Abstract: China has long-term high $PM_{2.5}$ levels, and its Oxidative Potential (OP) is worth studying as it may unravel the impacts of aerosol pollution on public health better than $PM_{2.5}$ alone. OP and $PM_{2.5}$ are influenced by meteorological factors, anthropogenic emissions sources and atmospheric aging. Although their impact on $PM_{2.5}$ have been studied, OP measurements only recently became available and on a limited scale, as they require considerable technical expertise and resources. For this, the joint relationship between $PM_{2.5}$ and OP for a wide range of meteorological conditions and emissions profiles remain elusive. Towards this, we estimated $PM_{2.5}$ and OP over China using the Danish Eulerian Hemispheric Model (DEHM) system with meteorological input from WRF weather forecast model. It was found that higher values of $PM_{2.5}$ and OP were primarily concentrated in urban agglomerations in the central and eastern regions of China, while lower values were found in the western and northeastern regions. Furthermore, the probability density function revealed that about 40% of areas in China had an annual average $PM_{2.5}$ concentrations exceeding the Chinese concentrations limit; 36% of the regions have OP below $1 \text{ nmol min}^{-1} \text{ m}^{-3}$, 41% have OP between 1 and $2 \text{ nmol min}^{-1} \text{ m}^{-3}$, and 23% have OP above $2 \text{ nmol min}^{-1} \text{ m}^{-3}$. Analysis of the simulations indicate that meteorological conditions and anthropogenic emission contributed 46% (65%) and 54% (35%) to the $PM_{2.5}$ concentration (OP) variability. The emission sensitivity analysis also highlighted $PM_{2.5}$ and OP levels are mostly determined by secondary aerosol formation and biomass burning.

Keywords: $PM_{2.5}$; Oxidative potential; Meteorology; Anthropogenic emission sources; Probability density function

1. Introduction

Fine particulate matter, with an aerodynamic diameter of less than 2.5 μm ($\text{PM}_{2.5}$), is the primary atmospheric pollutant in China (Chen et al., 2021; Chen et al., 2021; Liu et al., 2023) with respect to human health. $\text{PM}_{2.5}$ exposure in China for 2017 resulted in an estimated 1.8 (95% CI: 1.6, 2.0) million premature deaths (Liu et al., 2021). Many recent studies have suggested that the oxidative potential (OP) of $\text{PM}_{2.5}$ (the ability of $\text{PM}_{2.5}$ to produce reactive oxygen species (ROS) to *in-vitro* that consume intracellular antioxidants; (Campbell et al., 2021)) may better explain the negative impact of $\text{PM}_{2.5}$ exposure on human health than the well-established metric of mass concentrations (Yu et al., 2019; Gao et al., 2020). This is because exposure to high levels of OP (from compounds such as quinones and soluble transitional metals) induces an excess production of ROS in cells and lead to oxidative stress (OS) effects and ultimately trigger inflammation and disease. Therefore, reducing $\text{PM}_{2.5}$ pollution and its associated OP (the volume-normalized dithiothreitol activity) are critical to addressing China's environmental and environmental health issues.

Anthropogenic emissions, as the main source of $\text{PM}_{2.5}$ pollution and environmental health risks, have been studied extensively (Chen et al., 2019; Liu et al., 2022). Zhu et al. (2018) and Pui et al. (2014) summarized the studies on the PM sources in China and reported that secondary inorganic aerosols (SIA), industry, residential combustion, biomass burning, industry, and transportation are the main source categories in China in the historical and future business-as-usual scenarios. Due to the significant influence of various sectors on $\text{PM}_{2.5}$ emissions, and research (Liu et al., 2018; Liu et al., 2020) indicating a close association between $\text{PM}_{2.5}$ and OP, the connection between OP, serving as a toxicity indicator for $\text{PM}_{2.5}$, and its sources (Liu et al., 2020) is becoming increasingly crucial and the topic of numerous studies. For instance, Yu et al. (2019) used the dithiothreitol (DTT) assay to measure the $\text{PM}_{2.5}$ samples in Beijing throughout the year and identified vehicle emissions as the main contributing source based on the source analysis of OP. However, studies conducted in three coastal cities of the Bohai Sea region (Liu et al., 2018) and in Nanjing (Zhang et al., 2023) using the same DTT assay indicated that coal combustion was the most active source of OP. Together, these studies suggest that obtaining the spatial distribution characteristics of $\text{PM}_{2.5}$ and OP and their links to emission sources, is of paramount importance for implementing region-specific control measures.

Apart from anthropogenic emissions, meteorological conditions (i.e., temperature, humidity, wind speed, precipitation) also play a crucial role in the formation, accumulation, transformation, and dispersion of $PM_{2.5}$ (Liu et al., 2022; Liu et al., 2022). Utilizing a multiple linear regression model, Gong et al. (2022) conducted an analysis of the trends of meteorological elements and $PM_{2.5}$ levels across various regions in China from 2013 to 2020. Furthermore, they separated and quantified the impacts of meteorological factors and emissions on these trends. The findings indicate that meteorology alone can account for approximately 20~33% of the variability in $PM_{2.5}$ levels. Xing et al. (2023) conducted a study in the Shenzhen region using DTT, ascorbic acid (AA), and glutathione (GSH) OP assays. They analyzed meteorological conditions and $PM_{2.5}$ chemical composition to understand how the prevalence of monsoons in winter (northern and northeastern winds) and summer (southern and southeastern winds) affected the sources and contributed to the seasonal variation in $PM_{2.5}$ composition and OP (mass-normalized). Similarly, Molina et al. (2023) and Wang et al. (2019) revealed that meteorological conditions indirectly influence OP (volume-normalized and mass-normalized) through their impact on the chemical properties of the components. Ainur et al. (2023) employing a DTT assay, investigated outdoor health risks associated with atmospheric particulate matter in Xi'an, find a positive correlation between winter OP (volume-normalized) and relative humidity. Although several studies have identified linkages between meteorological conditions and $PM_{2.5}$ /OP, quantitative assessment of meteorological conditions to both $PM_{2.5}$ and OP variability is lacking.

