21 **Abstract**

22 Narrowing surface ozone disparities between urban and nonurban areas escalate health  
23 risks in densely populated urban zones. A comprehensive understanding of the impact  
24 of ozone photochemistry on this transition remains constrained by current knowledge  
25 of aerosol effects and the availability of surface monitoring. Here we reconstructed  
26 spatiotemporal gapless air quality concentrations using a novel Transformer deep  
27 learning (DL) framework capable of perceiving spatiotemporal dynamics to analyze  
28 ozone urban-nonurban differences. Subsequently, the photochemical effect on these  
29 discrepancies was analyzed by elucidating shifts in ozone regimes inferred from an  
30 interpretable machine learning method. The evaluations of model exhibited an average  
31 out-of-sample cross-validation coefficient of determination of 0.96, 0.92, and 0.95 for  
32 ozone, nitrogen dioxide, and fine particulate matter (PM<sub>2.5</sub>), respectively. The ozone  
33 sensitivity in nonurban areas, dominated by nitrogen oxide (NO<sub>x</sub>)-limited regime, was  
34 observed to shift towards increased sensitivity to volatile organic compounds (VOCs)  
35 when extended to urban areas. A third ‘aerosol-inhibited’ regime was identified in the  
36 Jiaodong Peninsula, where the uptake of hydroperoxyl radicals onto aerosols  
37 suppressed ozone production under low NO<sub>x</sub> levels during summertime. The reduction  
38 of PM<sub>2.5</sub> would increase the sensitivity of ozone to VOCs, necessitating more stringent  
39 VOC emissions abatement for urban ozone mitigation. In 2020, urban ozone levels in  
40 Shandong surpassed those in nonurban areas, primarily due to a more pronounced  
41 decrease in the latter resulting from stronger aerosol suppression effects and lesser  
42 PM<sub>2.5</sub> reductions. This case study demonstrates the critical need for advanced spatially  
43 resolved models and interpretable analysis in tackling ozone pollution challenges.

44

## 45 1. INTRODUCTION

46 Surface ozone ( $O_3$ ), fine particulate matter ( $PM_{2.5}$ ), and nitrogen dioxide ( $NO_2$ ) are  
47 among the most important trace gases in the atmosphere that significantly impact the  
48 ecological environment and public health (Han and Naeher, 2006; Yue et al., 2017).  
49 During the Action Plan on the Prevention and Control of Air Pollution (denoted as the  
50 Clean Air Action, 2013-2017) (Action Plan on Air Pollution Prevention and Control (in  
51 Chinese), 2023),  $PM_{2.5}$  and nitrogen oxide ( $NO_x = \text{nitric oxide (NO)} + NO_2$ ) emissions  
52 across China decreased by 33% and 21%, respectively (Zheng et al., 2018), while  
53 surface  $O_3$  exhibited an increasing trend (Lu et al., 2018). The increase in  $O_3$  could be  
54 partially attributed to the “aerosol-inhibited” effect, where the reduction in  $PM_{2.5}$  results  
55 in a diminished reactive uptake of hydroperoxyl radicals ( $HO_2$ ) onto aerosols (Ivatt et  
56 al., 2022; Li et al., 2019). The societal benefits of reducing premature deaths and  
57 economic losses from  $PM_{2.5}$  reductions have been diminished by the rising  $O_3$  (Liu et  
58 al., 2022). Thus, achieving the joint attainment objectives for  $PM_{2.5}$  and  $O_3$  has been put  
59 on the top priority of China’s long-term air pollution control policies.

