12 **Abstract.** Trade-wind clouds are ubiquitous across the subtropical oceans, including the Great Barrier Reef (GBR),  
13 playing an important role in modulating the regional energy budget. These shallow clouds, however, are by their  
14 nature sensitive to perturbations in both their thermodynamic environment and microphysical background. In this  
15 study, we employ the Weather Research and Forecasting (WRF) model with a convection-permitting  
16 configuration at 1 km resolution to examine the sensitivity of the trade-wind clouds to different local forcings  
17 over the GBR. A range of local forcings including coastal topography, sea surface temperature (SST), and local  
18 aerosol loading is examined.

19 Our simulations show a strong response of cloud fraction and accumulated precipitation to orographic forcing  
20 both over the mountains and upwind over the GBR. Orographic lifting and low-level convergence are found to be  
21 crucial in explaining the cloud and precipitation features over the coastal mountains downwind of the GBR.  
22 However, clouds over the upwind ocean are more strongly constrained by the trade wind inversion, whose  
23 properties are, in part, regulated by the coastal topography. On the scales considered in our study, the warm cloud  
24 fraction and the ensuing precipitation over the GBR show only a small response to the local SST forcing, with this  
25 response being tied to the simulated cloud type. Cloud microphysical properties, including cloud droplet number  
26 concentration, liquid water path, and precipitation are sensitive to the changes in atmospheric aerosol population  
27 over the GBR. While cloud fraction shows little responses, a slight deepening of the simulated clouds is evident  
28 over the upwind region in correspondence to the increased aerosol number concentration. A downwind effect of  
29 aerosol loading on simulated cloud and precipitation properties is further noted.

## 30 **1 Introduction**

31 Trade wind cumuli are ubiquitous across the subtropical oceans (Warren et al., 1988; Norris, 1998; Eastman et al.,  
32 2011; Boucher et al., 2013; Rauber et al., 2007), including the Great Barrier Reef (GBR) (Zhao et al., 2022).  
33 Despite their limited vertical and horizontal extent, these clouds play a fundamental role in maintaining the  
34 thermodynamic budget of the lower troposphere (Chen et al., 2000). These clouds reflect a significant fraction of  
35 incoming solar radiation and emit long-wave radiation at relatively high temperature, and thus exert a net cooling  
36 effect on the earth atmosphere system (Mumby et al., 2001; Jones et al., 2017). Globally, these clouds help govern  
37 earth's energy budget, but are known to be a leading source of uncertainty in future climate projections (Boucher  
38 et al., 2013).

39 The GBR has become increasingly threatened by thermal coral bleaching events (CBEs) over the past decade  
40 (Hughes et al., 2017; Stuart-Smith et al., 2018). Recent research has also found that local-scale cloud cover helps  
41 regulate the ocean temperature along the GBR with anomalies in the cloud fraction having been directly linked to  
42 thermal CBEs (Zhao et al., 2021; Leahy et al., 2013). However, while the large-scale circulation has a fundamental  
43 influence on shallow cloud formation, these cloud systems by their nature are sensitive to perturbations in both  
44 their thermodynamic environment and microphysical background (Stevens and Brenguier, 2009; Rauber et al.,  
45 2007). It is, therefore, important to understand the sensitivity of these low clouds in response to different local  
46 forcings.

47 The GBR contains the world's largest complex collection of coral reefs. It has been hypothesised that the coral  
48 reef emissions of dimethylsulfide (DMS) may be an important contributor to the regional atmospheric aerosol  
49 loading (Cropp et al., 2018; Fiddes et al., 2021). Any perturbation to the aerosol population would potentially  
50 affect the cloud properties and thus the radiative forcing (Lohmann and Feichter, 2005), for instance through a  
51 Twomey effect (Twomey, 1997). It has further been hypothesized that the aerosol loading can also affect the  
52 precipitation efficiency of these clouds, and thus their lifetime (Cropp et al., 2018; Fischer and Jones, 2012;  
53 Deschaseaux et al., 2016; Jones, 2015) through an Albrecht effect (Albrecht, 1989).

54 Over the GBR, a recent climatology study by Zhao et al. (2022) revealed little to no difference in low-level cloud  
55 properties between the open ocean (reef-free region) and the coral reef region, using long-term satellite datasets.  
56 These results suggest that low clouds over the GBR do not show a measurable response to the reef-related  
57 microphysical perturbations, at least using spaceborne observations. However, subtle signals may be obscured or  
58 diminished when averaged over extensive periods in long-term climatological analyses. In addition, a very small  
59 natural contribution to the cloud condensation nuclei (CCN) population from coral derived DMS was noted over  
60 the GBR (Fiddes et al., 2021). A higher temporal resolution analysis including the diurnal cycle of these low-level  
61 clouds may be critical in understanding their effect on the radiation budget. It is, therefore, appropriate to employ  
62 high-resolution convection-permitting modelling as an investigation tool to elucidate the full life cycle of these  
63 clouds, the development of the precipitation and their response to any perturbations in the aerosol loading (Colle  
64 et al., 2005; Smith et al., 2015).

65 Variations in Sea Surface Temperature (SST), from the shallow water area off the coast to the deeper open ocean  
66 and from low to high latitudes over the GBR, could also lead to differences in cloud properties, especially for

67 boundary layer clouds (Crook 1996). SST directly contributes to the thermodynamic conditions, which modulate  
68 the sensible and latent heat fluxes, and, consequently, cloud properties such as cloud cover, cloud top height and  
69 cloud base (Bony et al., 2004). Significant positive SST anomalies are known to be a key driver of severe thermal  
70 coral bleaching periods across the GBR (Berkelmans et al., 2004; Hughes et al., 2017). These large SST anomalies,  
71 which could be prevalent for a few months and may spike during periods of weak winds (Filipiak et al., 2012;  
72 Gentemann et al., 2003; Zhang et al., 2016), are hence expected to produce a strong local forcing that could change  
73 the local thermodynamic conditions.

74 In addition to the aerosol and SST variations, clouds over the GBR can experience other local forcing mechanisms  
75 unique to this region. For example, orographic forcing could potentially be important when the south easterly  
76 trade winds blow clouds across the Queensland coast and encounter the Great Dividing Range (Houze, 2012).  
77 The Wet Tropics of Queensland stretches along the northeast coast of Australia for around 450 km roughly 15-19  
78 °S (between the towns of Cairns and Townsville), where significant topography of ~1000m with a peak height of  
79 1612 m at Mount Bartle Frere (Sumner and Bonell, 1986) is present. Pronounced precipitation enhancement over  
80 the windward slopes of the mountain barrier (Roe, 2005) is commonly observed. The mean annual accumulated  
81 rainfall over this large area is among the greatest in Australia (e.g. Bonell and Gilmour, 1980), with the Bellenden  
82 Ker Top station receiving over 8000 mm of annual precipitation (Herwitz, 1986) on average. Zhao et al. (2022)  
83 found significant orographic enhancement of low-level clouds not only over the Wet Tropics, but also over the  
84 upwind ocean extending partially over the GBR. It is therefore of interest to examine any upwind effect of  
85 orographic enhancement on shallow cloud and precipitation through high-resolution numerical simulations, where  
86 interactions of local variability associated with topography and coastal processes are better resolved.

87 In this paper, we undertake a case study using a series of simulations to explore the sensitivity of trade wind  
88 cumulus over the GBR to these different local forcings. In particular, we seek to address three scientific questions:  
89 (a) How does the topography of the Great Dividing Range affect the shallow clouds and precipitation over the  
90 Wet Tropics including the GBR? (b) Is there any evidence of changes in cloud and precipitation properties in  
91 response to SST variations across the GBR? (c) How do the shallow cloud and precipitation properties respond to  
92 enhanced local aerosol loading, both over the GBR and downwind over the coast of Queensland? Unlike the study  
93 of Fiddes et al. (2021), this study does not aim to test the effects of DMS directly. Rather, it focuses on  
94 understanding how strongly, if at all, cloud and precipitation properties respond to changes in the atmospheric  
95 aerosol number concentration related to surface emissions. This analysis is also relevant to understanding the  
96 integrated effects of potential weather and climate interventions, such as marine cloud brightening, in the heat-  
97 sensitive environment of the GBR and its adjacent communities.