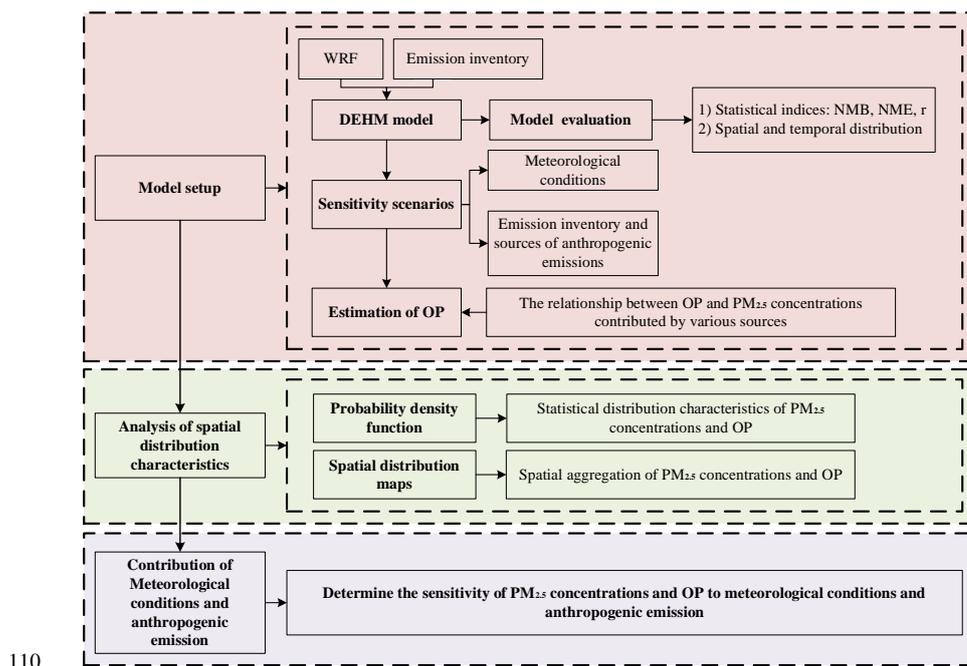

As of the present, research on the influence of both meteorological conditions and anthropogenic emissions on OP primarily relies on measurement methods (Yu et al., 2019; Gao et al., 2020; Campbell et al., 2021), such as DTT, AA, and GSH, which are difficult and costly to test and hard to provide the spatial distribution of OP comprehensively. Although mechanistic models of OP do exist (Shahpoury et al., 2024), their links to experimental metrics of OP are qualitative. For this, we propose a hybrid approach combining existing observations of OP with a chemistry transport model (CTM). So, using OP from assays and their observed links to sources and chemical constituents can then be parameterized and implemented in CTM for a comprehensive assessment of OP exposure over large areas and time periods. This study quantifies the contribution of meteorological and anthropogenic emission factors (i.e., coal combustion, biomass burning, secondary aerosol formation that originate from a series of atmospheric reactions, industry, and transportation source) to OP and $PM_{2.5}$ levels throughout China with the Danish Eulerian Hemispheric Model (DEHM) model. The study hence provides a method for calculating OP

across China and using OP as an indicator to assess the impacts of anthropogenic emission sources on
95 human health in China.

2. Materials and methods

2.1 Methodological flow

The research strategy of this study consists of three main parts: model setup, spatial distribution
characteristic analysis, and quantification of meteorological conditions and anthropogenic emissions'
100 contributions (Figure 1). In the first part, DEHM was employed to obtain hourly pollutant concentrations,
followed by model evaluation, where the numerical weather prediction model WRF v4.1 (Skamarock et
al., 2008) driven by ERA5 was used as meteorological input to DEHM and with exactly same spatial
setup for China as in DEHM. Sensitivity experiments were designed for meteorological conditions,
emission inventories, and anthropogenic emission sources. From these simulations, the spatial-scale
105 estimation of OP was conducted using model outputs and the relationship between OP (this study focuses
on the volume-normalized dithiothreitol activity) and $PM_{2.5}$ concentrations from various anthropogenic
sources (Zheng et al., 2018; Tong et al., 2018; Yun et al., 2020; MEE, 2020; Wang et al., 2020; Tang
et al., 2020; Lin et al., 2021; Chen et al., 2022).

110

Figure 1. Schematic diagram of the study strategy; NME, NMB, r, and OP are normalized mean error, normalized mean bias, correlation coefficient, and oxidative potential, respectively.

In the second part, the spatial distribution characteristics of PM_{2.5} and OP were determined using probability density functions (PDF) and spatial distribution maps. In the third part, quantitative analysis was conducted based on the simulation results from the sensitivity experiments to determine the extent of influence of meteorology and emissions on PM_{2.5} and OP, as well as the primary sources of PM_{2.5} and OP.

115

2.2 Model setup

The DEHM can well capture many features of PM and its precursors' changes in large-scale space (Christensen, 1997; Brandt et al., 2012; Im et al., 2019). To date, the DEHM model has been widely used in air pollution and health risk assessment research in Europe and Asia (Brandt et al., 2013a; b; Zare et al., 2014; Geels et al., 2015; Im et al., 2018; Im et al., 2019; Lehtomäki et al., 2020; Cramer et al., 2020; Liu et al., 2021; Geels et al., 2021; Thomas et al., 2022; Im et al., 2023), but this will be the first time that DEHM is applied to estimate OP. Thus, The DEHM model system was used to simulate the pollutant concentrations in 2014 by using a two-way nested domain in this study (Kumar et al., 2016). A mother domain with a resolution of 150 km × 150 km was employed on a polar stereographic projection,

125

true at 60°N to cover the entire Northern Hemisphere. The nested domain covered the whole of China consisting of 150 × 150 grid cells with a resolution of 50 km × 50 km. Vertically, there were 29 unevenly distributed layers, with the highest level reaching 100 hPa, and the lowest layer was approximately 20 m
130 in height. The meteorological fields were simulated using the WRF model (Skamarock et al., 2008) with the same domain and resolution driven by global reanalysis as ERA5 or global climate data from CESM. The time resolution of the DEHM model output is one hour. The gas-phase chemistry module included 66 species, 9 primary particles (including natural particles such as sea salt), and 138 chemical reactions (Brandt et al., 2012). The secondary organic aerosols (SOA) were calculated using the
135 volatility basis set (see details in Im et al. (2019)). In addition to the anthropogenic emissions, DEHM also includes emissions from biogenic emissions, such as vegetation, sea salt, lightning, soil, etc. The current version of the DEHM model does not include wind-blown, resuspended dust emissions or road dust.

In the current study, the DEHM model used anthropogenic emissions from the Emissions Database for
140 Global Atmospheric Research – Hemispheric Transport of Air Pollution (EDGAR-HTAP) database and biogenic emissions are calculated online based on the Model of Emissions of Gases and Aerosols from Nature (MEGAN) (see details in Im et al. (2019)).

2.3 Estimation of OP

Most of current data on OP of PM_{2.5} in China are obtained by means of measurement, and the research
145 objects are basically limited to specific cities, which to some extent hinders the conduct of research on OP in a large-scale region. Considering that Liu et al. (2018) collected samples across four seasons from multiple representative locations in China, their developed OP prediction model (Equation (1)) can support us in estimating OP in China, thereby exploring the spatial distribution characteristics of OP and the contributions of different anthropogenic sources to OP. In the present study, we have used this
150 relationship, in combination with the sensitivity simulations (section 2.4), to calculate the OP.

$$OP = 0.088 \times re + 0.076 \times bi + 0.041 \times se + 0.034 \times in + 0.017 \times tr \quad (1)$$

where, *re*, *bi*, *in*, and *tr* represent the primary PM_{2.5} concentrations for coal combustion, biomass burning, industry source, and transportation source, respectively. In this study, the coal combustion is primarily from heating during the local cold season. Biomass burning includes open burning of agricultural biomass, domestic biomass burning for cooking and heating, and biomass burning from

155 power plants. Industry source is primarily from specific industry processes. Transportation source
primarily comes from pipe emissions. *se* (secondary aerosol formation) refers to the concentrations of
secondary organic and inorganic (SOA and SIA, respectively) components. It's worth mentioning that
secondary aerosol formation originates from a series of atmospheric reactions. Some identified sources
(i.e., coal combustion, biomass burning, industrial processes, and transportation) may generate secondary
160 inorganic and organic aerosols through the emission of their precursor components. Therefore,
coefficient reflect the intrinsic OP of each source.