60 The complexity of the  $O_3$  formation is partly reflected by the nonlinear response  
61 to changes in precursors (i.e. volatile organic compounds (VOCs) and  $NO_x$ ), as well as  
62 the presence of heterogeneous reactions in aerosols. Understanding these dynamics is  
63 crucial to investigate current narrowing differences in  $O_3$  concentrations between urban  
64 and nonurban areas, which have traditionally shown higher levels in rural (Han et al.,  
65 2023). The formaldehyde-to- $NO_2$  ratio ( $HCHO/NO_2$  or FNR) serves as a theoretical

66 gauge of the relative abundance of total organic reactivity to hydroxyl radicals (OH)  
67 and NO<sub>x</sub> (Wei et al., 2022c; Sillman, 1995), and as such, it can function as a useful  
68 indicator of O<sub>3</sub> sensitivity. Previous studies have utilized the HCHO/NO<sub>2</sub> from satellite  
69 remote sensing to infer O<sub>3</sub> production regimes for guiding O<sub>3</sub> control policies (Jin et al.,  
70 2023; Li et al., 2021a; Jin et al., 2020). However, the changes of HCHO/NO<sub>2</sub> threshold  
71 in O<sub>3</sub> regimes classification modulated by meteorology and localized atmospheric  
72 chemistry in space and time, and uncertainties relating column to surface, precluding  
73 robust applications over larger spatial scales (Lee et al., 2023; Jin et al., 2017; Sourì et  
74 al., 2023). While the observation-based model method alleviates some of these  
75 limitations, constraints remain including computational demands and priori chemical  
76 mechanisms (Song et al., 2022b; Chu et al., 2023). The advent of interpretable machine  
77 learning models affords new opportunities to unravel intricate dependencies governing  
78 O<sub>3</sub> formation purely from actual observational data. However, sparse ground-based  
79 monitoring stations, especially in rural areas, pose great challenges to the spatially full  
80 coverage of studies. Thus, the high-spatiotemporal-resolutions estimations of surface  
81 air pollutants are urgently needed to improve our understanding of how these pollutants  
82 are changing and interacting.

83       Recent studies have utilized spatially resolved remote sensing data to estimate the  
84 continuous distribution of air pollutants in space by diverse machine learning (ML)  
85 models (Lyapustin and Wang, 2022; Lamsal et al., 2022; Huang et al., 2021; Li and  
86 Wu, 2021; Ren et al., 2022b), such as random forest (RF), full residual deep learning,

87 and Bayesian ensemble model. These attempts have demonstrated the tremendous  
88 potential of machine learning as an alternative to atmospheric chemical models (Jung  
89 et al., 2022). Nevertheless, there are still several aspects that have not been fully  
90 considered. For instance, coarse-resolution maps limit the ability to characterize the  
91 fine-scale variation of air pollution within urban areas, which has significant  
92 implications for environmental justice disparities of disadvantaged communities  
93 (Jerrett et al., 2005; Ren et al., 2022b; Dias and Tchepel, 2018). Additionally, existing  
94 ML models may not fully account for the complex atmospheric chemistry and physics  
95 processes that influence pollutant concentrations due to the single-pixel-based  
96 processing mode (Huang et al., 2021; Requia et al., 2020; Thongthammachart et al.,  
97 2022; Li et al., 2022b; Geng et al., 2021). Although several efforts have been made by  
98 using the neural network with convolutional layers (Di et al., 2016), and explicitly  
99 incorporating spatiotemporally weighted information to machine learning models (Wei  
100 et al., 2022b), the global spatiotemporal self-correlation of multi-dimensional features  
101 in the input array remained unaddressed. Meanwhile, the convolutional operations  
102 extract features from all neighboring grids of the target, ignoring the fact that the  
103 environmental knowledge of the target grid itself is the most significant, with the  
104 adjacent features being secondary.

105 In this study, we aim to analyze the evolving dynamics of urban-nonurban O<sub>3</sub>  
106 differences between 2019 and 2020. The roles of emission discrepancies and  
107 nonlinearity of O<sub>3</sub>-NO<sub>x</sub>-VOCs-aerosols photochemical processes in shaping these O<sub>3</sub>

