u \rightarrow 0}$ when $u = 0$ mm, and $x \neq 0$ mm;

309 $PAS|_{u \rightarrow 0}$ denotes the PAS for the case of observed precipitation $0 < u \leq 0.1$ mm;

310 (2) $PAS = 0.6PAS|_{x \rightarrow 0}$ when $x = 0$ mm, and $0 < u < 10$ mm;

311 $PAS|_{x \rightarrow 0}$ denotes the PAS for the case of forecasted precipitation $0 < x \leq 0.1$ mm.

312 1. When the observed precipitation $u = 0$ mm and the forecasted precipitation $x > 0$ mm (Fig.

313 3a), let $PAS = 0.6PAS|_{u \rightarrow 0}$, then,

$$314 \quad PAS = 0.6e^{-\left(\frac{x}{10}\right)^2} \quad x > 0 \quad (6)$$

315 2. When the forecasted precipitation $x = 0$ mm and the observed precipitation $0 < u < 10$ mm

316 (Fig. 3b), let $PAS = 0.6PAS|_{x \rightarrow 0}$, then,

$$317 \quad PAS = 0.6 \sin\left(\frac{\pi}{2} \cdot \frac{10-u}{10}\right), \quad 0 < u < 10 \quad (7)$$

318 The coefficient was set to 0.6. According to Eqs. (6-7), when the situation is the observation

319 $u=0$ mm and forecast $x=0.1$ mm or the observation $u=0.1$ mm and forecast $x=0$ mm, $PAS=0.6$,

320 suggesting that the forecast effect has just reached the standard, like when the ACC reaches 0.6,

321 which indicates that the model forecast effect is available (Zhao and Zhang, 2018).

322 3. When the observed precipitation $0 < u < 10$ mm and the forecasted precipitation $x \neq 0$ (Fig.

323 3c), then,

$$324 \quad PAS = \begin{cases} \sin\left(\frac{\pi}{2} \cdot \frac{x-u+10}{10}\right), & 0 < x < u, \quad 0 < u < 10 \\ e^{-\left(\frac{x-u}{10}\right)^2}, & u \leq x, \quad 0 < u < 10 \end{cases} \quad (8)$$

325 4. When the observed precipitation $u \geq 10$ mm (Fig. 3d), then

$$\text{PAS} = \begin{cases} \sin\left(\frac{\pi}{2} \cdot \frac{x}{u}\right), & 0 \leq x < u, \quad u \geq 10 \\ e^{-\left(\frac{x-u}{u}\right)^2}, & u \leq x, \quad u \geq 10 \end{cases} \quad (9)$$

327 To compare with the traditional scoring method, the new scoring method for precipitation
 328 forecasting adopts the “classification before verification, no classification during verification”
 329 approach. Scoring for precipitation processes over different accumulation periods is referenced but
 330 not limited to the commonly used precipitation classification approaches in practical operations, as
 331 shown in Tables 3-5.

322 **3 Ideal experimental validation of the new verification method**

333 **3.1 Validation of forecast scoring results for general precipitation**

334 General precipitation refers to precipitation ranging from light rain to heavy rain, i.e., 24-hour
 335 accumulated precipitation within [0.1 mm, 50 mm). Figure 4 shows the schematic diagram of PAS
 336 scores for general precipitation. The forecasted amounts are compared under conditions when the
 337 24-hour accumulated precipitation is 10 mm, 25 mm and 45 mm and the PAS scores are 0.8, 0.7, 0.5
 338 and 0.3 (Table 6). When the observed precipitation is 10 mm, the forecasted amounts of 5.9 mm and
 339 14.7 mm both have a PAS score of 0.8, with differences from the perfect forecast value (10 mm) of
 340 4.1 mm and 4.7 mm, respectively; the forecasted amounts with a PAS score of 0.3 are 1.9 and 21.0
 341 mm, differing by 8.1 mm and 11.0 mm from the perfect forecast value (10 mm), respectively. When
 342 the observed precipitation is 25 mm, the forecasted amounts with a PAS score of 0.8 are 14.7 mm
 343 and 36.8 mm, with differences from the perfect forecast value (25 mm) of 10.3 mm and 11.8 mm,
 344 respectively; the forecasts with a PAS score of 0.5 are 8.3 mm and 45.8 mm, differing by 16.7 mm
 345 and 20.8 mm from the perfect forecast value (25 mm), respectively.

346 For forecasts with the same observed precipitation and the same scores, the absolute errors of an

347 insufficient forecast and observation are smaller than those of an excessive forecast and observation,
348 and the higher the scores are, the closer the absolute errors of the forecasts. When the observed
349 precipitation is 50 mm, only the insufficient precipitation forecast is scored since a precipitation
350 forecast exceeding 50 mm is not considered within the scope of general precipitation evaluation. The
351 scoring experimental results align with expectations.

352 **3.2 Validation of forecast scoring results for precipitation at the level of torrential** 353 **rain and above**

354 Figure 5 shows a schematic diagram of the PASs when the amount of precipitation exceeds the
355 storm magnitude. The predicted precipitation is compared when the 24-hour cumulative observed
356 precipitation is 25 mm, 50 mm, and 100 mm with PAS scores of 0.877, 0.7, 0.5, 0.3, and 0.1 (Table
357 7). When the observed precipitation is 25 mm, only forecasts ≥ 50 mm are involved in the rating,
358 with PASs of 0.3 and 0.1 for forecasts of 52.4 and 62.9 mm, respectively.