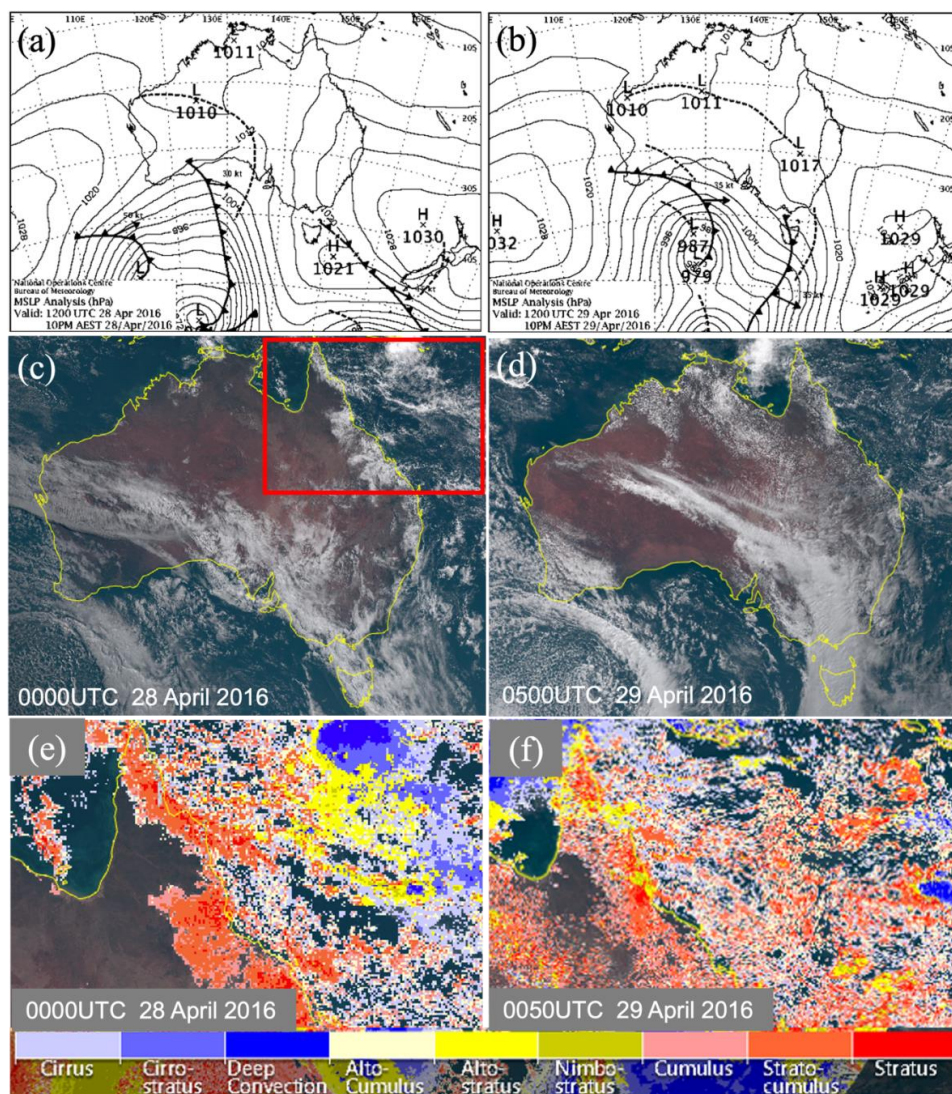

98 To address these questions, a range of sensitivity experiments are conducted using convection-permitting  
99 numerical simulations. This paper is divided into five sections as follows: Section 2 gives a brief description of  
100 the background climate the meteorological conditions of the region, Section 3 details the data and methods used  
101 in this study. The main results and discussion are presented in Section 4 and Section 5. Section 6, finally,  
102 summarizes the results and provides prospects for future research.

103 **2 29 April 2016 Case Study**

104 The GBR is characterized by a warmer than average monthly sea surface temperature during April 2016 when a  
105 thermal coral bleaching event was reported (Zhao et al., 2021). An SST anomaly of over 1°C is identified across  
106 much of the GBR (Figure S2), with this SST anomaly being likely to affect the cloud properties, especially low-  
107 level clouds through marine atmospheric boundary layer (MABL) processes (Qu et al., 2015; Takahashi et al.,  
108 2021). This selected case is characterised by local trade wind cumulus over the Wet Tropics and associated with  
109 orographic precipitation on 29<sup>th</sup> April 2016. This event is also chosen due to the absence of high cloud cover  
110 across the Wet Tropics, which are often linked to deeper convection governed by large-scale climate modes such  
111 as El Niño-Southern Oscillation (ENSO) and Madden-Julian Oscillation (MJO), as well as the Australian  
112 monsoon or tropical cyclones (Tian et al., 2006; Yuan et al., 2013; Eleftheratos et al., 2011; Wu et al., 2012). Note  
113 that there is a weak El Niño phase of ENSO during the case study period. Further, the MJO is weak, with the  
114 Real-time Multivariate MJO index (Wheeler and Hendon, 2004) less than 1, and no tropical cyclones are recorded  
115 across the Northeast Queensland and the GBR.

116 The mean sea level pressure (MSLP) analysis at 1200UTC of 28<sup>th</sup> and 29<sup>th</sup> April 2016 (Figure 1a-b) reveals a  
117 Tasman High maintaining the south-easterly trade winds along the northeast coast of Queensland during the case  
118 period. Originating in southwest Australia on 22 April, this high-pressure system gradually progressed eastward  
119 (not shown). By 26 April, it was positioned over southeast Australia, consequentially producing a high ridge along  
120 the northeast coast of Queensland during the following four days. As shown in the Himawari-8 true color images  
121 (Figure 1c) at 0000UTC 28<sup>th</sup> April 2016, northeast Queensland has mostly a clear sky with patches of low-level  
122 clouds (stratocumulus, cumulus and stratus, as shown in Figure 1e) extending southwest from the coast in the Wet  
123 Tropics. Satellite observations at 0500UTC 29<sup>th</sup> April 2016 (Figure 1f) reveal a well-developed cloud system  
124 consisting of stratocumulus, altocumulus and altostratus. Orographic precipitation associated with trade wind  
125 cumuli is captured by land-based rain gauges at several weather stations (Figure 2) on 29<sup>th</sup> April. The heaviest  
126 precipitation was recorded over the eastern slopes and mountain peaks, which is expected under the influence of  
127 upslope lifting under the prevailing southeasterly wind regime. From 0600UTC 30<sup>th</sup> April, the cloud system over  
128 the Wet Tropics started dissipating, as observed by satellite images (not shown).

129

130 Figure 1: Mean Sea-Level Pressure (MSLP) analyses for 2016 April case at (a) 1200UTC 28<sup>th</sup> and (b) 1200UTC 29<sup>th</sup>.  
131 Himawari-8 true color imagery for (c) 0000UTC on 28<sup>th</sup> April and (d) 0500UTC on 29<sup>th</sup> April 2016. Himawari-8 cloud  
132 type classification for (e) 0000UTC on 28<sup>th</sup> April and (f) 0500UTC on 29<sup>th</sup> April 2016 for the domain shown by red  
133 rectangle in (c). Cloud types as listed on the colorbar for (e-f) are Cirrus, Cirrostratus, Deep Convection, Alto-  
134 cumulus, Altostratus, Nimbostratus, Cumulus, Strato-cumulus, and Stratus. Images (a-b) are provided by the Australian Bureau  
135 of Meteorology. Images (c-f) are supplied by the P-Tree System, Japan Aerospace Exploration Agency (JAXA).