108 variations were deeply dissected. To achieve a comprehensive analysis, we employed a  
109 new spatiotemporal Transformer framework that paid special attention to air mass  
110 transport and dispersion affected by the spatial-temporal correlations, to reconstruct the  
111 spatially gapless air quality datasets based on satellite data, ground-level observations,  
112 and meteorological reanalysis. The estimations are particularly vital for regions lacking  
113 dense ground-based monitors, ensuring that our understanding of O<sub>3</sub> dynamics in urban-  
114 nonurban areas and formation regimes is not limited by geographical constraints in data  
115 availability. Surface O<sub>3</sub> formation regimes in Shandong province were inferred by the  
116 classic XGBoost model (Chen and Guestrin, 2016) coupled with Shapley Additive  
117 exPlanations (SHAP) (Lundberg and Lee, 2017), which identifies the impact of  
118 meteorological conditions and photochemical indicators (i.e. PM<sub>2.5</sub> as a proxy for  
119 aerosols, NO<sub>2</sub> as a proxy for NO<sub>x</sub>, and HCHO as a proxy for VOCs) on O<sub>3</sub>. The  
120 innovative Transformer-based modeling and interpretable machine learning analysis  
121 approaches are expected to enable new applications such as those of air quality  
122 simulation and O<sub>3</sub> formation regimes studies.

## 123 **2. MATERIALS AND METHODS**

### 124 **2.1 Predictor Variables**

125 The study domain covered the Shandong province of China, which has a high  
126 mortality burden of air pollution (Liu et al., 2017). The surface PM<sub>2.5</sub>, O<sub>3</sub>, and NO<sub>2</sub>  
127 concentration measurements were collected from the regulatory air quality stations of  
128 the China National Environmental Monitoring Center (CNEMC, with a total of 179

129 locations) and the Shandong Provincial Eco-environmental Monitoring Center (SDEM,  
130 with a total of 166 locations) (Figure S1). The SDEM stations were included to fill the  
131 spatial gaps in the county and rural areas where CNEMC stations were lacking. The  
132 study area was divided into 1.22 million grid cells with a spatial resolution of 500  
133 meters. We utilized a range of predictor data, including tropospheric NO<sub>2</sub> vertical  
134 column densities (VCDs) and O<sub>3</sub> total VCDs measured by TROPospheric Monitoring  
135 Instrument (TROPOMI) (Lamsal et al., 2022; Copernicus Sentinel-5P (processed by  
136 ESA), 2020), aerosol optical depth (AOD) data and atmospheric properties obtained  
137 from Moderate Resolution Imaging Spectroradiometer (MODIS) Multi-Angle  
138 Implementation of Atmospheric Correction products (Lyapustin and Wang, 2022),  
139 AOD estimates from Modern-Era Retrospective Analysis for Research and  
140 Applications as the supplement to MODIS (2015), meteorological reanalysis obtained  
141 from the fifth generation atmospheric reanalysis dataset of European Centre for  
142 Medium-Range Weather Forecasts (ECMWF) (ERA5) (Hersbach et al., 2023, p.5),  
143 daily dynamic industrial emissions, moonlight-adjusted nighttime lights product  
144 (Román et al., 2018), vegetation index (Didan, 2021), population density (WorldPop,  
145 2018), road density, land use data (Jun et al., 2014), and the shuttle radar topography  
146 mission digital elevation model. The detailed information for all predictive variables  
147 is listed in Table S1 and discussed in Text S1-2. Taking space-variant and seasonal  
148 patterns into consideration, several spatiotemporal indicators such as geographical  
149 coordinates, Euclidean spherical coordinates, year, Julian date, and helix-shaped

150 trigonometric sequences, were also included as predictor variables (Text S3) (Sun et al.,  
151 2022). Geographic Information Systems techniques, including reprojection and  
152 resampling, were used to consolidate all the data obtained for consistent projection and  
153 spatial scale. Finally, the Light Gradient Boosting Machine was used to fill satellite data  
154 gaps (Text S4) (Ke et al., 2017).