2.4 Sensitivity scenarios

2.4.1 Relative contributions from meteorological conditions and emissions

165 Table 1 summarizes the scenarios for assessing the relative contributions of meteorological conditions
and emissions to PM_{2.5} and OP variability in 2014. Scenarios C₁ and C₂ used the same meteorological
reanalyse dataset (ERA5) as input to WRF, while Scenario C₃ utilized CESM climate model based
meteorological data as input. ERA5 (Hersbach et al., 2020; ERA, 2023) is a global reanalysis dataset
that is based on the assimilation of historical observations and model data. CESM (2023), on the other
170 hand, is a global climate and Earth system model supported by the US National Science Foundation, and
its meteorological outputs serve as inputs for the WRF model as well. CESM version 2.1.1 (Danabasoglu
et al., 2020) was first ran from 1850-2015 with the standard input component set BHISTcmp6 on
f09_g17 resolution (i.e., 0.9°x1.25° resolution). Scenarios C₂ and C₃ employed the Eclipse V6 emissions
inventory, while Scenario C₁ used the EDGAR-HTAP inventory.

175 The ECLIPSE project by the International Institute for Applied Systems Analysis (IIASA) aims to
generate a global gridded anthropogenic emission inventory for various emission scenarios. The
Greenhouse Gas - Air Pollution Interactions and Synergies (GAINS) model has been employed to
estimate emissions using source characteristics and emission factors at a resolution of 0.5°x0.5°latitude-
longitude (Upadhyay et al., 2020; Eclipse, 2020). The following sector-layers are available: energy,
180 industry, solvent use, transport, domestic combustion, agriculture, open burning of agricultural waste,
waste treatment. a number of scenarios are provided for which the key economic assumptions and energy
use originate from IEA World Energy Outlook (IEA, 2011), the POLES model, or Energy Technology
Perspectives (IEA, 2012) for the period 2010-2050, while statistical data for the period 1990-2010 came

from IEA. For agriculture the FAO databases and long-term global projections were used (Alexandratos
185 et al., 2012). It is noteworthy that this inventory takes into account China 13th 5-year plan. The
EDGAR-HTAP (Joint et al., 2011; Crippa et al., 2023) emission inventory endeavors to employ official
or scientific inventories within a national or regional scale, with a spatial resolution of $0.1^\circ \times 0.1^\circ$. The
temporal coverage spans from the year 2000 to 2018. EDGAR-HTAP comprehensively accounts for all
major emission sectors, including residential, transportation, industrial, energy, and agricultural sectors.
190 Equations (2-5) were used to quantitatively evaluate the contributions of meteorological conditions and
emission inventories.

$$\text{Con(Met)} = \frac{C_2 - C_3}{C_3} \quad (2)$$

$$\text{Con(Emi)} = \frac{C_1 - C_2}{C_2} \quad (3)$$

$$\text{NCon(Met)} = \frac{\text{abs(Con(Met))}}{\text{abs(Con(Met))} + \text{abs(Con(Emi))}} \quad (4)$$

$$\text{NCon(Emi)} = \frac{\text{abs(Con(Emi))}}{\text{abs(Con(Met))} + \text{abs(Con(Emi))}} \quad (5)$$

where, C_1 , C_2 and C_3 represent the $\text{PM}_{2.5}$ concentrations and OP from scenarios C_1 , C_2 and C_3 ,
respectively. Con(Met) represents the impact of changing meteorological datasets on changes in $\text{PM}_{2.5}$
and OP. Con(Emi) represents the impact of changing emission inventory on changes in $\text{PM}_{2.5}$ and OP.
195 abs represents the absolute value. NCon(Met) and NCon(Emi) represent the normalized contributions of
meteorology and emission.

Table 1. Emission inventory and meteorological datasets in three simulation scenarios.

Scenarios	Emission inventory	Meteorological datasets
C_1	EDGAR-HTAP	ERA5
C_2	Eclipse V6	ERA5
C_3	Eclipse V6	CESM

2.4.2 Relative contributions from individual emissions

As mentioned above, OP's main source contributions include five parts, i.e., coal combustion, biomass
200 burning, secondary aerosol formation, industrial sources, and transportation sources (Equation (1)), we
conducted perturbation experiments targeting these five sources to quantitatively assess their
contributions to $\text{PM}_{2.5}$ concentration and OP (Figure 2). These experiments were carried out within the
three scenarios proposed in Section 2.4.1, and we performed a total of 15 runs. Under the non-

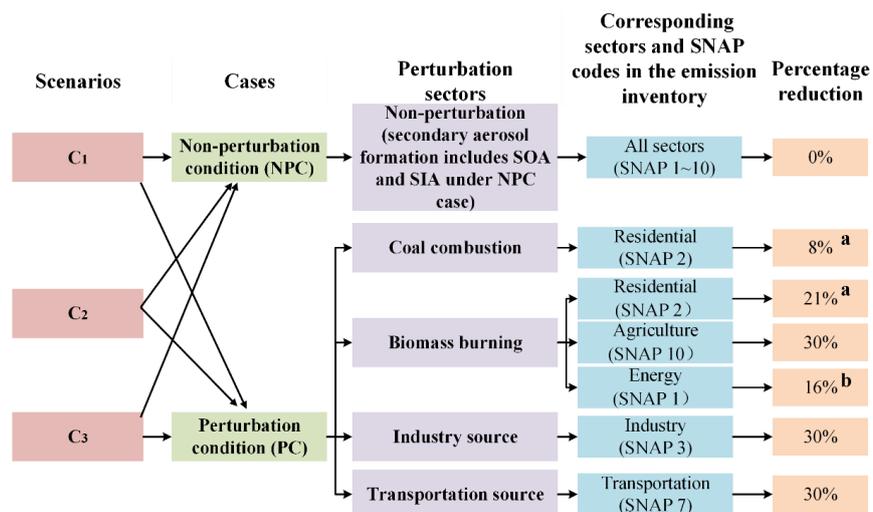

perturbation condition (referred to as the NPC case), all aforementioned emission sources were
205 considered. Under the perturbation condition (referred to as the PC case), reduction designs were
implemented for emissions from coal combustion, biomass burning, industrial sources, and
transportation sources. The emission from each individual source is reduced by 30%. Notably, to estimate
the PM_{2.5} concentrations and OP from coal and biomass burning, it is necessary to obtain the percentage
contributions of PM_{2.5} emissions from coal combustion for residential heating, domestic biomass burning
210 for cooking and heating to PM_{2.5} emissions of the residential sector, respectively, as well as the
percentage contributions of PM_{2.5} emissions from biomass combustion in power plants to the total PM_{2.5}
emissions from the power sector. The percentage contributions of each anthropogenic source can be
estimated using Equations (6–8).