138 **23:00UTC to 2016-04-29 23:00 UTC overlaid with the precipitation observed by rain gauges shown as filled circles**  
139 **using the same color scale. Black contours indicate the topography map from 250 to 1500 m by 250 m-interval.**

### 140 **3 Data and Methodology**

#### 141 **3.1 Model configuration**

142 The Weather Research and Forecasting (WRF, version 4.2; Skamarock et al., 2019) model is used to simulate the  
143 interactions between trade wind cumulus and local forcings. In this study, the model is configured with unevenly  
144 distributed 65 levels in the vertical, allowing for 30 levels in the lowest 3 km where most of the trade cumulus  
145 clouds reside. Three nested domains with horizontal grid spacing of 9km, 3km, and 1km are utilized (Figure 3a).  
146 The innermost domain (d03) is set up with  $562 \times 457$  grid points covering most of the significant topography over  
147 the Wet Tropics, extending over the GBR. The model uses the fifth-generation atmospheric reanalysis (hourly,  
148  $0.25^\circ \times 0.25^\circ$  grid, 37 set pressure levels and surface level) from the European Centre for Medium Range Weather  
149 Forecast (ERA5 reanalysis, Hersbach et al., 2018; 2020) for initial and lateral boundary conditions, as part of the  
150 standard WRF pre-processing system (WPS). The control (CTRL) simulation is initialized at 1200UTC 27 April  
151 2016 and run for three days (i.e. 72 hours) with the first 12 hours being used as the spin-up time. It is worth noting  
152 that sensitivity to different spin-up times (e.g. 12h, 18h, and 24h) has been tested, and the simulation with a shorter  
153 spin-up time (12h) produces a better agreement with observations for this case (not shown).

154

155 **Figure 3:** (a) The WRF three nested domains shown by different color boxes used in this study. (b) Zoomed-in  
156 topographic-bathymetric map of the two inner domains (shown by colored rectangles) with the locations of two  
157 sounding stations (Townsville and Willis Island). The solid red rectangle points out the location of the Wet Tropics.  
158 Black lines indicate the GBR general reference map. (c)  $1^\circ \times 1^\circ$  downwind sub-domain shown by red rectangles. (d)  
159 same as (c), but for upwind sub-domain

160 The history intervals of prediction outputs are set to be 6h for d01, 3h for d02, and 1h for d03. Simulations are  
161 performed with the Yonsei University (YSU, Hong et al., 2006, first-order nonlocal) planetary boundary layer  
162 (PBL) scheme, “Noah” land surface model (Chen and Dudhia, 2001), and the RRTMG (Mlawer et al., 1997)  
163 scheme for shortwave and longwave radiation, respectively. The same schemes are used for each domain, with  
164 the exception of the cumulus scheme. The Kain-Fritsch (Janjić 2000) cumulus parameterization is used only for  
165 the coarsest domain (d01) to represent sub-grid convection. For the microphysical parameterization, the  
166 Thompson Aerosol Aware microphysics scheme (Thompson and Eidhammer, 2014) is used. Rather than assuming  
167 all model horizontal grid points have the same vertical profiles of cloud condensation nuclei (CCN) and ice  
168 nucleating (IN) aerosols, this study uses an auxiliary aerosol climatology as the aerosol background condition  
169 placed into WRF model. The aerosol input data are derived from multiyear (2001-2007) global model simulations  
170 (Calarco et al. 2010). This scheme incorporates the activation of aerosols as CCN and IN, which is determined by  
171 a lookup table that employs the simulated temperature, vertical velocity, number of available aerosols, and  
172 hygroscopicity parameter applied in Köhler activation theory. Rather than considering multiple aerosol categories,  
173 this scheme simply refers to the hygroscopic aerosol as a “water friendly” aerosol and the nonhygroscopic ice-  
174 nucleating aerosol as “ice friendly”. The activation of aerosols as droplets is done at cloud base as well as  
175 anywhere inside a cloud where the lookup table value is greater than the existing droplet number concentration  
176 (Thompson and Eidhammer, 2014). The Thompson Aerosol Aware scheme has been shown in previous studies

177 to have promising skill in representing both supercooled and warm liquid conditions of grid-scale clouds (Weston  
178 et al., 2022; Wilkinson et al., 2013).

179 An overview of the parameterization schemes used in the CTRL simulation is provided in Table 1. It is worth  
180 noting that other configurations with different microphysics, boundary layer, and cumulus schemes have also been  
181 tested, and the simulation with the configuration listed in Table 1 is found to be most skilful when evaluated  
182 against observations. This configuration is therefore used as our CTRL run and the same configuration settings  
183 are applied to all sensitivity experiments.

184 **Table 1: A list of configuration settings for numerical study**

Parameterisation	Option No. (d01, d02, d03)	Comments
Microphysics	mp_physics = 28	Thompson Aerosol Aware (2014) scheme
PBL	bl_pbl_physics = 1	YSU PBL scheme
Cumulus	cu_physics = 1 (d01 only)	Kain-Fritsch scheme (d01 only)
Land/Sea surface	sf_surface_physics = 2	Noah Land Surface Model
Short wave radiation	ra_sw_physics = 4	RRTMG shortwave
Long wave radiation	ra_lw_physics = 4	RRTMG scheme

185

### 186 3.2 Sensitivity experiments

187 Five sensitivity experiments are undertaken to examine the impacts of various local forcings, as detailed below:

188 In the topography experiment, the orography above 300 m is reduced by 75% (Figure S1), named ‘Topo300’, as  
189 similarly done in Flesh and Reuter (2012) and Sarmadi et al. (2019). A threshold of 300m is chosen because it is  
190 approximately the mean altitude of the Wet Tropics region, hence representing the background geography. A 75%  
191 reduction is used in order to preserve some of the topographic features, and to avoid drastic changes of topography  
192 that may induce dramatic changes in the larger-scale circulations. We note that a 500 m threshold is also tested  
193 and yielded similar results (not shown).

194 For the local SST forcing, two sensitivity simulations have been conducted in which the monthly mean  
195 climatological SST condition for April (namely ‘SST-climatology’, Figure S2) and 1°C cooler than real SST  
196 condition (namely ‘SST-cooler’) are used to initialize the simulation. SST modifications are applied to the whole  
197 ocean area for all three domains. It should be noted that, as with CTRL, the SST conditions are fixed through the  
198 3-day simulations.

199 Finally, the climatological surface water-friendly aerosol (WFA) emissions ( $\text{kg}^{-1} \text{s}^{-1}$ ) over the GBR (see general  
200 reference map in Figure 3b) is increased by a factor of 2 and 5, respectively, to test the sensitivity of warm cloud  
201 and precipitation to the aerosol loading to emulate a scenario of enhanced aerosol population associated with coral  
202 reef emissions (named ‘Aerosol2’ and ‘Aerosol5’, respectively, Figure S3).

203 Table 2 summarizes the details of these sensitivity experiments.

204 **Table 2: Detailed information of numerical experiments conducted in this study.**

		Modification description
CTRL-run		N/A
Sensitivity experiments	Topo300	Decreases elevation by 75% for elevations above 300m
	Aerosol2	Climatological surface WFA emissions increased by 200%, GBR only
	Aerosol5	Climatological surface WFA emissions increased by 500%, GBR only
	SST-cooler	SST reduced by 1°C, whole ocean domain
	SST-climatology	SST replaced by 21-yr (from 1998 to 2018) April climatology, whole ocean domain

205

### 206 3.3 Observational Data

207 Several observational datasets and reanalysis are used to evaluate the simulation across a range of spatial-temporal  
208 scales. In this study, sounding data at 0000 UTC and 1200UTC during the simulation period are obtained from  
209 the University of Wyoming upper-air sounding database for two selected radiosonde stations (Townsville, code:  
210 94294 and Willis Island, code: 94299). To evaluate the large-scale meteorological background conditions in the  
211 simulation, hourly mean sea level pressure (MSLP) and wind field at 10 m are also obtained from ERA5 reanalysis  
212 with a resolution of 0.25° for the case period (Hersbach et al., 2020). It is worth noting that the simulated synoptic  
213 conditions are reasonably consistent with ERA5, although this is largely expected as the simulations are initialized  
214 with ERA5 reanalysis in this study. Channel 13 brightness temperatures from the Himawari-8 satellite dataset  
215 (Bureau of Meteorology, 2021) and daily rainfall datasets from continuous weather stations are obtained from the  
216 Australian Bureau of Meteorology for the case study period. A total of 60 stations are selected, and their spatial  
217 distribution is shown in Figure 6.