359 When the PAS is 0.877 and the observed precipitation is 50 mm, the predicted values are 34.1
360 and 68.1 mm, respectively; when the observed precipitation is 100 mm, the predicted values are 68.1
361 and 136.2 mm, respectively. When the observed precipitation is 50 or 100 mm, the prediction is 68.1
362 mm, with a score of 0.877. The absolute error is 18.1 mm for the excessive precipitation forecast and
363 31.9 mm for the insufficient precipitation forecast. This result indicates that the scoring tolerance
364 increases as the grade of observed precipitation increases and gradually expands through continuous
365 changes, avoiding discontinuous increases caused by changes in magnitude.

366 When the observed precipitation is 50 mm and the PAS is 0.3, the insufficient forecast is 9.7
367 mm and the excessive forecast is 104.9 mm. When the observed precipitation is 100 mm, the
368 predictions for a PAS of 0.3 are 19.4 and 209.7 mm, respectively. When the observed precipitation is

369 50 mm, the insufficient forecast with a PAS of 0.1 is 3.2 mm, and the excessive forecast is 125.9 mm.
370 When the observed precipitation is 100 mm, the predictions with a PAS of 0.1 are 6.1 and 251.7 mm,
371 respectively.

372 Under constant observed precipitation conditions, for forecasts with the same score, the absolute
373 error between the insufficient forecast and the observed precipitation is smaller than that between the
374 excessive forecast and the observed precipitation. The higher the score is, the smaller the absolute
375 error between the forecast and the observation. Moreover, the scoring tolerance increases with
376 increasing observed precipitation. The scoring experimental results conform to expectations.

377 **4 Example-based comparative experiments for the new verification method**

378 Different examples are selected for the new precipitation verification method, and its
379 multifaceted characteristics are demonstrated through comparative experiments. In Section 4.1, two
380 typical cases are selected, the performance characteristics of the PAS and TS are compared, and the
381 indicators of insufficient and excessive forecasts and spatial verification in the GCEM are analyzed.
382 In Section 4.2, typical case of extreme precipitation event is selected, and the forecast results of
383 different high-resolution models using the PAS, TS, and FSS methods are evaluated to verify the
384 advantages and characteristics of the new precipitation verification method for extreme precipitation
385 events.

386 **4.1 Comparative experiments of two typical processes**

387 **4.1.1 Introduction of typical cases**

388 Comparative experiments of PAS and traditional TS are conducted for 12-hour accumulated
389 precipitation for two typical cases. One case pertains to the precipitation weather process occurring
390 during 00:00 to 12:00 UTC on 16 July 2019 (referred to as “Case 1”), which is dominated by a weak

391 weather system. The other case relates to the precipitation weather process occurring during 00:00 to
392 12:00 UTC on 13 June 2020 (referred to as “Case 2”), which is predominantly associated with a
393 strong weather system.

394 Both precipitation cases are associated with precipitation during the Meiyu period. Case 1,
395 which occurred during the Meiyu period of 2019 and was characterized by scattered precipitation
396 under weak synoptic-scale forcing. The low-intensity shear line system is located south of the
397 Yangtze River. There are two precipitation concentration areas, one at the intersection of Hunan
398 Province and Jiangxi Province and the other covering the majority of Zhejiang Province. The
399 precipitation process in Case 2 (12–13 June) was the first round of widespread rainstorms during the
400 Meiyu period of 2020, including heavy precipitation affected by a low-level vortex shear system.
401 The western section of the low-level vortex shear is relatively stable, while the eastern section
402 slightly presses southwards. Southwesterly airflow developed and pushed northwards, and a strong
403 wind speed belt persisted for a long time in the Jianghuai region. Moreover, the Jiangnan–Jianghuai
404 region maintained a high-energy and high-moisture state, resulting in persistent heavy rainfall.

405 A subjective analysis of these two weather processes reveals that for the event on 16 July 2019
406 (Fig. 6), the forecasted precipitation intensity and rainfall areas are relatively consistent with the
407 observations. There are two distinct heavy rainfall areas in the eastern and southern parts of the
408 Yangtze River, with particularly high accuracy in forecasting scattered rainstorms in Zhejiang
409 Province located in the eastern section. In contrast, for the precipitation weather process on 13 June
410 2020 (Fig. 7), it is evident that there is an overestimation of the precipitation forecast.

411 **4.1.2 Data and methods**

412 The observed precipitation data are provided by the China Meteorological Administration

413 multisource merged precipitation analysis system (CMPAS), developed by the National
414 Meteorological Information Centre of China. The CMPAS integrates hourly precipitation data from
415 nearly 40,000 automatic meteorological stations in China and provides radar-based quantitative
416 precipitation estimation and satellite-retrieved precipitation products with a spatial resolution of
417 $0.05^\circ \times 0.05^\circ$. The predicted precipitation data with 3 km resolution are from the Precision Weather
418 Analysis and Forecasting System (PWAFS) model, a regional refined forecast model, developed by
419 the Jiangsu Provincial Meteorological Bureau. These data are output once per hour.