## 155 **2.2 Air Transformer**

156 AiT is an individual Transformer model that adopts an encoder-decoder  
157 architecture with multidimensional self-attention computation to dynamically capture  
158 the spatiotemporal autocorrelation of atmospheric pollution changes from the  
159 sequences of pixels and variables for more reliable spatial maps of estimation.  
160 Compared with existing image and video recognition Transformers, such as ViT  
161 (Dosovitskiy et al., 2021), Timesformer (Bertasius et al., 2021), and Uniformer (Li et  
162 al., 2021b), AiT is innovative in incorporating self-attention across channels after the  
163 pixels-based self-attention and taking advantage of the decoder. The former can capture  
164 the correlations between predictor variables. The decoder was employed to enable  
165 interaction between the primary target grid and neighboring grids. Predictor variables  
166 with 8 timesteps within 1000 meters of the target grid cell were fed into the model to  
167 learn spatiotemporally disparities among atmospheric pollutants for predicting O<sub>3</sub>, NO<sub>2</sub>  
168 and PM<sub>2.5</sub> within the target grid point.

169 The overall architecture of the proposed AiT model and the dimensions of input  
170 data are illustrated in **Figure 1**. The encoder maps an input sequence with neighborhood

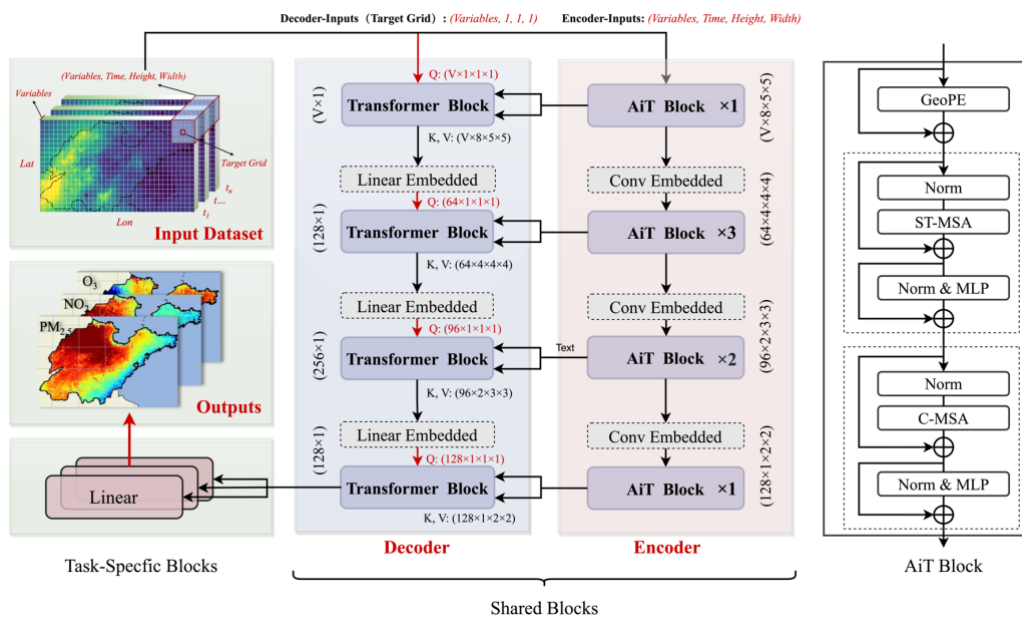

171 spatiotemporal data to a sequence with high-dimensional spatiotemporal characteristics,  
 172 and the decoder generates an estimation by computing self-attention representations  
 173 between the target grid and outputs of the encoder. The encoder of AiT takes as input a  
 174 clip  $X \in R^{V \times T \times H \times W}$  consisting of  $T$  multi-variable frames of size  $H \times W$  sampled  
 175 from the original dataset, where  $V$  is the number of variables and the target grid cell is  
 176 located at  $(\lfloor \frac{H}{2} \rfloor, \lfloor \frac{W}{2} \rfloor)$ . The decoder takes as input a clip  $X \in R^{V \times 1 \times 1 \times 1}$  consisting of  $V$   
 177 variables from the target grid. Several Transformer blocks with modified self-attention  
 178 computation (AiT blocks) are applied to the encoder. The AiT encoder block is similar  
 179 to the standard vision transformer block but specifically designed for atmospheric  
 180 estimation (Dosovitskiy et al., 2021). It is a stack of two self-attention schemes,  
 181 including global spatiotemporal self-attention on the pixels and channel self-attention  
 182 on variable predictors. The former contains  $N = HW$  effective input sequence length  
 183 for the self-attention to extract spatiotemporal information. The latter computes self-  
 184 attention based on  $V$  effective input sequence length to capture hidden information on  
 185 variables. The decoder part is symmetric to the encoder part, but it only has a block  
 186 with the spatiotemporal self-attention mechanism. We compute the matrix of self-  
 187 attention outputs as:

$$188 \quad \text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}} + B\right)V \quad (1)$$

189 where  $Q$ ,  $K$ , and  $V$  are the queries, keys, and values in the inputs of the particular  
 190 attention, respectively.  $d_k$  is the feature dimensionality of  $K$ , and  $B$  is the geographic  
 191 positional bias term. Another difference is that the attention function of the decoder is

192 computed on  $Q$  from the estimated grid data, and  $(K, V)$  from the outputs of encoder  
 193 blocks under the same stage, resulting in the outputs of the last decoder block being  
 194 sized  $1 \times 128$ . The description of the data transformation and design details in the  
 195 process of training can be found in Text S5. The multi-task learning strategy was also  
 196 applied for learning representation across multiple pollutant estimation tasks (Text S6).  
 197 The aggregated feature data from June 2019 to June 2021 were utilized to train and  
 198 validate the model through cross-validation (CV), where the optimal model, trained  
 199 based on out-of-sample CV, was used to estimate multiple pollutant concentrations  
 200 during the study period, which was then employed for subsequent analysis.

201

202 **Figure 1.** Schematic diagram of the AiT model. The white box of multi-dimension  
 203 inputs presents each pixel of raster data. The AiT Block is a Transformer block based  
 204 on self-attention across space, time, and variables. The GeoPE, Norm, MLP, ST-MSA  
 205 and C-MSA indicate respectively positional embedding, layer normalization, multi-  
 206 layer perceptron, spatial-temporal multi-head self-attention and multi-channels (multi-  
 207 variables) multi-head self-attention.

### 208 **2.3 Diagnosing O<sub>3</sub> Formation Sensitivity**

209 Interpretability can provide insight into how a model may be improved, bolster the  
210 understanding of the process being modeled, and engender appropriate confidence  
211 among researchers. SHAP is a coalitional game-theoretic approach based on Shapley  
212 values (Shapley, 1988) and then assigns each variable an importance value for a  
213 particular estimation. Deep SHAP, a high-speed approximation algorithm that builds on  
214 the connection between Shapely values and DeepLIFT (Shrikumar et al., 2019), is  
215 employed to compute the feature importance of AiT from all data with monitoring  
216 labels for interpreting the prediction. The sensitivity of the O<sub>3</sub> formation regime was  
217 deduced using a combination of the XGBoost model and SHAP interpretability method,  
218 employing the GPUShap algorithm (Mitchell et al., 2020), which simulated the  
219 response of surface O<sub>3</sub> to meteorological conditions, HCHO, NO<sub>2</sub> and PM<sub>2.5</sub>, by  
220 utilizing the continuous estimations from ERA5, AiT and TROPOMI between 2019 and  
221 2020. The incorporation of meteorology in the model ameliorated the inadequacies in  
222 the conventional method (HCHO-NO<sub>2</sub> ratio), where its thresholds for identifying O<sub>3</sub>  
223 regimes vary temporally and spatially. The positive or negative contributions of three  
224 atmospheric pollutants were used to identify their promoting or inhibitory effects on O<sub>3</sub>  
225 variability. Given the unbiased property of SHAP values regarding directionality, the  
226 normalized relative magnitudes of SHAP values were calculated for HCHO, NO<sub>2</sub>, and  
227 PM<sub>2.5</sub>. This allowed the differentiation of the O<sub>3</sub> formation regimes based on the locally  
228 maximal proportions of the SHAP values for each species. The ground-level monthly