### 218 3.4 Identifying the trade wind inversion

219 The trade wind inversion (TWI), which results from the interaction of large-scale subsiding air from the upper  
220 troposphere and rising air from lower levels that is driven by convection, plays an important role in defining cloud  
221 structure and vertical development (Riehl et al., 1979; Albrecht, 1984). Under a trade-wind regime, the top of a  
222 cloud layer typically marks the base of the inversion.

223 In this study, we use the same criteria identified in Murphy et al. (2017) to examine the TWI characteristics and  
224 its interaction with clouds. Four variables are used: (1) pressure, (2) height, (3) dry bulb temperature, and (4)  
225 relative humidity. The criteria used are as follows:

- 226 a) The TWI is restricted to the 850-600 hPa layer and environmental temperatures greater than 273 K.
- 227 b) The base of the TWI is defined where the temperature begins to increase, and relative humidity decreases  
228 with height.
- 229 c) The top of the TWI is defined by a vertical temperature decrease with height.

230 d) When multiple inversions are detected, the layer with the greatest relative humidity decrease is selected  
231 as the TWI.

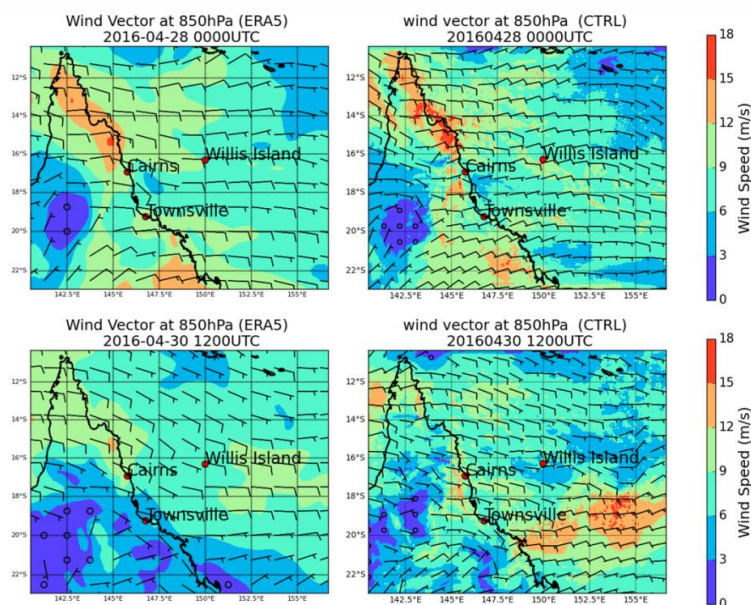

232 Two properties, in addition to the inversion base height, describing the TWI are defined also following the method  
233 described in Murphy et al. (2017). The inversion thickness (km) is the difference in height between the base and  
234 top of the inversion, while the inversion strength or magnitude (K) is the temperature increase across the inversion.

#### 235 4 Control simulation

236 In this section, the simulated synoptic and the surface features are first evaluated by comparing the results of the  
237 control simulation with observations. It is found that the control simulation skilfully simulated the evolution of  
238 the large-scale synoptic patterns of the MSLP in terms of both the progression and the magnitude of the surface  
239 pressure system (not shown). Simulated wind conditions at 850 hPa at 0000 UTC 28 April (the first hour after  
240 spin-up time) are compared with ERA5 reanalysis, and the 3 km WRF simulated pattern and magnitude of the  
241 wind field are found to be generally in good agreement with the reanalysis (Figure 4). Good agreement is also  
242 found towards the end of the simulation (1200UTC 30 April), with both wind speed and direction agreeing  
243 reasonably well with the reanalysis (Figure 4). Figure 5 shows the observed soundings (black) from the two  
244 available sounding stations (Willis Island and Townsville) within the domain and the simulated atmospheric  
245 profile (red) at the nearest grid point in the 3 km domain at 0000 UTC on 28 and 30 April. The simulated soundings  
246 at the two sites both have good agreement with observations at the beginning and the last day of the simulation,  
247 with both wind speed and direction well captured throughout the profile. The simulation accurately predicts the  
248 cloud base height (around 850 m) and surface temperature at the two sites, and it is worth noting that the wind  
249 inversion at 800 hPa at Townsville station is well captured throughout the simulation (Figure 5).

250 Figure 5 compares the observed and simulated brightness temperature throughout the simulation period. Note that  
251 the simulated brightness temperature is simply calculated assuming an emissivity of one for all surfaces and an  
252 effective cloud optical depth of one. It is used for a qualitative evaluation of the simulated cloud field only. Overall,  
253 the cloud field is reasonably well simulated in terms of the location and timing when compared against the  
254 Himawari-8 observation. Although the chaotic nature of shallow cumulus cloud means that details are not fully  
255 aligned, the major cumulus cloud features over the Wet Tropics throughout the three-day simulation period has  
256 been well captured.

257 Figure 2 shows the 48 h accumulated precipitation from the 1 km WRF simulation, overlaid with the observed  
258 rainfall shown as filled circles using the same color scale. The orographic signature (see Figure 3b and black  
259 contours in Figure 6), as shown in the correlation between the accumulated precipitation amounts and topography,  
260 is evident in both the observed and simulated precipitation. The overall distribution of the simulated accumulated  
261 precipitation shows a good agreement with the rain gauge observations, with the majority of the precipitation  
262 produced over the windward side of the topography. Although a bias is noted in the location of the peak  
263 precipitation, the simulated accumulated precipitation amounts agrees reasonably well with the rain gauge  
264 observations.

277

## 278 **5 Sensitivity analysis**

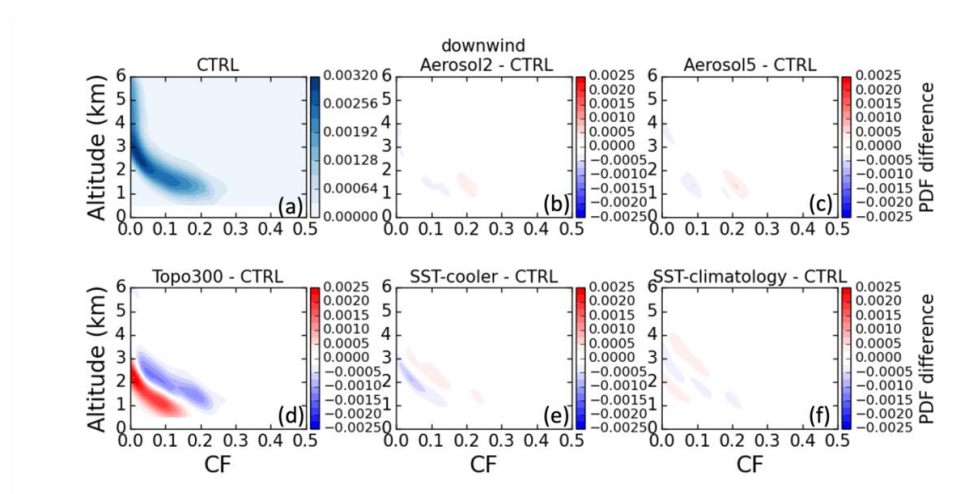

### 279 **5.1 Orographic effects**

280 To explore any upwind effect of the orography over the Wet Tropics, two  $1^\circ \times 1^\circ$  sub-domains are selected with  
281 one covering the primary orographic area (hereafter downwind sub-domain, Figure 3c) where the major  
282 precipitation occurs (see Figure 2 and Figure 9a), and another over the upwind water area (hereafter upwind sub-  
283 domain, Figure 3d). The simulated cloud fraction (CF) has been analysed over these two sub-domains,

284 respectively. In this study, CF is defined as the proportion of total grid points in the target domain that are classified  
285 as cloudy grids, denoted by the binary number 1, for each model level. For each model level from 0.5 to 6 km, the  
286 CF is calculated for each hour. Figures 7 and 8 show the 2-dimensional Probability Density Function (PDF)  
287 distribution of the CF across the domains for the 60 hours of simulation. To generate the PDF, 100 bins are applied  
288 to both variables CF and altitude. Then the probability density for each grid point is calculated based on CF  
289 samples at model levels from 60 simulations hours. The uppermost level of this analysis is set to 6 km as most of  
290 the clouds are observed to be at low to mid-level during the simulation period. As shown in Figure 7a and 8a, the  
291 simulated CF over these sub-domains from CTRL is between 0.5 and 2.5 km (i.e. boundary layer clouds and trade  
292 wind cumuli). Note that the boundary layer height over the Wet Tropics is around 950 m in the CTRL run (not  
293 shown) and the trade wind inversion base is at around 2 km (see Figure 10a).