420 The specific methods are as follows.

421 (1) Determine the verification domain and verification points. The verification domain covers
422 the Huang–Huai region of China (28°N - 38°N , 111°E - 123°E). The verification points are defined
423 based on the grid points of the observed precipitation data, their spatial resolution is $0.05^\circ \times 0.05^\circ$,
424 and the total number of verification grid points is 48,000 (200×240).

425 (2) Prepare the observed and forecasted precipitation data and interpolate the forecasted
426 precipitation data onto the observed grid points. The observed 12-hour accumulated precipitation
427 data are derived by accumulating the hourly precipitation data from the CMPAS. The forecasted
428 12-hour accumulated precipitation data are obtained by subtracting the zero-field data from the
429 12-hour forecast field data. Since the grid points of the observed and forecasted precipitation data do
430 not coincide and the grid spacing is small, the nearest neighbour method is used in this study to
431 match the forecasted data to the grid points of the observed precipitation. Specifically, the forecasted
432 data on the model grid nearest to the observed grid are used as the forecasted value at this observed
433 grid.

434 (3) Analyze the relationship between the forecasted precipitation and observed precipitation.

435 The scores for each verification grid point and the overall scores for each verification area are
436 calculated based on the scoring formula for each index in the GCEM system. Then, the verification
437 result file is generated in NetCDF format. On this basis, distribution maps for the scores of various
438 indices in the GCEM system are produced. Additionally, the total TS and clear/rainy TS for different
439 precipitation magnitudes within the verification area are calculated based on the TS and clear/rainy
440 TS formulas.

441 **4.1.3 Analysis of the comparative experiment results**

442 For the precipitation process on 16 July 2019, the traditional TSs for different rainfall
443 categories, such as clear/rainy and 12-hour accumulated precipitation ≥ 0.1 mm, ≥ 10 mm, ≥ 25 mm
444 and ≥ 50 mm, are all lower than the traditional TSs for the weather process on 13 June 2020. For
445 example, the TS is 0.381 for 12-hour accumulated precipitation ≥ 0.1 mm during 00:00 to 12:00
446 UTC on 16 July 2019 (Table 8), while this score is 0.625 for that during 00:00 to 12:00 UTC on 13
447 June 2020 (Table 9), which differs from the subjective judgement.

448 For the precipitation process during 00:00 to 12:00 UTC on 16 July 2019, the PASs for
449 clear/rainy and 12-hour accumulated precipitation ≥ 0.1 mm, ≥ 10 mm and ≥ 25 mm are all higher
450 than those for the precipitation process during 00:00 to 12:00 UTC on 13 June 2020. For instance,
451 the overall PAS is 0.617 for 12-hour accumulated precipitation ≥ 0.1 mm during 00:00 to 12:00 UTC
452 on 16 July 2019. This PAS is higher than the PAS of 0.457 for the precipitation process during 00:00
453 to 12:00 UTC on 13 June 2020, which aligns with subjective judgement.

454 For the precipitation process during 00:00 to 12:00 UTC on 16 July 2019, the PAS for each
455 magnitude is higher than the corresponding TS, addressing the issue of TSs being lower. For the
456 precipitation process during 00:00 to 12:00 UTC on 13 June 2020, the PASs for clear/rainy and the

457 magnitudes of ≥ 0.1 mm and ≥ 10 mm are lower than the corresponding TSs, whereas the PASs for
458 the magnitudes of ≥ 25 mm and ≥ 50 mm are higher than the corresponding TSs. This result indicates
459 that the PAS is different from the magnitude-improved TS and the neighbourhood spatial verification
460 method. Both the magnitude-improved TS and the neighbourhood spatial verification method
461 increase the tolerance, leading to a monotonous increase in scores. This result also demonstrates that
462 the PAS has good discrimination ability for extreme events. The PAS assigns scores based on the
463 proximity of the forecast to the observation, making it more reliable for precipitation evaluation than
464 the TS.

465 **4.1.4 Analysis of the indices in the new verification method**

466 Modern forecast verification is based mainly on spatial verification methods to compensate for
467 the shortcomings of traditional methods. The literature review of Gilleland et al. (2009) defines four
468 main categories of methods: neighbourhood, scale separation, features based, and field deformation
469 (Ahijevych et al., 2009). These methods can analyze more comprehensively in specific individual
470 cases, but seem to be less able to provide direct overall scoring results than traditional scoring
471 methods in the statistics of long time series. GCEM is based on point-to-point scoring statistics,
472 without a radius of influence, no isolation of features at each scale, and no definition of objects in the
473 forecast and observation to analyze the similarity of the objects or to fit the forecast objects through
474 deformation operations. However, the GCEM still has spatial attributes that can discriminate spatial
475 forecast characteristics (e.g., insufficient or excessive forecasting scenarios) for different categories
476 of precipitation, and the GCEM can carry out statistical verification of long time series and produce
477 overall scoring results.

478 Regarding the issue of analyzing the sources of errors from the verification results, objectively

479 tracing these errors back from a single score can only determine whether an error was “insufficient
480 (missed alarm)” or “excessive (false alarm)”. However, the advantage of the GCEM lies in its ability
481 to decompose the score for each verification point and examine the forecasting performance at each
482 point, which is different from the dichotomous evaluation approach with only 0 and 1 outputs. These
483 indices not only provide overall scores for individual cases similar to the TS but also offer
484 two-dimensional score distribution plots, which can comprehensively reflect the performance and
485 characteristics of precipitation forecasts.