$$PC_{re-j} = \frac{E_{re-j}}{E_{re}} \quad (6)$$

$$E_{pp-bi} = EF \times FQ \quad (7)$$

$$PC_{pp-bi,cf} = \frac{E_{pp-bi} + E_{pp,cf}}{E_{pp}} \quad (8)$$

where, PC_{re-j} denotes the percentage contribution of PM_{2.5} emissions from the residential subsector j
215 (including coal cooking, coal heating, biomass cooking, biomass heating, clean energy, and
nonresidential) to the total PM_{2.5} emissions from the residential sector. E_{re-j} represents the PM_{2.5}
emissions from the residential subsector j, while E_{re} represents the total PM_{2.5} emissions from the
residential sector. The values of E_{re-j} and E_{re} are obtained from the literature (Yun et al., 2020). E_{pp-bi}
refers to the PM_{2.5} emissions from biomass power plants, EF refers to the PM_{2.5} emission factor of
220 biomass power plants, and FQ refers to the fuel quantity. $PC_{pp-bi,cf}$ refers to the percentage contribution
of PM_{2.5} emissions from biomass power plants and coal-fired power plants to the PM_{2.5} emissions of the
power plants. $E_{pp,cf}$ refers to the PM_{2.5} emissions from coal-fired power plants, and E_{pp} refers to the
PM_{2.5} emissions from power plants. EF , FQ , $E_{pp,cf}$, and E_{pp} are obtained from the literature (Zheng et
al., 2018; Tong et al., 2018; Yun et al., 2020; MEE, 2020; Wang et al., 2020; Tang et al., 2020; Lin
225 et al., 2021; Chen et al., 2022). More and more studies (Hodan et al., 2004; Chen et al., 2018; Zhang
et al., 2022) showed that in China, the proportion of secondary and primary PM_{2.5} mass to the total PM_{2.5}
mass is close, so we assume that they account for 50% respectively. Figure 2 showed the emission
reduction design for perturbed emissions.

230 **Figure 2. Emission reduction design for perturbed emissions; ^a was obtained from the literature (Yun et al., 2020), ^b were obtained from the literature (Zheng et al., 2018; Tong et al., 2018; Yun et al., 2020; MEE, 2020; Wang et al., 2020; Tang et al., 2020; Lin et al., 2021; Chen et al., 2022).**

Furthermore, the $PM_{2.5}$ concentration for each sector is calculated using Equations (9~11).

$$C_{P,i} = \frac{C_{NPC,i} - C_{PC,i}}{30\%} \quad (9)$$

$$C_{P,primary\ PM_{2.5}} = C_{P,total\ PM_{2.5}} - C_{P,SIA} - C_{P,SOA} \quad (10)$$

$$C_{secondary} = C_{NPC,SOA} + C_{NPC,SIA} \quad (11)$$

where, i refers to the type of pollutants, i.e., total $PM_{2.5}$, SOA, SIA, and primary $PM_{2.5}$. $C_{NPC,i}$ represents

235 concentrations of the pollutant i in the NPC case. $C_{PC,i}$ represents concentrations of the pollutant i in the

PC case. $C_{P,i}$ represents concentrations of the pollutant i by the specific emission sector P which is

perturbed (perturbation sectors P include coal combustion, biomass burning, industry, traffic source).

$C_{P,primary\ PM_{2.5}}$ represents concentrations of primary $PM_{2.5}$ by the perturbation sectors P. $C_{secondary}$

represents $PM_{2.5}$ concentrations by the secondary aerosol formation.

240 2.5 Probability density function

Taking into account the substantial spatial heterogeneity of $PM_{2.5}$ concentration and OP, we employ probability distribution functions (PDF) to characterize the statistical distribution characteristics of $PM_{2.5}$

concentration and OP across China. This offers a more generalized and robust probability for criteria limits. In this study, all three functional types (Lognormal, exponential, and Gamma) were tested for
245 annual average of $PM_{2.5}$ concentrations and OP at the monitoring stations. To determine the representative distributions for the datasets, we further performed goodness-of-fit tests such as the Sum of Squared Error (SSE) and the Kolmogorov-Smirnov (K-S) test (de Melo et al., 2000), using the fitter package in Python.

3. Results and discussion

250 3.1 Model evaluation

The hourly observation data was obtained from the Ministry of Ecology and Environment of China (MEE, 2014). The MEE website first released $PM_{2.5}$ measurement data in January 2013. In accordance with the Chinese environmental protection standards, the hourly $PM_{2.5}$ concentrations are measured using the micro-oscillation balance method and beta absorption method, with an uncertainty of less than
255 $5 \mu g m^{-3}$ (Zeng et al., 2021). The $PM_{2.5}$ monitoring stations are primarily distributed in urban areas, particularly in major metropolitan areas of China (Zeng et al., 2021). In 2014, the observation stations were mainly concentrated in eastern China, while stations in western China are limited. Therefore, in the present study, we also evaluated with the gridded annual-mean global reanalysis Dalhousie surface $PM_{2.5}$ dataset (van Donkelaar et al., 2021), which combines satellite retrievals of aerosol optical depth,
260 chemical transport modeling, and ground-based measurements for the period 1998-2019. The Dalhousie dataset compensated for the non-uniform distribution spatially of observation stations to comprehensively evaluate the performance of the DEHM model. The density scatter plot of model performance and evaluation based on annual mean MEE observations and the Dalhousie dataset were shown in Figure 3. Overall, the model performance in terms of correlation coefficient (R) and normalized
265 mean error (NME) calculated based on annual mean observations met the performance criteria suggested by Emery et al. (2017) ($NME < 0.5$, $R > 0.4$), and the normalized mean bias (NMB) was also close to the performance criteria suggested by Emery et al. (2017) ($NMB < \pm 0.3$). Compared to the observations, the model performance in terms of R, NME, and NMB calculated based on the Dalhousie dataset was slightly poorer but still close to the performance criteria suggested by Emery et al. (2017). Therefore, the
270 simulated annual mean $PM_{2.5}$ concentrations is considered reliable.