294 Comparing the simulated CF distribution between Topo300 and CTRL runs over the orographic area (Figure 7d),  
295 there appears to be a noticeable decrease in cloud cover in the Topo300. The most pronounced reduction is evident  
296 at lower altitudes, specifically below 2 km. Cloud top height is generally reduced in Topo300, with a greater  
297 number of simulation hours in Topo300 indicating a CF near zero above 2km. This same feature is also seen over  
298 the upwind coral reef area (Figure 8d), though the magnitude of the CF is relatively small compared to the  
299 mountain area. Larger differences in CF are, once again, found at lower altitudes (below 2 km). It is interesting to  
300 note that the orographic enhancement of the low-level cloud fraction, extending to the eastern water area,  
301 potentially provides a sheltered area for the coral reefs, protecting them from severe bleaching through reducing  
302 the solar radiation heating. This result is consistent with the observational analysis presented by Zhao et al. (2022),  
303 which highlighted a notable increase in the frequency of low-level clouds associated with orographic enhancement  
304 in the Wet Tropics.

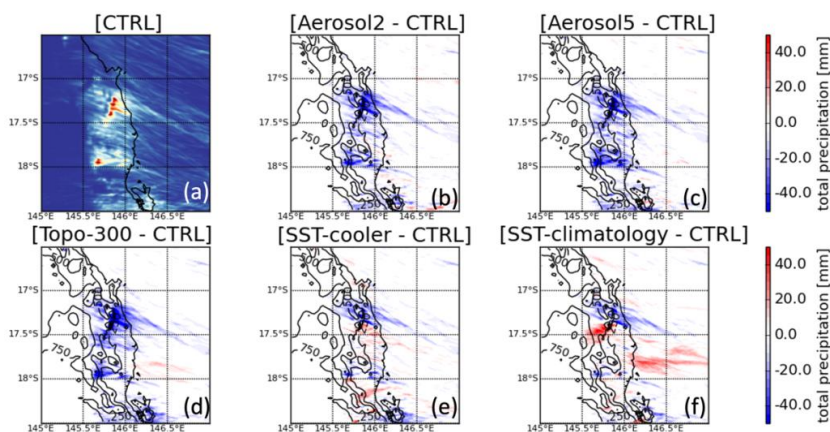

305  
306 **Figure 7:** (a) Vertical PDF distribution of 1 km resolution simulated cloud fraction over the downwind mountain area  
307 (shown by red square in Figure 3c) from CTRL-run. (b-f) Difference plots between CTRL-run and Aerosol2, Aerosol5,  
308 Topo300, SST-cooler, SST-climatology. The analysis is for 60h simulation time after the spin-up from 2016-04-28  
309 0000UTC to 2016-04-30 1200UTC.

310

311 **Figure 8:** Same as Figure 7, but for the upwind water area (shown by red square in Figure 3d).

312

313 **Figure 9:** (a) Accumulated precipitation for the time period of 2016-04-28 0000UTC to 2016-04-30 1200UTC from 1  
 314 km resolution with CTRL-run. (b-f) Difference plots of accumulated precipitation between CTRL-run and Aerosol2,  
 315 Aerosol-5, Topo300, SST-cooler, SST-climatology, separately. Black contours indicate the topography map from 250  
 316 to 1500 m by 250 m-interval.

317

318 Figure 9 shows the map of accumulated precipitation over the inner-most domain from 1 km WRF simulations  
 319 from the CTRL-run, and the difference between CTRL-run and sensitivity studies, respectively. The accumulation  
 320 period is the 60-h simulation time after the spin-up (i.e. from 0000UTC 28 to 1200UTC 30 April 2016). As shown  
 321 in Figure 9d, a strong reduction in precipitation over the topography is evident when the topography is modified,  
 322 particularly over the windward slopes. Over 40 mm difference in the accumulated precipitation is noted at the  
 323 points of highest precipitation grids between the TOPO300 and CTRL simulations, highlighting the major role of

324 terrain in the development of precipitation. In addition to the mountain area, this precipitation reduction has also  
325 been seen over the upwind region, extending to the GBR. We note a slight increase in the accumulated  
326 precipitation in the southern part of the upwind domain, indicating the chaotic nature of cloud and precipitation  
327 in weakly-forced locations.

328 The local cloud and precipitation differences shown in Figure 7d, 8d and 9d can be elucidated through the  
329 examination of convection-related variables, including convective available potential energy (CAPE), 10 m wind  
330 convergence (calculated as  $(-1) \times (\partial u/\partial x + \partial v/\partial y)$ , Schneider et al., 2018), and velocity difference ( $w_{\text{diff}}$ ) between  
331 the maximum vertical velocity below the level of free convection (LFC) and the required updraft velocity to  
332 overcome convective inhibition (CIN), calculated as  $\sqrt{2 \times CIN}$  (Trier 2003). Positive values of  $w_{\text{diff}}$  indicate that  
333 air parcels can reach their respective LFC, release CAPE and initiate convection. Additionally, we have analysed  
334 simulated trade wind inversion (TWI) properties, including its base height, thickness, and strength. This analysis  
335 is important because trade-wind cumuli are constrained by the TWI, particularly over the oceanic regions. It is  
336 also perhaps more difficult to directly link changes in cloud and precipitation process over the upwind domain to  
337 the direct mountain-induced lifting and low-level wind convergence. Note that all these variables are calculated  
338 for each grid point at each hour.

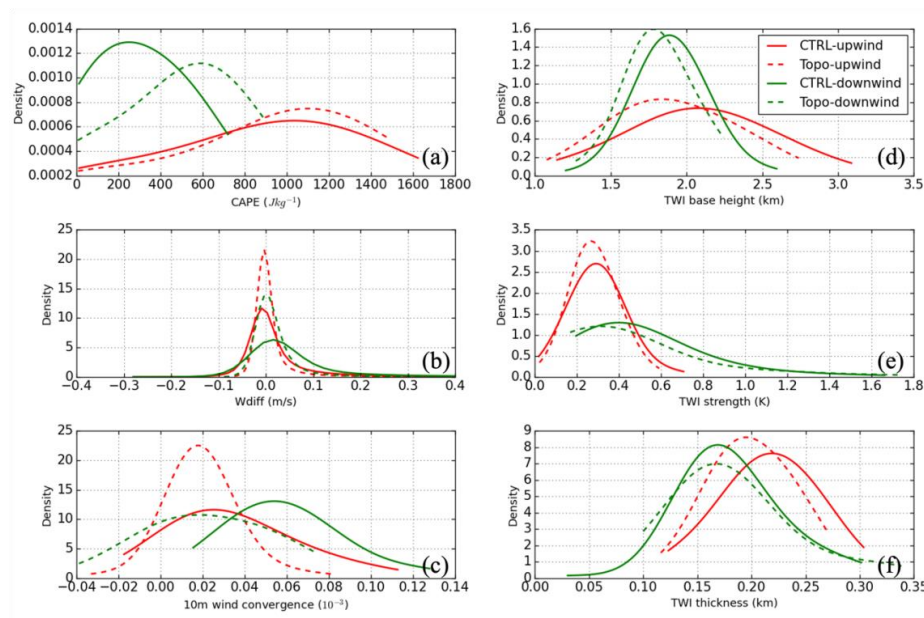

339 As seen from Figure 10a, a notable increase in CAPE is seen in the Topo300 over the downwind area, whereas  
340 only small increases are found at the upwind. The change in CAPE is clearly explained by the change in orography.  
341 The atmosphere deepens when the mountains are reduced, leading to higher temperatures at the surface. Because  
342 the relative humidity is essentially unchanged, the LFC is lower, which results in higher CAPE values over the  
343 topography in the Topo300 experiment. However, fewer grid points are simulated with positive  $w_{\text{diff}}$  in the  
344 Topo300 run over the downwind area (Figure 10b), making the CAPE more challenging to release. This therefore  
345 results in a reduced cloud fraction and precipitation in the Topo300, despite the presence of higher CAPE values  
346 at the downwind area. Low-level wind convergence over the downwind area is much stronger in the CTRL run,  
347 as the lack of strong orographic lifting in the Topo300 run produces only weak low-level convergence. However,  
348 this is not as significant over the upwind area, where little to no difference in  $w_{\text{diff}}$  and low-level convergence is  
349 seen between CTRL and Topo300 (Figure 10b-c).