486 Figure 8 shows the distributions of the 12-hour accumulated precipitation PASC scores. In these
487 two cases, due to the high accuracy of non-precipitation forecasts, the overall PASC scores are
488 relatively high. However, for Case 1, the scores in Zhejiang are lower and scattered within a small
489 area. In contrast, for Case 2, there is a large area occupying most of the Jianghuai region with low
490 scores. Therefore, the PASC score of Case 1 (0.808) is higher than that of Case 2 (0.734).

491 Figure 9 shows the PAS distributions of 12-hour accumulated precipitation with magnitudes of
492 ≥ 0.1 mm, ≥ 10 mm and ≥ 25 mm. The blank points in the figure are the points that are excluded in
493 the scoring, following the scoring principle of “classification before verification, no classification
494 during verification” described in Section 2. From the PAS distributions of different magnitudes, for
495 Case 1, the high and low scores in the Zhejiang region are scattered among them. In contrast, for
496 Case 2, the scoring areas in the Jianghuai region have a larger area of low scores than high scores.
497 Therefore, Case 1 has higher PASs for the three categories (≥ 0.1 mm, ≥ 10 mm and ≥ 25 mm) than
498 Case 2, and the distributions also allow for distinguishing the areas with better and worse forecasting
499 performance.

500 Figure 10 shows the IPI, EPI and IEPI distributions of 12-hour accumulated precipitation. In

501 terms of the IPI, for Case 1, the large-value IPI areas are located at the intersection of Anhui,
502 Zhejiang and Jiangxi, in the Hunan-Jiangxi region, as well as in the southern part of Hebei. For Case
503 2, the large-value IPI areas are situated along the Yangtze River in Anhui and Jiangxi, as well as at
504 the intersection of Henan and Shanxi. The IPIs for Case 1 and Case 2 are -0.376 and -0.400,
505 respectively, indicating that Case 2 shows a slightly higher level of insufficient forecasts (Table 10).
506 In terms of the EPI, for Case 1, the large-value EPI areas are in Zhejiang and Jiangxi. In contrast, for
507 Case 2, the large-value EPI areas are located in most of Hunan, Hubei, Anhui and Jiangsu, exhibiting
508 a wide southwest–northeast orientation with a large area and degree. The EPI for Case 2 is larger
509 than that for Case 1. The IEPI is a comprehensive reflection of under- and over- precipitation, and its
510 value reflects the degree of insufficient and excessive precipitation forecasts. From the distributions
511 of insufficient and excessive precipitation forecasts in Case 1, it is evident that the insufficient and
512 excessive forecasts are roughly equivalent, with an IEPI of 0.057. However, for Case 2, the
513 distribution of the excessive forecasts is obviously larger than that of the insufficient forecasts, with
514 an IEPI of 0.325. This result indicates that Case 2 has poorer forecasting performance, with larger
515 excessive forecasts being an important factor.

516 Consequently, analyzing the locations of insufficient and excessive precipitation forecasts from
517 the figures in conjunction with the characteristics of the forecasting process can provide useful
518 insights for improving forecasts.

519 **4.2 Comparison experiment of extreme rainfall events**

520 **4.2.1 Introduction of the “21.7” extreme rainstorm event in Henan, China**

521 From 17 to 23 July 2021, a rare extreme rainstorm event occurred in Henan Province, China.
522 The extremely heavy rainstorm started in the southeastern of Henan Province in the morning of 17

523 July, then extended to the northern region, and ended in the morning of 23 July, lasting more than 6
524 days. The rainstorm occurred against the background of typhoon, Huang-Huai vortex, shear line and
525 convergence line, and was caused by the coupling of the low-level jet and boundary layer jet,
526 combined with the uplift of terrain (Wang et al., 2022; Su et al., 2021; Shi et al., 2021).

527 The period from 00:00 UTC on 18 July to 00:00 UTC on 22 July 2021 is the concentrated
528 period of heavy precipitation. To facilitate the study, the heavy rainstorm process is divided into three
529 periods: (1) 00:00 UTC on 19 July - 00:00 UTC on 20 July 2021. (2) 00:00 UTC on 20 July - 00:00
530 UTC on 21 July 2021. (3) 00:00 UTC on 21 July - 00:00 UTC on 22 July 2021. (Figs. 11a-c).

531 **4.2.2 Data and methods**

532 The observed precipitation data are provided by the CMPAS, with a spatial resolution of $0.05^\circ \times$
533 0.05° , similar to the case in Section 4.1. The forecast data come from two models. One is the PWAFS
534 model, which has a horizontal resolution of 3 km, similar to the case in Section 4.1. The other is the
535 global-regional assessment and prediction system (GRAPES) model independently developed by the
536 China Meteorological Administration, which has a horizontal resolution of 3 km.

537 (1) Determine the verification domain and verification points. The verification domain covers
538 the region of (30°N - 40°N , 107.5°E - 117.5°E). The verification points are defined based on the grid
539 points of the observed precipitation data, their spatial resolution is $0.05^\circ \times 0.05^\circ$, and the total
540 number of verification grid points is 40,401 (201×201).