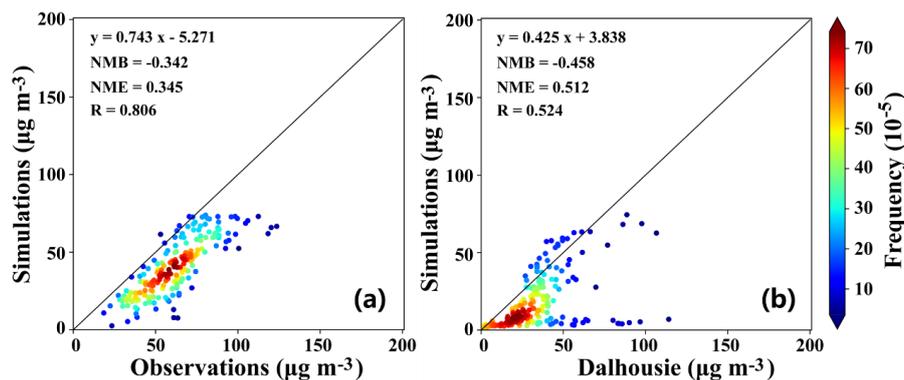

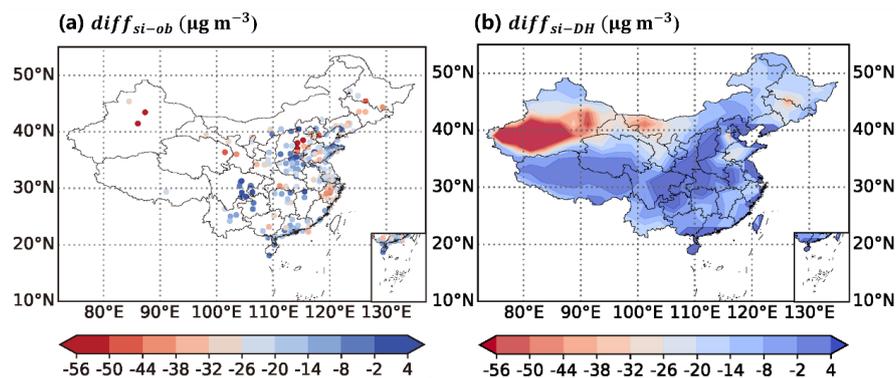

Figure 3. Density scatterplots of model performance and validation for China based on (a) MEE observations and (b) the Dalhousie dataset.

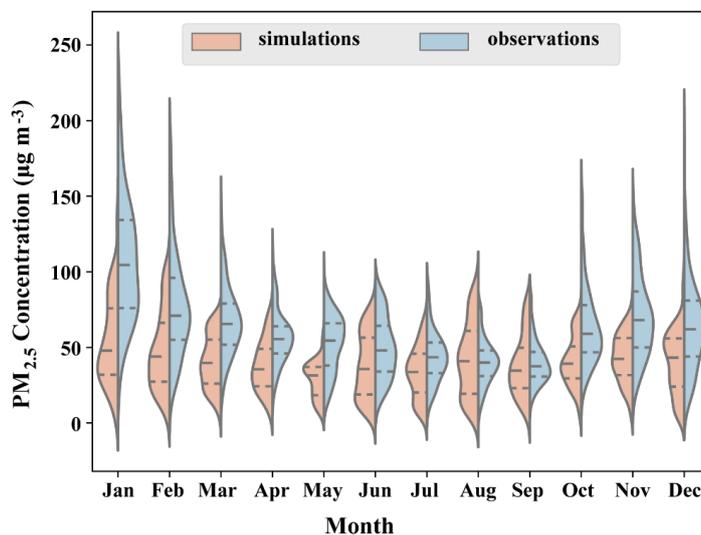

To verify the spatial accuracy, a comparison of the spatial distribution of simulated and observed $PM_{2.5}$, both from MME and Dalhousie, was conducted. Figure 4 showed the spatial distribution of the difference between simulated and MME observed values (denoted as $diff_{si-ob}$) (Figure 4a) and same for Dalhousie dataset (denoted as $diff_{si-DH}$) (Figure 4b). Both Figure 4a and Figure 4b indicated that the majority of regions (northeastern, central, and eastern China) exhibited differences ranging from $-18 \mu g m^{-3}$ to $0 \mu g m^{-3}$. However, the $PM_{2.5}$ concentrations in western China are largely underestimated, and the region with the worst performance has a difference reaching up to $-54 \mu g m^{-3}$. This is mainly due to the lack of mineral dust emissions in the DEHM model, which is one of the main sources of pollutants in western China. This also explains the poorer performance shown in Figure 3b. Considering that we focus on the impact of anthropogenic emission sources on $PM_{2.5}$ concentrations and OP due to their health effects, and that the vast majority of anthropogenic emission sources and populations are concentrated in central, eastern, and northeastern China, the well performance of DEHM model in these areas demonstrate its ability to support us exploring the role of different anthropogenic emission sources on $PM_{2.5}$ concentrations and OP in various regions, thereby identifying the main anthropogenic emission sources.

290 **Figure 4. Spatial distribution of differences between (a) observations and (b) the Dalhousie dataset, and simulations.**

Similarly, the model performance over time scales was also investigated. Scatter density plots and distribution characteristics of monthly average observations and simulations for all monitoring sites in 2014 were depicted in Figure S1 and Figure 5, respectively, with Figure S1a~ Figure S1l representing January to December. The results indicated that the simulated values were in good agreement with the observations from June to September. Although the model underestimated $PM_{2.5}$ concentrations in other months, its performance in terms of R and NME met the performance standards recommended by Emery et al. (2017) in all months except for December. We conclude that the model performs well in simulating the seasonal variation of $PM_{2.5}$ concentrations.

295

300 **Figure 5. Violin plots of monthly average observations and simulations averaged over various observation stations; The red and blue colors represent the statistical distribution of simulated and observations, respectively; The width of the violin represents the sample size; The solid black line inside the violin indicates the median. The upper and lower dashed black lines within the violin indicate the upper quartile (the 75th percentile) and lower quartile (the 25th percentile), respectively.**

305 **3.2 Spatial distribution characteristics of PM_{2.5} and OP**

In order to determine the spatial distribution characteristics of PM_{2.5} concentrations and OP, we explored the spatial distribution of both in scenario C₁, as shown in Figure 6a and 6b respectively. The findings demonstrated spatial clustering characteristics in PM_{2.5} concentrations and OP. High PM_{2.5} concentrations and High OP are mainly located in central and eastern urban clusters such as the Beijing-Tianjin-Hebei region, the Shandong Peninsula, the middle reaches of the Yangtze River, the Yangtze River Delta, and the Central Plains, which have experienced rapid urbanization, industrialization, and coal burning in winter, which lead to a large amount of pollutant emissions. Low PM_{2.5} concentrations and Low OP are mainly distributed in most urban areas of Xinjiang, Tibet, Qinghai, Gansu, Yunnan, Inner Mongolia, Northeast China, Pearl River Delta, Beibu Gulf, etc.

315 Due to differences in city types, pollutant emission intensities, and pollutant chemical components in different regions, there are significant spatial heterogeneity in PM_{2.5} concentrations and therefore in OP. Due to high population density, socio-economic activities and winter heating needs of northern residents in China's right region, large amounts of anthropogenic emissions, especially from industry, transportation, coal burning and biomass burning, exacerbate PM_{2.5} and redox active component
320 pollution.