350 As expected, the upwind area experiences weaker effects of mountain-induced lifting, and so the impacts of the  
351 alteration in mountain height are attenuated. However, changes in topography do lead to modifications in the  
352 upwind airstream (Chu et al., 2000; Zhang et al., 2022). Altered upwind temperature and wind profiles are likely  
353 to result in modifications of TWI characteristics. It is possible that the height and thickness of trade wind inversion  
354 is being modified in the Topo300, which constrains the trade cumulus development over the upwind area. To  
355 explore this possibility, we compared the simulated TWI properties in the CTRL and Topo300 runs (Figure 10d-  
356 f). The results show that that a higher inversion base height with a relatively larger inversion thickness is present  
357 in the CTRL run over both downwind and upwind areas, whereas a reduction in orography results in a lower TWI  
358 base height and a smaller inversion thickness over the upwind area. The lower TWI in the Topo300, as a result,  
359 constrains the vertical development of the clouds, resulting in a lower cloud top height and less developed cloud  
360 and precipitation systems. To summarize, the vertical velocity and low-level wind convergence, coupled with the  
361 TWI, are crucial in explaining the cloud and precipitation features over the downwind area, which can be directly

362 linked to the mountain induced lifting and flow deviation. On the other hand, the upwind effect of orographic  
363 enhancement is more closely associated with the alterations in TWI properties.

364  
365 **Figure 10: PDF distribution of the (a) trade inversion base height, (b) inversion strength, (c) inversion thickness, (d)**

368 **from CTRL, and dashed lines are for Topo300 sensitivity experiment.**

369

## 370 5.2 Local aerosol loading

371 We have also explored the hypothesis that regional aerosol loading may affect the cloud and precipitation  
372 properties over the GBR. As shown in Figure 11a, doubling the surface WFA emission over the GBR (Aerosol2  
373 experiment) results in an increase of  $\sim 700/cm^3$  in the near-surface WFA number concentration over the upwind  
374 sub-domain (from  $572/cm^3$  to  $1250/cm^3$ ), throughout the evolution of the simulation. The increase in WFA  
375 emission at the surface also leads to an increase in the atmospheric WFA population to levels above 2 km (Figure  
376 13a). Pertaining to the Aerosol5 experiment, the near-surface WFA number concentration increases by  
377 approximately  $1400/cm^3$ , from  $572/cm^3$  to  $2241/cm^3$ , in comparison to the CTRL (Figure 11a) as well as an  
378 enhancement in the upper-level profile of the WFA concentration (Figure 13e). A slight time-variation in WFA  
379 number concentration (WFANC) is seen for both Aerosol2 and Aerosol5, which primarily results from the  
380 advection and diffusion of the aerosol during the model integration (Thompson and Eidhammer, 2014). The  
381 notable spike of the WFA number concentration during the last day of the simulation is primarily attributed to the  
382 strong inflow from the southern portion of the GBR when the surface wind changes from easterly to southeasterly  
383 (Figure 4). It is worth noting that a fairly similar increase in the WFANC is also seen over the downwind

384 subdomain in both Aerosol sensitivity experiments (Figure 12a, Figure 13a and 13e). Given the predominance of  
385 trade wind patterns in this region, this downwind impact is not unexpected.

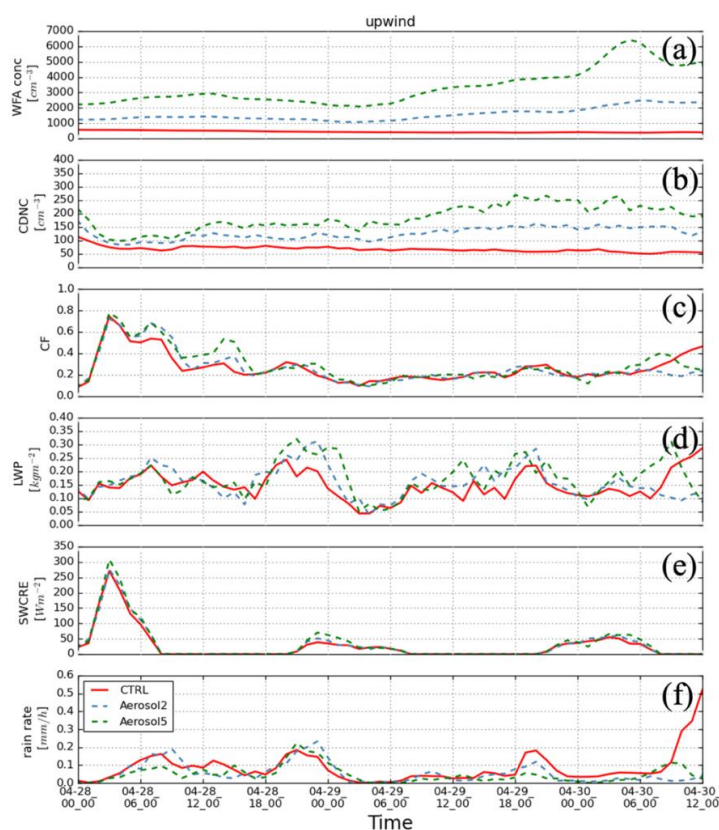

386 Cloud droplet number concentration (CDNC), considered both upwind and downwind, is sensitive to the changes  
387 in the atmospheric aerosol number concentration (Figure 11b and 12b). A higher CDNC corresponds to an increase  
388 in the WFA population is evident from the cloud base to the cloud top (Figure 13b and 13f). Total CF, however,  
389 is found to be essentially unaffected by the changes in the aerosol concentration over both sub-domains (Figure  
390 11c and 12c). The vertical profile of CF over the upwind subdomain (Figure 13c) suggests a slight deepening of  
391 the trade cumulus with an increase in domain-averaged CF at cloud top, especially in Aerosol5 experiment (also  
392 shown in Figure 8c). Minimal response is seen at cloud base. This is consistent with an increase of the liquid water  
393 path (LWP), which is evident in both the Aerosol2 and Aerosol5 experiments (Figure 11d and 13d) over the  
394 upwind. Looking downwind, even though the CF remains largely unchanged across the altitudes (Figure 13g, 7b  
395 and 7c), a cloudy layer with higher CDNC could also result in a larger LWP as shown in Figure 12d. Additionally,  
396 the cloud radiative effect (CRE) has been considered through the CTRL run and the Aerosol sensitivity  
397 experiments. CRE is defined as the net radiation flux (downward flux minus upward flux) under all sky conditions  
398 minus the net radiation flux under clear sky conditions and can be applied to both the surface and top of atmosphere  
399 (Imre et al., 1996; Bao et al., 2020). Here, in this analysis, we focus on the shortwave CRE (SWCRE) at the  
400 surface, as it represents the effective solar heating of the sea surface. As shown in Figure 11e and 12e, a rise in  
401 SWCRE, though small with a maximum of  $50 \text{ W/m}^2$ , is evident with increase in aerosol population over both sub-  
402 domains. This is primarily attributed to the higher CDNC, as the cloud reflectance is enhanced with increased  
403 droplets number concentration.