541 (2) Prepare the observed and forecasted precipitation data and interpolate the forecasted
542 precipitation data onto the observed grid points. The 24-hour cumulative precipitation observation
543 data of the three periods were obtained from the 24-hour precipitation data of the CMPAS. The
544 forecast precipitation data in the three periods are the cumulative precipitation with a forecast time of

545 12 to 36 hours. For the case described in Section 4.1, the nearest neighbour method is used to match
 546 the forecast data to the grid points of the observed precipitation.

547 (3) Analyze the relationship between the forecasted precipitation and observed precipitation.
 548 PAS, TS and FSS were compared for the extreme rainstorm event in Henan, China.

549 As mentioned earlier, the FSS belongs to the neighbourhood category of spatial verification
 550 methods and is an advanced evaluation method widely used in recent years. It can still yield valuable
 551 scores when the model prediction intensity is spatially biased and can also represent the scale
 552 information of forecasting skills. Therefore, in this case, the FSS scoring method was added for
 553 comparative experiments. For FSS verification, 15 km, 25 km, 45 km, 75 km and 120 km are used as
 554 the neighbourhood distances.

555 The brief steps of FSS calculation are as follows: 1. Determine the domain scope. Set the
 556 neighbourhood point n , such as when $n=3$ (n is odd), the neighbourhood range is $15 \text{ km} \times 15 \text{ km}$, 2.
 557 Calculate the spatial density in the observed binary observation fields (Eq.10), 3. Calculate the
 558 spatial density in the binary forecast fields (Eq.11), 4. Calculate $FSS_{(n)}$ (Eq.12). (Please refer to the
 559 article of Roberts and Lean (2008) for details.)

$$560 \quad O_{(n)}(i, j) = \frac{1}{n^2} \sum_{k=1}^n \sum_{l=1}^n I_o \left[i + k - 1 - \frac{n-1}{2}, j + l - 1 - \frac{n-1}{2} \right] \quad (10)$$

$$561 \quad M_{(n)}(i, j) = \frac{1}{n^2} \sum_{k=1}^n \sum_{l=1}^n I_M \left[i + k - 1 - \frac{n-1}{2}, j + l - 1 - \frac{n-1}{2} \right] \quad (11)$$

$$562 \quad FSS_{(n)} = 1 - \frac{\frac{1}{N_x N_y} \sum_{i=1}^{N_x} \sum_{j=1}^{N_y} [O_{(n)ij} - M_{(n)ij}]^2}{\frac{1}{N_x N_y} \left[\sum_{i=1}^{N_x} \sum_{j=1}^{N_y} O_{(n)ij}^2 + \sum_{i=1}^{N_x} \sum_{j=1}^{N_y} M_{(n)ij}^2 \right]} \quad (12)$$

563 where i ranges from 1 to N_x , N_x is the number of columns in the domain and j ranges from 1 to N_y ,
 564 N_y is the number of rows. I_o and I_M are binary fields. $O_{(n)}(i, j)$ is the resultant field of observed
 565 fractions for a square of length n . $M_{(n)}(i, j)$ is the resultant field of model forecast fractions obtained.

566 4.2.3 Analysis of the comparative experiment results

567 (1) Questionnaire survey of the effectiveness of model forecasting

568 Fifty-two questionnaires were completed by 32 researchers and 20 forecasters. The names of the
569 PWAFS and GRAPES models used for comparison were omitted and replaced with Model 1 and
570 Model 2, respectively.

571 The survey results show that 52 people believe that the forecasting effect of periods A and C of
572 Model 2 (GRAPES) is good, 19 people believe that the forecasting effect of period B of Model 1
573 (PWAFS) is good, and 33 people believe that the forecasting effect of period B of Model 2
574 (GRAPES) is good. Fifty-two people think that Model 2 (GRAPES) is good in general.

575 (2) Indices analysis and comparison between the two models

576 The high-resolution regional models used for evaluation are (1) PWAFS 3km and (2) GRAPES
577 3km, and the modelled precipitation is the accumulated precipitation of 24 hours in the forecast
578 12-36 hours. The evaluation results are as follows (Tables 11-16):

579 The results show that in this process, the evaluation results of different methods on the forecast
580 skill of the PWAFS and GRAPES models are basically consistent and in line with the subjective
581 evaluation statistical results. However, PAS scores have obvious advantages in the evaluation of
582 rainstorms and above, especially extreme rainstorms. It can be seen from the six rating scales that the
583 TS and FSS have almost no ability to evaluate precipitation above 250 mm, and the scores are
584 generally at the unskilled end of 0 and no more than 0.2 (Chen et al., 2019). The PAS scores can also
585 distinguish differences and provide different scores for situations where the forecasting effect is
586 good.

587 For example, when evaluating precipitation above 250 mm, the scores of TS for PWAFS in all
588 three periods are 0.000, and the scores of GRAPES in the three periods are 0.000, 0.045 and 0.044.

589 The scores of FSS (45 km) for the PWAFS in all three periods are 0.000, and the scores of GRAPES
590 in the three periods are 0.000, 0.218 and 0.137, respectively. This indicates that the TS and FSS (45
591 km) have little ability to assess the heavy rainfall of this process.