229 HCHO concentrations were derived using a combination of column-to-surface  
230 conversion factor (CF) simulated from the ECMWF Atmospheric Composition  
231 Reanalysis 4 and the tropospheric HCHO VCDs obtained from TROPOMI (Cooper et  
232 al., 2022; Su et al., 2022; Inness et al., 2019). A detailed description of the CF method  
233 as used here is discussed in Text S7. To ensure consistency in resolution between  
234 TROPOMI and AiT, we employed the oversampling method to downscale the  
235 TROPOMI VCDs to the resolution of AiT estimation, which has been proven effective  
236 in achieving finer resolution (Su et al., 2022; Cooper et al., 2022; van Donkelaar et al.,  
237 2015).

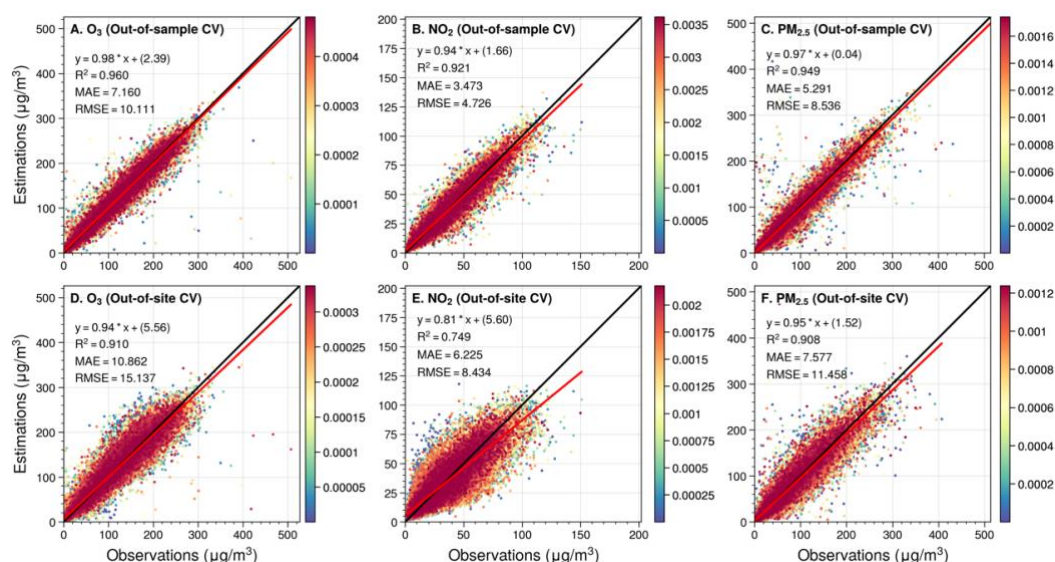

## 238 **3. RESULTS AND DISCUSSION**

### 239 **3.1 Performance Evaluation for the AiT**

#### 240 **3.1.1 Cross-validation Metrics**

241 We evaluated the AiT performance using the 10-fold CV approach (Text S8), with  
242 correlation coefficient ( $R^2$ ) measuring the extent to which model simulations explain  
243 variability in atmospheric pollutants, and root mean square errors (RMSE) and mean  
244 absolute errors (MAE) evaluating the bias/error of the estimates. As shown in **Figure**  
245 **2**, out-of-sample CV daily ground-level O<sub>3</sub>, NO<sub>2</sub>, and PM<sub>2.5</sub> estimations are highly  
246 consistent with ground observations ( $R^2 = 0.96, 0.92, 0.95$ ), indicating low uncertainties,  
247 with RMSE of 10.1, 4.7, and 8.5  $\mu\text{g}/\text{m}^3$  and MAE of 7.2, 3.5, and 5.3  $\mu\text{g}/\text{m}^3$  for the  
248 2018-2021 period. The linear regression comparing the O<sub>3</sub> predictions versus  
249 observations yields a slope of 0.98 and an intercept of 2.39, which demonstrates that

250 there is no systematic bias in the estimations. Meanwhile, as shown in Figure S3, our  
 251 AiT model performs well at the individual-site scale with high CV-RMSE for O<sub>3</sub>, NO<sub>2</sub>,  
 252 and PM<sub>2.5</sub> ( $10.5 \pm 8.6$ ,  $4.7 \pm 1.1$ , and  $8.3 \pm 2.8$   $\mu\text{g}/\text{m}^3$ ). In general, the AiT model is  
 253 robust for multi-pollutant simultaneous estimations.