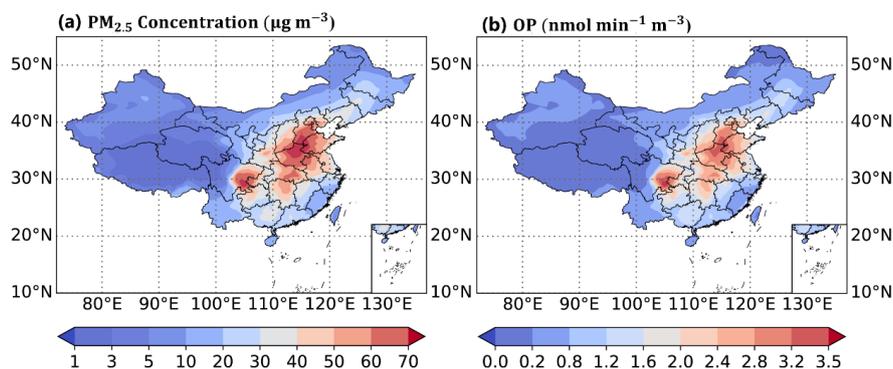

Figure 6. Spatial clustering of PM_{2.5} concentrations (a) and OP (b) in China.

To quantitatively analyze the regional distribution characteristics of $PM_{2.5}$ concentrations and OP in China, we determined the distribution function that is suitable for a specific dataset (Table 3),
325 investigated the frequency histogram (FH) of $PM_{2.5}$ concentrations and OP, fitted the PDF, and then
obtained the cumulative distribution function (CDF) by integrating PDF, as shown in Figure 7. It was
found that the gamma distribution performed the best in fitting $PM_{2.5}$ concentrations and OP from Table
2. Considering the test results, the gamma distribution was used to explore the spatial distribution
characteristics of $PM_{2.5}$ concentrations and OP. Figure 7a depicted the probability distribution of $PM_{2.5}$
330 concentrations, while Figure 7b depicted the probability distribution of OP. The wide distribution interval
indicated that both $PM_{2.5}$ concentrations and OP have a similar and large spatial heterogeneity. According
to the FH, the highest frequency density of $PM_{2.5}$ concentrations ranges from 10.5 to 12.9 $\mu g m^{-3}$; The
maximum frequency density of OP ranges from 0.26 to 0.34 $nmol min^{-1} m^{-3}$. This reflects the overall
pollution levels of $PM_{2.5}$ and OP in the Chinese region. Taking into account the annual average $PM_{2.5}$
335 concentrations limits set out in China's ambient air quality standard (AAQS, 2012), we focused on
primary (15 $\mu g m^{-3}$) and secondary concentrations (35 $\mu g m^{-3}$) limits. The PDF and CDF results
showed that 84.8% of the total area was above the primary concentrations limit and 39.7% was above
the secondary concentrations limit. In addition, 35.7% of regions in China have an OP below 1.00
 $nmol min^{-1} m^{-3}$, 41.3% have an OP between 1.00 and 2.00 $nmol min^{-1} m^{-3}$, and 23.0% have an OP
340 above 2.00 $nmol min^{-1} m^{-3}$.

Table 2. Goodness-of-fit test results

Item	goodness-of-fit test	Gamma	Lognormal	Exponential
$PM_{2.5}$ concentrations	SSE	0.002	0.023	0.003
	KS_pvalue	0.329	0.000	0.000
OP	Sumsquare_error	0.654	0.746	1.209
	KS_pvalue	0.231	0.271	0.000

Bold values indicate the best results.

*Note:

SSE is Sum of Squared Error

KS_pvalue is the P-value of the Kolmogorov-Smirnov test

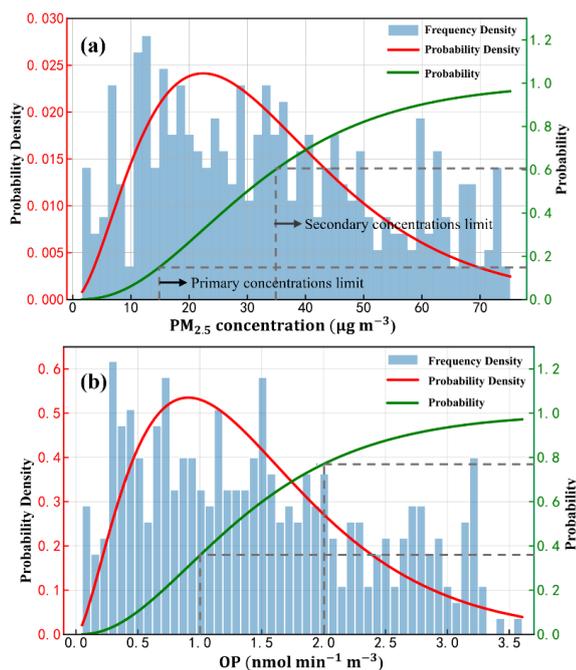

Figure 7. Probability distribution of (a) PM_{2.5} concentrations and (b) OP in China

3.3 Contributions of meteorological conditions and emission inventories to the variations in PM_{2.5} and OP

345

To determine the sensitivity of PM_{2.5} pollution and oxidation potential (OP) to meteorological conditions (emission inventories), this study compared scenarios C₂ and C₃ (C₁) and investigated the impacts and contributions due to ERA5 and CESM (HTAP and Eclipse V6 emission inventories) on PM_{2.5} and OP.

Figure 8 illustrated the spatial distribution maps of PM_{2.5} concentrations and OP under scenarios C₁, C₂, and C₃. Figure 8a~8c represented PM_{2.5} concentrations under scenarios C₁, C₂, and C₃, respectively, while

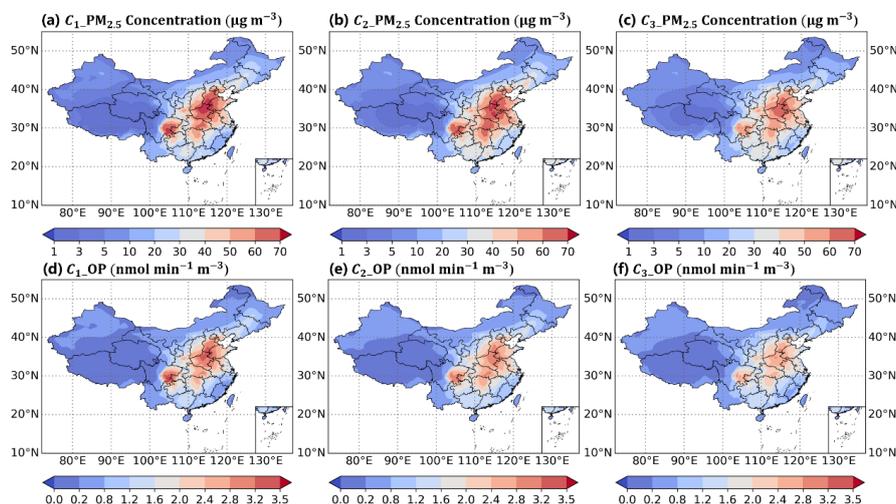

350

figure 8 d~8f represented OP under the same scenarios. Figure 9a presented the annual average PM_{2.5} concentrations and OP under different scenarios, and Figure 9b showed the relative contributions of meteorological conditions and emission inventories. From Figures 8 and 9, it can be observed that,