592 The PAS scores for PWAFS in the three periods are 0.229, 0.302 and 0.153, and those for
593 GRAPES in the three periods are 0.338, 0.637 and 0.528, indicating that PAS has the ability to
594 evaluate heavy rainstorms (above 250 mm) in this process. The evaluation results show that
595 GRAPES is superior to PWAFS in predicting heavy rainfall.

596 The evaluation capabilities of PAS, TS, and FSS for precipitation above 100 mm are further
597 analyzed. The scores of TS for the PWAFS (GRAPES) are 0.035, 0.257, and 0.042 (0.178, 0.451,
598 and 0.284) in the three periods, respectively. The scores of FSS (45 km) are 0.129, 0.550, and 0.103
599 (0.432, 0.767, and 0.613) for the PWAFS (GRAPES) in the three periods, respectively. The
600 evaluation effect of FSS (45 km) is better than that of TS. The evaluation feature of FSS is to
601 examine the predictability scale of the model to reflect its predictive ability; however, due to the
602 subjectivity of selecting neighbourhood scales, its score lacks comparability. While the PAS scores
603 are 0.246, 0.492 and 0.253 (0.573, 0.581 and 0.492) for the PWAFS (GRAPES) in the three periods,
604 it can be seen that the PAS also has a good ability to assess heavy rainstorms in this process.

605 In small-magnitude precipitation (above light and moderate rain) verification, the FSS scores
606 tend to approach 1 as the neighbourhood distance expands, making it difficult to compare forecast
607 differences between models. The PAS scores can also distinguish the differences in forecast
608 effectiveness for small-magnitude precipitation.

609 In conclusion, different scoring methods were used to evaluate the skill of different models to
610 predict extreme precipitation events in July 2021 in Henan, China, and the evaluation characteristics

611 of different scoring methods were indicated. The results show that the PAS scoring method has
612 obvious advantages in the evaluation of extreme precipitation events and can also reflect the
613 differences in the small magnitude precipitation forecasting effects of the models well compared to
614 those of the TS and FSS methods.

615 **5 Discussion and conclusion**

616 By analyzing the advantages and disadvantages of the traditional TS, magnitude-improved TS
617 and neighbourhood spatial verification methods, a new precipitation verification method, GCEM,
618 was designed and constructed from the perspective of the proximity of the forecast to the observation.
619 This method consists of the core indicator of the PAS, as well as multiple indicators such as IPI, EPI,
620 IEPI and PASC.

621 The PAS index consists of sine and e-exponential functions. Additionally, considering the
622 characteristics of large fluctuations in the function curves when observed precipitation is less than 10
623 mm, the formula has been smoothed for optimization. The PAS method adopts the principle of
624 “classification before verification, no classification during verification”, which can serve as an
625 alternative to skill scores such as the TS and ETS for verifying quantitative precipitation forecasts.
626 This method is characterized by objective and transparent rules and easy generalization. Moreover,
627 this approach possesses attributes of an ideal precipitation scoring method, such as fairness,
628 boundedness and moderate symmetry. Therefore, it can be used to calculate the accuracy of
629 numerical models or quantitative precipitation forecasts, as well as evaluate the comprehensive
630 forecasting capabilities of various refined quantitative precipitation forecast products. The GCEM
631 can also evaluate the performance of numerical forecasts on clear/rain forecasts, as well as
632 insufficient precipitation forecasts, excessive precipitation forecasts and precipitation forecast biases.

633 In addition to the overall score, two-dimensional score distribution maps can be generated for each
634 index in the GCEM system. These maps offer a comprehensive reflection of the precipitation
635 forecasting performance of the numerical models and serve as a reference for improving model
636 forecasts.

637 This new verification method is validated based on the forecast scoring results for general
638 precipitation and precipitation at the level of torrential rain and above, and the verification results
639 align with expectations. Comparative experiments are also conducted on two typical processes using
640 the new verification method. For Case 1, the subjective judgement is relatively good, but the TS is
641 lower. Conversely, for Case 2, the subjective judgement is poorer, yet the TS is higher. Verification
642 using the PAS reveals that forecasts with better subjective judgement receive higher scores, and
643 forecasts with poorer subjective judgement receive lower scores. Therefore, PAS aligns with public
644 expectations.

645 The PAS, TS and FSS methods were used to compare and verify the “21.7” extreme
646 precipitation event in Henan, China, to reflect the evaluation characteristics of different scoring
647 methods. The results show that the PAS scoring method can not only reflect the difference in the
648 small-magnitude precipitation forecast effect of models, but also has obvious advantages in the
649 evaluation of extreme precipitation events.

650 In addition, the National Meteorological Centre of China conducted long-term series large-scale
651 sample testing on this method in 2023. Based on the ECMWF model’s 24-hour and 48-hour
652 precipitation forecasts from March 2022 to February 2023, the assessment results show that
653 compared to the TS, the PAS is less affected by the randomness of the sample, and the relative size
654 relationship of different time forecast scores is more stable.

655 From the construction of the GCEM to ideal experiments and case analysis, it is evident that
656 this evaluation system, especially the PAS method, is a suitable method for quantitative precipitation
657 evaluation. However, the PAS still has subjective flaws, such as the determination of coefficients in
658 the PAS expression [0.6 in Eqs. (6) and (7)] when the observed or forecasted precipitation is 0 mm.
659 Once these coefficients are determined, they apply to all precipitation scoring, thus becoming an
660 objective component in practice.