404 As shown in Figure 9b and 9c, a reduction in total precipitation is seen in both Aerosol sensitivity experiments,  
405 primarily over the downwind mountain area, with a maximum 30mm difference (~30% reduction) noted around  
406 the peak precipitation points. This decreased precipitation is evident throughout the simulation hours between the  
407 CTRL and Aerosol sensitivity runs (Figure 12f). Relatively small changes (less than 20 mm) in accumulated  
408 precipitation are seen over the upwind area, where the decreased accumulated precipitation mainly originates from  
409 a few hours in the last day of simulation (Figure 11f). Although small in magnitude, the warm cloud precipitation  
410 over the GBR is found to show considerable responses to the changes in the local aerosol loading.

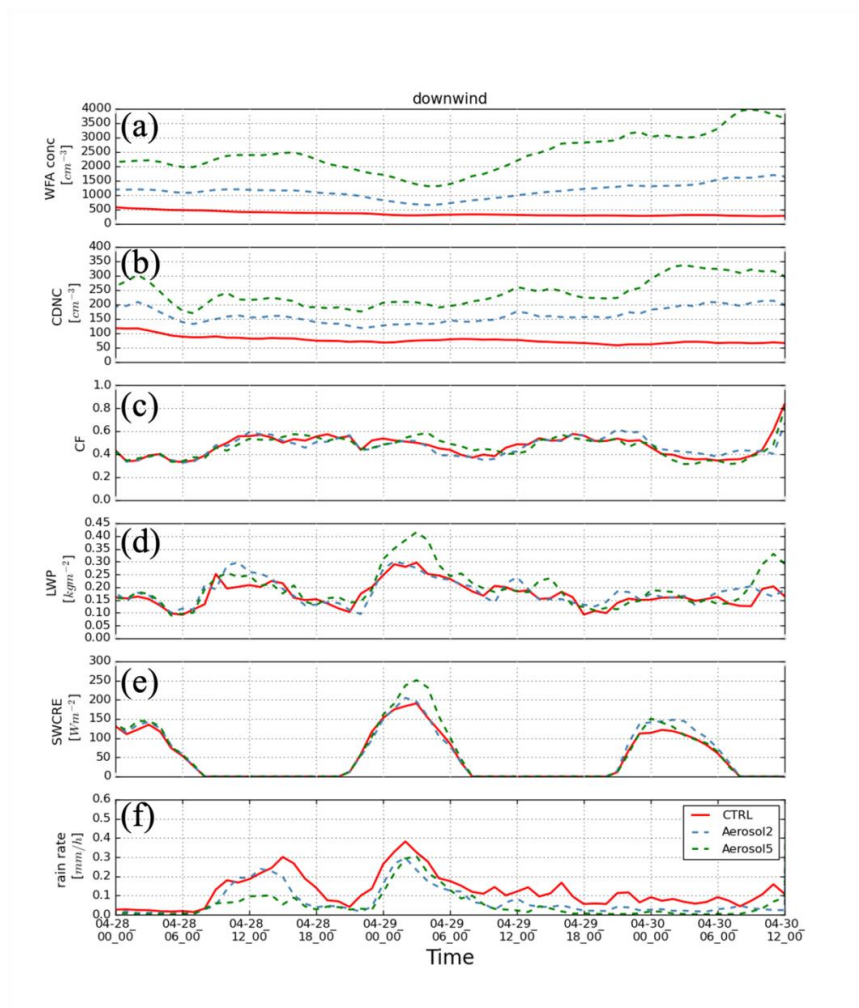

411 Increased CCN concentrations can be expected to produce smaller droplets for a given liquid water content  
412 (Twomey, 1997). The smaller cloud droplets can reduce the efficiency of collision and coalescence, which may  
413 inhibit precipitation development (Albrecht, 1989). Over the GBR, our sensitivity experiment indicates  
414 consistently that, cloud microphysical properties, including CDNC and LWP, and precipitation respond strongly  
415 to changes in the local WFANC. A significant rise in CDNC is correlated with an increase in the aerosol  
416 population is seen over the GBR, and predominantly leads to suppressed precipitation over both upwind and  
417 downwind areas. While the total CF is showing less sensitivity to the aerosol perturbations. It's worth noting that  
418 the Aerosol sensitivity experiments also show evidence of deepened trade cumulus over the upwind region, which  
419 will increase the LWP and the SWCRE. A notable downwind effect featured by a significant reduction of surface  
420 precipitation is simulated when changing the surface aerosol emissions over the GBR.

421 We note that how convection may interact with changes in aerosol is still a large source of uncertainty (Tao et al.,  
422 2012) and our experiment only focus on perturbing the water friendly aerosol loading over the GBR. Previous  
423 studies have shown that the thermodynamic environment is strongly modulated by the large-scale forcing, whose  
424 impact on the cloud field might surpass that of local aerosol perturbations (Dagan et al., 2018; Spill et al., 2021).  
425 Spill et al. (2021) show that the response of cumulus cloud and precipitation to the aerosol perturbation is much  
426 stronger in the idealised simulations without the large-scale forcing. This suggests a potentially limited effect of  
427 aerosols on cumulus cloud fields in the realistic condition due to the predominant influence of large-scale forcing.  
428 The nature variability of the marine shallow clouds and precipitation process could also explain some of the  
429 differences between the CTRL and Aerosol sensitivity runs.

430

 439 cloud droplet number concentration, (c) domain-averaged cloud fraction, and (d) domain-averaged liquid water  
 440 content over the upwind sub-domain from CTRL (in red), Aerosol2 (in blue), and Aerosol5 (in green). The analysis is  
 441 for 60h simulation time after the spin-up from 2016-04-28 0000UTC to 2016-04-30 1200UTC. (e-h) same as (a-d), but  
 442 for downwind sub-domain.

443

### 444 5.3 Local SST forcing

445 In this section, we have explored the sensitivity of cloud and precipitation properties over the GBR in response to  
 446 the local SST changes. It is important to note that, unlike the SST alteration in the SST-cooler experiment, part of  
 447 the ocean area in the SST-climatology is warmer than the actual SST at the beginning of the simulation (Figure  
 448 S2). Nevertheless, the sea surface temperature over the majority of the GBR is reduced in the SST-climatology  
 449 experiment.

450 A reduction in CF is noted over the upwind in the SST-cooler run, with the most notable difference apparent at  
 451 lower altitudes (Figure 8e). This small decrease in CF might be associated with a consistent decrease in surface  
 452 heat flux and moisture flux in the SST-cooler experiment (Figure 14). Over the downwind sub-domain, the CF  
 453 has only a small difference between the CTRL and SST-cooler experiments (Figure 7e). However, a decrease in  
 454 the accumulated precipitation is discernible over downwind points with the peak accumulated precipitation  
 455 (Figure 9e). Similar but more variable findings are evident from the SST-climatology experiment. Figure 7f shows  
 456 small but more complex changes in CF in the downwind area with associated positive and negative changes in

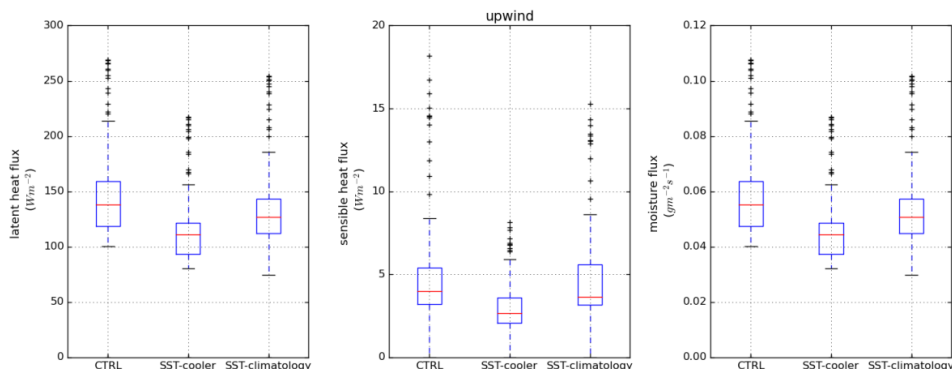

457 accumulated precipitation (Figure 9f). These variable impacts are likely due to the non-uniform (positive and  
458 negative) changes in SST associated with the differences between the CTRL and SST-climatology runs. (Figure  
459 S2). The downwind effect on precipitation is similarly discernible in the SST-climatology, however there are no  
460 noteworthy results related to the cloud fraction (Figure 7f). There is a minor decrease in averaged surface heat  
461 flux and moisture flux in the SST-climatology experiment (Figure 14). However, a notable number of grid points  
462 have larger values, potentially associated with the warmer water over the southern part of ocean domain in the  
463 SST-climatology run (Figure S1).