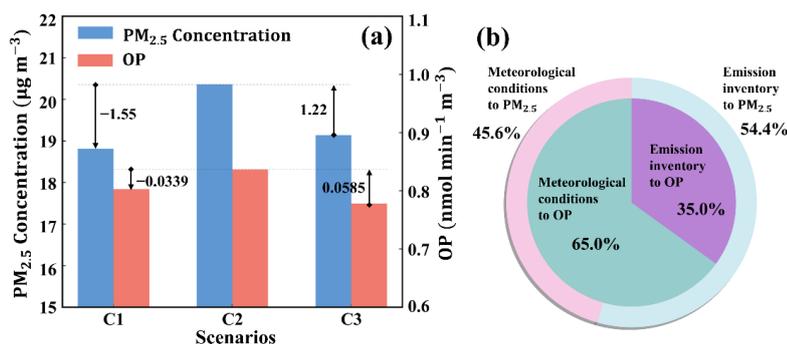

355

compared to scenario C₂, PM_{2.5} concentrations and OP are lower in the western region and slightly higher in some eastern areas under scenario C₁, primarily due to changes in emission inventories attributed to the inclusion or exclusion of specific local sources during the compilation process. Compared to scenario C₃, PM_{2.5} concentrations and OP are lower in the western region and higher in some eastern areas under

scenario C_2 , primarily attributed to meteorological contributions. For the entire China region, the transition in emission inventories from Eclipse V6 to HTAP resulted in an overall decrease in $PM_{2.5}$ concentrations of $1.55 \mu g m^{-3}$, approximately 7.61%, and a decrease in OP of $0.0339 nmol min^{-1} m^{-3}$, approximately 4.05%. The shift in meteorological data from CESM to ERA5 led to an increase in $PM_{2.5}$ concentrations of $1.22 \mu g m^{-3}$, approximately 6.4%, and an increase in OP of $0.0585 nmol min^{-1} m^{-3}$, approximately 7.5%. According to the normalization process using equations (4)–(5), meteorological conditions contributed approximately 45.6% to the variations in $PM_{2.5}$ and approximately 65.0% to the variations in OP. Meanwhile, emission inventories contributed approximately 54.4% to the variations in $PM_{2.5}$ and approximately 35.0% to the variations in OP. Our findings highlight the significance of the quality of model input data, including emission inventories and meteorological data, for model performance.

370 **Figure 8. Spatial distribution of $PM_{2.5}$ concentrations and OP in different scenarios; (a)–(c) are $PM_{2.5}$ concentrations in scenarios C_1 , C_2 and C_3 , respectively; (d)–(f) is the OP in scenarios C_1 , C_2 , and C_3 , respectively; The meteorological datasets (emission inventories) employed for scenarios C_1 , C_2 , and C_3 are ERA5 (EDGAR-HTAP), ERA5 (Eclipse V6), and CESM (Eclipse V6), respectively**

380

3.4 Contribution of anthropogenic emission sources to PM_{2.5} and OP

Considering that anthropogenic emission sources play an important role in PM_{2.5} concentrations and OP, we explored the spatial distribution characteristics of PM_{2.5} and OP from different anthropogenic sources to reveal the reasons behind the spatial heterogeneity in PM_{2.5} concentrations and OP, as shown in Figure 10. The spatial distribution of PM_{2.5} concentrations from coal combustion for residential heating, biomass combustion, secondary aerosol formation, industry, and transportation are shown in Figures 10a~10e, respectively, and same for OP are shown in Figures 10f~10j, respectively. It was evident that the spatial distribution features of PM_{2.5} concentrations and OP from each emission source closely resemble those in Figure 6, and they all adhere to the principle that the eastern region is higher than the western. Nonetheless, the PM_{2.5} and OP concentrations from various anthropogenic sources varied significantly across the two regions.

390

As seen in Figure 10, secondary aerosol formation are the primary contributors to PM_{2.5} concentrations and OP. The main components of the secondary aerosol formation, such as sulfate, nitrate, ammonium salt, and water-soluble organic carbon (WSOC), are formed primarily from their precursor components, such as SO₂, NO_x, and volatile organic compounds (VOC), through a sequence of atmospheric reactions. This revealed that the role of secondary aerosol formation in OP is significant from their high contribution to mass and intrinsic OP.