661 **Code and data availability.** The source code and data of this work can be found at
662 <https://doi.org/10.5281/zenodo.10951799> (Zhang et al., 2024). The readme file can be found at
663 <https://doi.org/10.5281/zenodo.10951799> (Zhang et al., 2024), which includes the compiling
664 environment and steps to repeat this work, as well as other relevant content descriptions (code, data,
665 output files, module code main interfaces, etc.).

666 **Author contributions.** BZ designed the evaluation method, completed the experiments, and wrote
667 the paper. MZ provided advice on the planning and application of the evaluation method. AH
668 provided suggestions for the evaluation method and contributed to paper revisions, ZQ contributed to
669 paper revisions, and CL provided long-term series large-scale sample comparison test results for the
670 evaluation method. All authors discussed the results and commented on the paper.

671 **Competing interests.** The contact author has declared that none of the authors has any competing
672 interests.

673 **Disclaimer.** Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional
674 claims made in the text, published maps, institutional affiliations, or any other geographical
675 representation in this paper. While Copernicus Publications makes every effort to include appropriate
676 place names, the final responsibility lies with the authors.

677 **Acknowledgements.** This study was supported by grid precipitation analysis data, forecasted
678 precipitation data and numerical computing capabilities provided by the Jiangsu Provincial
679 Meteorological Bureau of China, as well as long-term series large-scale sample testing conducted at
680 the National Meteorological Centre of China.

681 **Financial support.** This research is supported by the National Key Research and Development
682 Program of China under Grant 2021YFC3000904, the Beijige Open Research Fund under Grant
683 BJG202403 and the Jiangsu Collaborative Innovation Center for Climate Change.

862

863

864 **Figure 1.** Schematic diagram of the precipitation forecast accuracy score (PAS) curves when the observed
 865 precipitation amounts are 10, 25, 50 and 100 mm.

866

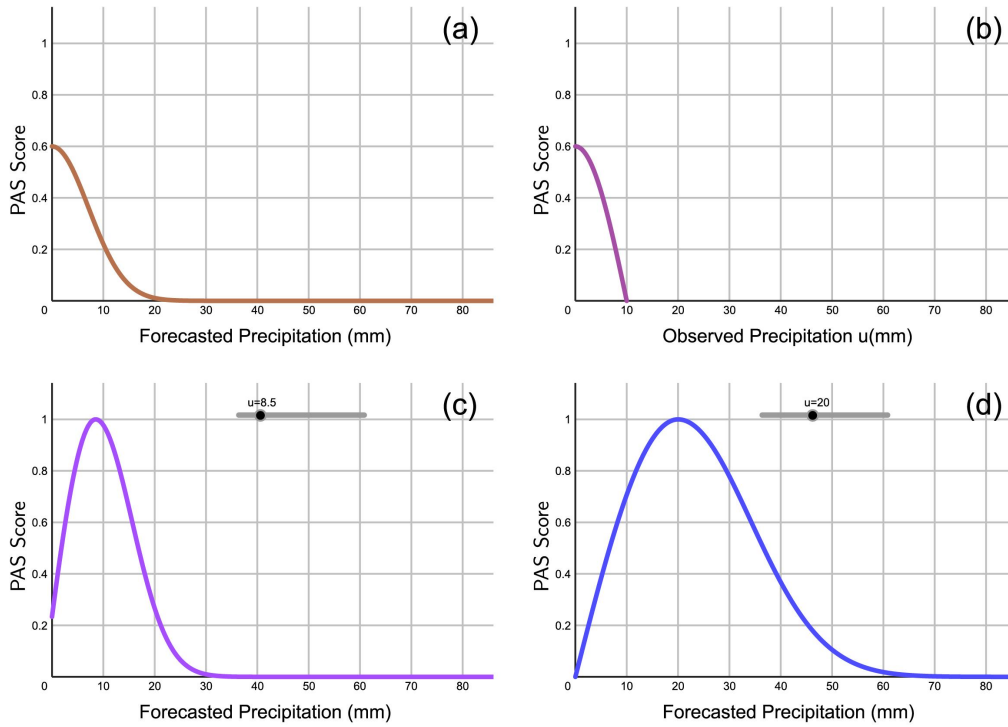

867

868

869 **Figure 2.** PAS curves corresponding to different forecasted precipitation amounts ($u = 10, 25, 50$ and 100 mm).

870

871

872 **Figure 3.** PAS curves of precipitation forecasts when (a) the observed precipitation $u = 0$ mm and the forecasted

873 precipitation $x > 0$ mm, (b) the observed precipitation $0 < u < 10$ mm and the forecasted precipitation $x = 0$ mm

874 (the horizontal coordinate denotes the observed precipitation u), (c) the observed precipitation $0 < u < 10$ mm and

875 the forecasted precipitation $x > 0$ mm, and (d) the observed precipitation $u \geq 10$ mm.

876

877

878

879 **Figure 4.** PAS curves of the forecasts under general precipitation conditions ($u = 10, 25$ and 45 mm). The solid line

880 part of the curve in the figure is involved in the comparison, the dashed line part is not involved in the comparison,

881 10 mm observed precipitation is represented by the orange line, 25 mm observed precipitation is represented by the

882 blue line, 45 mm observed precipitation is represented by the red line, and 50 mm observed precipitation is
 883 represented by the green line.