254  
 255 **Figure 2.** Out-of-sample cross-validation (A-C) and out-of-site cross-validation (D-F)  
 256 of daily ground-level O<sub>3</sub>, NO<sub>2</sub> and PM<sub>2.5</sub> concentration in the validation set.

257 The spatial generalization ability of the AiT is then examined by the out-of-site CV  
 258 evaluation method (**Figure 2**). The daily spatial variations of O<sub>3</sub>, NO<sub>2</sub>, and PM<sub>2.5</sub> at  
 259 locations without ground measurements can be well estimated by our model (i.e., CV-  
 260  $R^2 = 0.91, 0.75, 0.91$ ), representing a core contribution of such studies. We also probe  
 261 the model performance for each site separately based on spatial CV estimations (Figure  
 262 S4). This general model yields an RMSE of  $15.2 \pm 8.8$ ,  $8.1 \pm 2.7$ , and  $11.1 \pm 2.8$   $\mu\text{g}/\text{m}^3$ ,  
 263 respectively. Furthermore, we trained the AiT model using data exclusively from  
 264 CNEMC and assessed its generalizability by validating it with data from SDEM. The  
 265 model demonstrates strong performance with high out-of-sample CV  $R^2$  values in the

266 validation dataset of CNEMC (Figure S5), and when evaluated with SDEM data, it  
267 exhibits only an acceptable degradation in predictive accuracy (Figure S6,  $R^2$  for  $O_3$ ,  
268  $NO_2$ , and  $PM_{2.5}$ : 0.90, 0.73, 0.79). Meanwhile, our framework utilizes multi-task  
269 learning to enhance computational efficiency through a single iteration and leverages  
270 the interactions among multiple pollutants to optimize the performance at individual  
271 pollutant levels (Table S2). In summary, AiT provides relatively stable estimations in  
272 areas without available ground-level monitoring and reliably extends ground  
273 monitoring from the site scale to the full-coverage spatial scale with high spatial  
274 resolution.