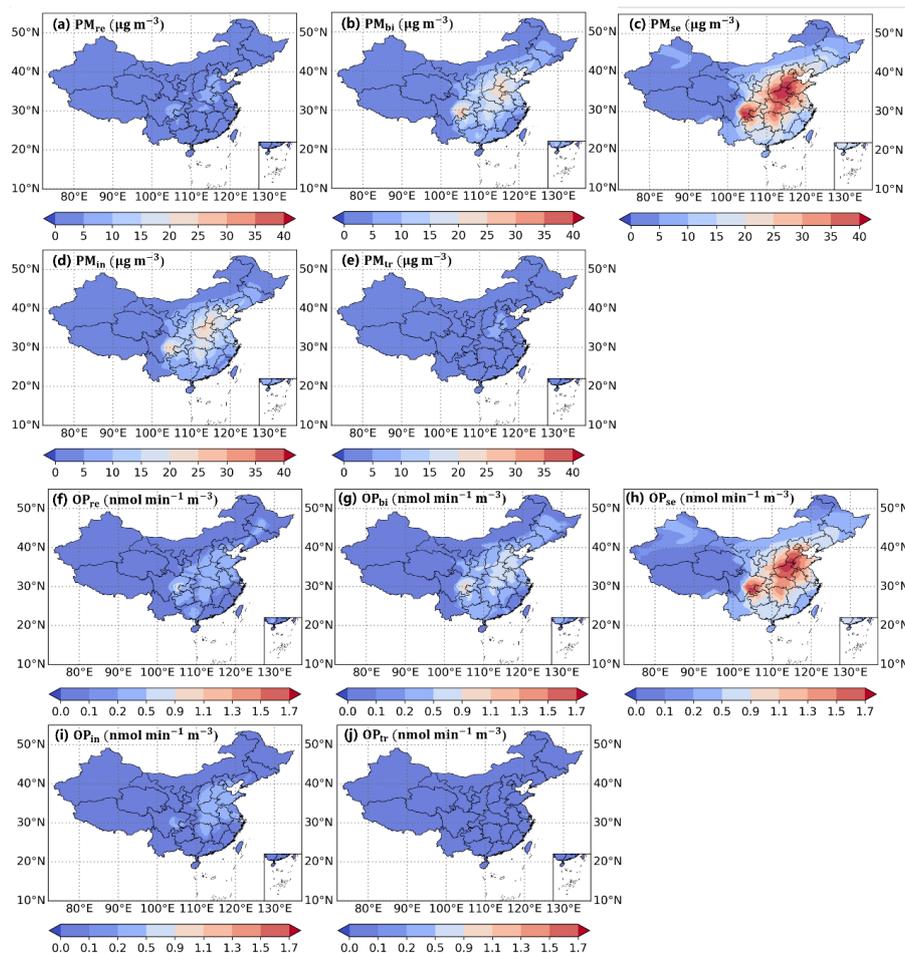

395

Biomass combustion is mainly derived from open-air agricultural waste burning, residential biomass fuels used for heating and cooking, coal- and biomass-power plants burning (Zhang et al., 2017). It is worth noting that Chinese crops, especially corn straw, and power plants are mainly concentrated in central and eastern regions, northeast and part of the western region, which provides greater potential for biomass combustion in the eastern part of China. In addition, (Chen et al., 2023) demonstrated that aerosols emitted from biomass combustion significantly influenced the development of PBL by changing meteorological conditions, and subsequently led to the accumulation of $PM_{2.5}$ concentrations. The increase of OP is also associated with carbonaceous aerosols (Liu et al., 2020). This means that biomass burning plays a significant role in regional pollution and environmental health risks.

Coal burning increases secondary inorganic and organic aerosols in the air (Liu et al., 2018), which leads to stronger oxidative toxicity. Particularly, due to greater heating demand in locations with high population density and chilly winters, $PM_{2.5}$ concentrations and OP linked to coal burning are higher.

Industrial emissions mainly include glass manufacturing, fertilizer production, organometallic metallurgy plants and iron and steel industrial bases. This is one main source for metals. Considering the correlation between these transition metals and OP (Fang et al., 2017; Liu et al., 2018), China's four industrial zones (Liaozhong-South Heavy Industry Base, Beijing-Tianjin-Tangshan Industrial Base, Shanghai-Nanjing-Hangzhou Industrial Base, and Pearl River Delta Light Industry Base) are undoubtedly important contributors to $PM_{2.5}$ and OP emissions from industrial sources.

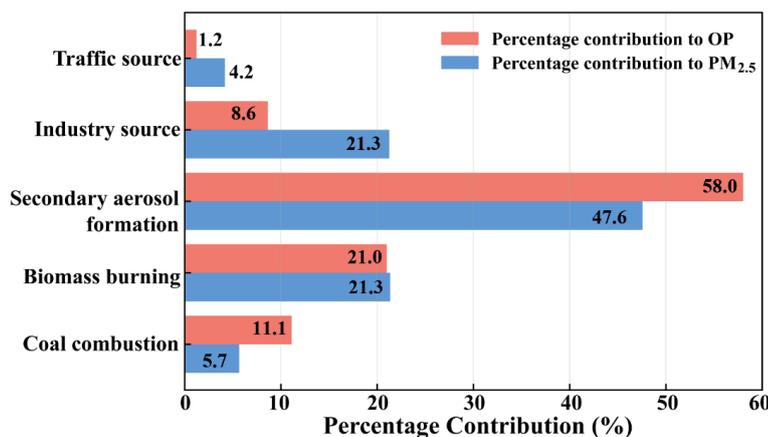

Transportation-related emissions encourage the accumulation of Fe, Cu, Mn, Zn, and other elements (Fang et al., 2017). Compared with other anthropogenic sources, Figure 10 demonstrated that the contribution of traffic sources to $PM_{2.5}$ and OP is the lowest, mainly concentrated in Henan, Hebei, and Shandong. This is valid for the top three provinces in terms of vehicle particulate matter and nitrogen oxide emissions in 2014 according to China Annual Vehicle Pollution Prevention and Control Report (MEE, 2015).

425 **Figure 10.** Spatial distribution of PM_{2.5} concentrations and OP from different anthropogenic sources; (a)–(e) are PM_{2.5} concentrations derived from coal combustion for residential heating (PM_{re}), biomass burning (PM_{bi}), secondary aerosol formation (PM_{se}), industry (PM_{in}), and traffic (PM_{tr}) respectively; (f)–(j) are the OP derived from coal combustion for residential heating (OP_{re}), biomass burning (OP_{bi}), secondary aerosol formation (OP_{se}), industry (OP_{in}), and traffic (OP_{tr}) respectively.

To determine the impact of anthropogenic emissions on PM_{2.5} and OP, we quantified their percent contribution (Figure 11). Secondary aerosol formation, biomass combustion, industrial, coal combustion
430 for residential heating, and transportation sources contributed 47.6%, 21.3%, 21.3%, 5.7% and 4.2% to PM_{2.5}, respectively. Secondary aerosol formation, biomass combustion, coal combustion for residential heating, industrial sources, and transportation sources contributed 58.0%, 21.0%, 11.1%, 8.6% and 1.2%

to OP, respectively. This means that secondary aerosol formation and biomass burning are the main sources of PM_{2.5} and OP.

435

Figure 11. Percentage contribution of different anthropogenic sources.

4. Conclusions

This study established a spatial modelling for PM_{2.5} concentrations and OP, provided a method for calculating OP across China, and quantitatively assessed the impacts of meteorological conditions and anthropogenic emissions on PM_{2.5} and OP variability and levels in China. The following conclusions can be obtained:

440

- PM_{2.5} and OP exhibited spatial clustering characteristics, with higher values mainly located in the central and eastern urban areas. About 85% and 40% of the areas had PM_{2.5} annual average concentrations exceeding the first-grade concentrations limit ($15 \mu\text{g m}^{-3}$) and second-grade concentrations limit ($35 \mu\text{g m}^{-3}$), respectively. Additionally, about 36% of the areas had OP concentrations lower than $1 \text{ nmol min}^{-1} \text{ m}^{-3}$, while 23% of the areas had OP concentrations higher than $2 \text{ nmol min}^{-1} \text{ m}^{-3}$.
- Variability in both PM_{2.5} and OP are influenced by a combination of meteorological conditions and emission inventories. Meteorological conditions contributed about 46% of PM_{2.5} variation and 65% of OP variation. The emission inventory contributed about 54% of the change in PM_{2.5} and about 35% of the change in OP.
- The percentage contributions of secondary aerosol formation, biomass burning, industry, coal combustion for residential heating, and traffic to PM_{2.5} were about 48%, 21%, 21%, 6%, and 4%,

450

respectively. The percentage contributions of secondary aerosol formation, biomass burning, coal
455 combustion for residential heating, industry, and traffic to OP were approximately 58%, 21%, 11%,
8%, and 1%, respectively.

A main finding of this study is that meteorological variability is the prime driver of OP variability, and
not emissions. Furthermore, secondary aerosol formation and biomass burning are the main sources of
OP. Thus, air pollution strategies should focus more on biomass combustion and the emissions of the
460 precursors taking part in the secondary aerosol formation, and it would be efficient to introduce special
emissions controls during stagnation or other periods where OP accumulates.

Author contributions

465 Jiemei Liu performed the simulation and its validation, data analysis, investigation, and writing – original
draft. Jesper H. Christensen conducted investigation, worked on methodology, and performed validation.