884

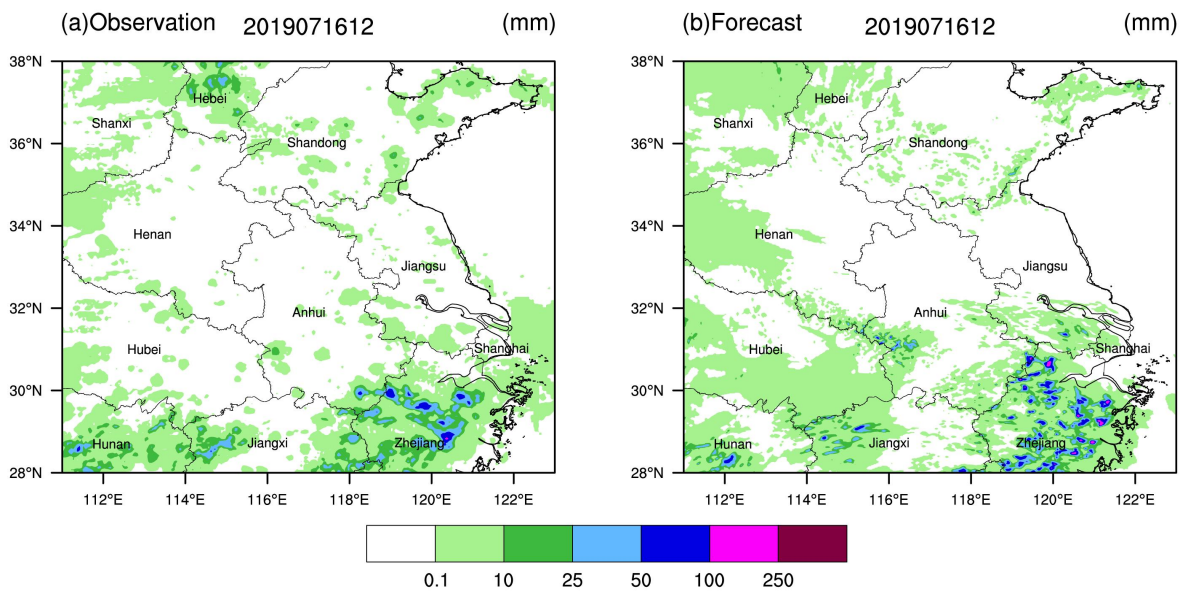

885

886 **Figure 5.** Same as Fig. 4, but for precipitation at the level of torrential rain and above ($u = 25, 50$ and 100 mm).

887 The solid line part of the curve in the figure is involved in the comparison, the dashed line part is not involved in
 888 the comparison, 10 mm observed precipitation is represented by the orange line, 25 mm observed precipitation is
 889 represented by the blue line, 50 mm observed precipitation is represented by the green line, and 100 mm observed
 890 precipitation is represented by the red line.

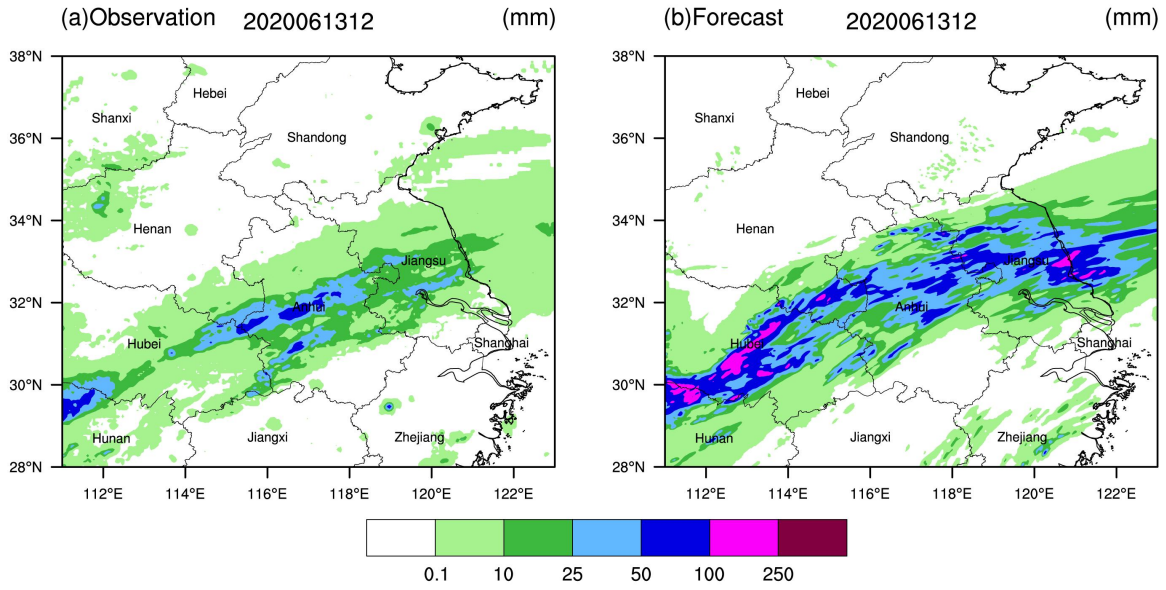

891

892