464 Theoretically, a warmer SST will likely provide more water vapor in the atmosphere through increased surface  
465 latent heat fluxes. The increased atmospheric water vapor, under such conditions, will consequently induce more  
466 rainfall at local and downstream regions. Over the tropics, the SST has been noted in several studies to be a key  
467 factor controlling the location of rainfall over various timescales (Lu and Lu, 2014; Jo et al., 2019; Wu et al., 2009;  
468 Wu and Kirtman, 2007). Takahashi and Dado (2018) highlight the impact of local and/or nearby SST on local and  
469 regional climate. In particular, they found that warmer local SST results in greater rainfall over the downstream  
470 land region in the mid-latitudes based on observational dataset, which suggests strong air-sea coupling processes.  
471 Our numerical sensitivity experiments, to some extent, show consistent results, indicating that precipitation over  
472 the GBR shows response to the underlying SST conditions, though the effect is weak on the scales considered  
473 here. A downwind effect on the precipitation has been found over the Wet Tropics. Sensitivity of cloud fraction  
474 in response to SST variation is seen over the water area, though the magnitude is minor in comparison with the  
475 major orographic impacts. The relationship between cloud fraction and SST in the lower levels have been found  
476 to largely depend on the type of cloud and its height (Cesana et al., 2019). Stronger response of “lower-top”  
477 shallow cloud properties (i.e. stratocumulus) to the changes in SST is noted in Cesana et al. (2019) in comparison  
478 with “higher-top” shallow clouds, for example, cumulus. As such, much minor responses to the changes in SST  
479 are expected when considering cloud fields with the higher cloud tops. In our experiment, instances of simulated  
480 cloud field with cloud tops over 3km could largely contribute to the variety of the responses to SST forcing.

481 Overall, our simulations suggest that warm-cloud precipitation over the GBR is sensitive to the underlying local  
482 SST forcing, though the responses are weak on the scales considered in this study. Our work supports the  
483 important role of local SST on the regional climate over the GBR, but further work on understanding the synoptic  
484 and thermodynamic background and air-sea coupling processes is necessary to help elucidate the mechanisms  
485 involved.

486

487

488 **Figure 14: Boxplots showing the comparison of latent heat flux, sensible heat flux, and moisture flux from 1 km**  
489 **resolution simulation with CTRL, SST-cooler, and SST-climatology. The analysis is for 60h simulation period, and**  
490 **over the upwind sub-domain.**

491

## 492 6 Summary and conclusions

493 A primary aim of this research is to study the sensitivity of trade cumulus precipitation to different local forcings  
494 over the GBR using a case study of an orographic precipitation event associated with low-level trade cumulus at  
495 the end of April 2016. The selected days for the simulations are characterised by well-defined cumulus and  
496 stratocumulus under the trade wind regime without any overlying high clouds. These trade cumuli are observed  
497 to generate precipitation over the Wet Tropics around Townsville.

498 The large-scale meteorology is well captured in the CTRL simulation in terms of the location, duration and  
499 magnitude of the surface pressure system and wind fields. Comparison of the upper air profiles from both  
500 Townsville and Wills Island sounding stations showed good agreement in wind speed, wind direction and  
501 temperature profiles. The CTRL simulation also demonstrated a considerable level of skill in simulating both the  
502 spatial distribution and the intensity of precipitation over the Wet Tropics as compared to ground observations.

503 Sensitivity experiments are conducted to investigate the sensitivity of trade cumulus and precipitation in response  
504 to the local forcings. Our major findings from the sensitivity analysis are summarized as follows:

- 505 • Reducing the elevation above 300m by 75% decreases the cloud fraction and accumulated precipitation  
506 over the Wet Tropics, including both downwind and upwind areas. Weaker vertical velocity and low-  
507 level wind convergence are generated in the Topo300 run over the downwind sub-domain, suggesting  
508 their crucial role in rainfall production. The reduced TWI base height in the Topo300 run is found to  
509 limit the cloud-precipitation development over the upwind water area.
- 510 • Cloud microphysical properties, including CDNC, LWP, and precipitation are sensitive to the changes  
511 in atmospheric aerosol population over the GBR. Higher CDNC and LWP correlated to increased aerosol  
512 number concentration leads to a rise in SWCRE, though the magnitude is small, over both sub-domains.

513            Although CF remains largely unchanged, a deepened cloud is evident over the upwind when WFANC is  
514            increased. A downwind effect on cloud and precipitation properties is further noted.

- 515            • Cloud fraction and total precipitation over the GBR show a small response to the underlying local SST
- 516            forcing. A reduction in cloud fraction is noted over the upwind water area when the initial SST is reduced,
- 517            but any difference is negligible over the downstream orographic region. There is a decrease in the
- 518            accumulated precipitation in the SST sensitivity experiments over downwind girds where the peak
- 519            accumulated precipitation generated. These small decreases in cloud fraction and accumulated
- 520            precipitation are likely associated with the consistently decreased surface heat flux and moisture flux in
- 521            the SST experiments.

522            Although a range of responses of cloud and precipitation to the local forcings are produced across the GBR in our  
523            simulations, it is recognised that ensemble analysis is necessary in the future to better represent the natural  
524            variability of these trade clouds and precipitation properties. In situ observations will also be necessary to help  
525            investigate the detailed lifecycle of these low-level clouds and the development of the topographic precipitation.  
526            Furthermore, there is a need to carry out case studies during the time of intense SST increases that may induce  
527            thermal coral bleaching over the GBR. Nevertheless, our analysis sheds some light on understanding the  
528            interactions between trade wind cumuli and local forcings across the GBR and Wet Tropics, where the importance  
529            of the local low-level cloud in thermal coral bleaching has recently been identified.

530 **Data availability statement**

531 All data sets used in this study are freely and publicly available online and may be accessed directly as follows.  
532 The University of Wyoming upper-air sounding is downloaded from  
533 <http://weather.uwyo.edu/upperair/sounding.html>. The ERA5 reanalysis data is available at the website:  
534 <https://cds.climate.copernicus.eu/cdsapp#!/search?-type=dataset>. The Australian Bureau of Meteorology Daily  
535 rainfall can be downloaded from the website: <http://www.bom.gov.au/climate/data/index.shtml>. The Himawari-8  
536 full disk observational products are available at NCI THREDDS Data Server:  
537 <https://dapds00.nci.org.au/thredds/catalogs/ra22/satellite-products/arc/obs/himawari-ahi/fldk/fldk.html>. The  
538 Himawari-8 true color imagery and cloud types classification are available at JAXA Himawari Monitor supplied  
539 by P-Tree System: <https://www.eorc.jaxa.jp/ptree/>.

540 **Author contribution:** W.Z., Y.H., S.S. and M.M. developed the ideas and designed the study. W.Z. collected the  
541 data, performed the analysis and prepared the draft manuscript. Y.H., S.S., M.M. and D.H. supervised and  
542 reviewed the manuscript. All authors made substantial contributions to this work and approved the final version  
543 of the manuscript.

544 **Competing Interests:** Some authors are members of the editorial board of journal Atmospheric Chemistry and  
545 Physics.  
546

547 **Acknowledgments:** This work is supported by Reef Restoration and Adaptation Program which is founded by  
548 the partnership between the Australian Governments Reef Trust and the Great Barrier Reef Foundation. Wenhui  
549 Zhao was also supported by Monash Graduate scholarship while working at Monash University. Yi Huang, and  
550 Steve Siems are further supported by Australian Research Council Discovery Grant (ARC DP230100639). The  
551 Australian National Computational Infrastructure is also thanked for providing the computational resources. We  
552 have also benefited from discussions with Greg Thompson. The authors would like to acknowledge the Traditional  
553 Owners of the Great Barrier Reef, particularly the Wulgurukaba and Bindal people of the Townsville region  
554 nearby the area of our case study.