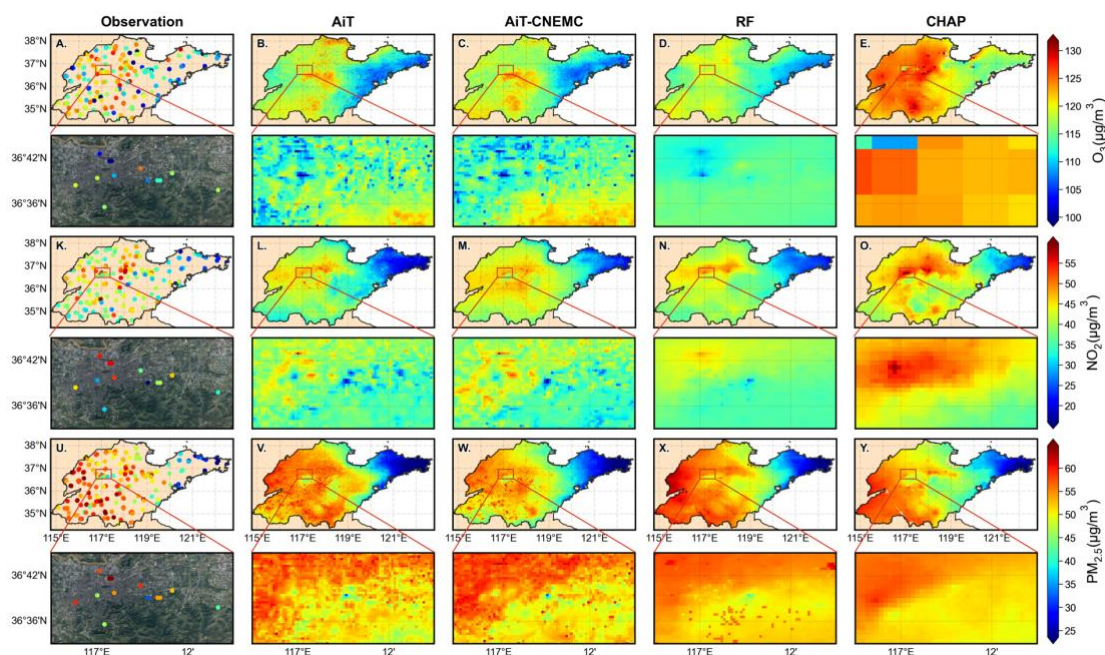

### 275 **3.1.2 Compared with Other ML Models**

276 Since ground-level air quality measurements across the target regions are  
277 extremely limited at a 500 m spatial resolution, representing only roughly two-  
278 thousandths of the total grid cells, we seek implicit approaches to validate our estimated  
279 near surface pollutant concentrations. We compared the model performance with  
280 previous studies that applied different ML methods to estimate these three air pollutants  
281 individually and found out that our cross-validation results are comparable or even  
282 better than those (Table S3). We also created a new dataset in our study by applying the  
283 classic RF algorithm which is the most common ML model for estimating atmospheric  
284 pollution in recent years (Wei et al., 2022a; Requia et al., 2020; Xiao et al., 2018; Geng  
285 et al., 2021; Lu et al., 2021) with the same variables as AiT. The statistical comparisons  
286 between AiT and RF are also shown in Table S3. We then compared the spatial

287 distribution of our results with estimations from CHAP, AiT-CNEMC, and RF.

288 **Figure 3** shows the spatial maps of near-surface air pollutants with partially  
289 zoomed satellite images for monitoring sites, AiT, CNEMC-trained AiT, RF, and CHAP  
290 in 2019 (see Figure S7 for 2020). We found that the estimated NO<sub>2</sub> and PM<sub>2.5</sub> from the  
291 AiT share a similar spatial distribution to those estimated by RF and CHAP. However,  
292 enlarged city-level urban regions in **Figure 3** reveal that AiT estimates fine structures  
293 and intra-urban disparities in near-surface multi-pollutant concentrations, which cannot  
294 be captured by either RF or CHAP products. This spatial gradient is also captured by  
295 AiT trained with CNEMC data, revealing the reliability of the deep learning model  
296 structure. In general, while RF and CHAP can only identify the hotspots of air pollutants  
297 at a regional scale, the spatial distribution of air pollutants estimated by AiT shows  
298 much more detailed differences with high spatial and temporal variability across the  
299 city scale. The differences of near-surface annual averaged pollutants between 2019 and  
300 2020 for measured and multi-estimated data are presented in Figure S8. The reductions  
301 or increases of O<sub>3</sub>, NO<sub>2</sub>, and PM<sub>2.5</sub> in distinct locations can be simulated by our model,  
302 which is relatively consistent with the changes of measurements. The zoomed maps in  
303 Figure S7 show the differences in three pollutant concentrations at the city scale of the  
304 capital of Shandong Province, Jinan. It can be found that the change in pollutant levels  
305 in 2020 compared to 2019 exhibits substantial regional variations and intra-urban  
306 heterogeneity, with some areas experiencing an increase while others a decrease.  
307 Compared to the estimations of RF and CHAP, our results successfully capture the

308 complex distribution of air pollution in reality and reveal that the decline in  $PM_{2.5}$  is  
 309 primarily concentrated in suburban areas, while an increase is pronounced in some  
 310 regions of urban during 2020. Notably, this spatial trend may be consistent with  
 311 underlying emission patterns and meteorological conditions.

312 **Figure 3.** Spatial distribution of the annual mean (A-E)  $O_3$ , (K-O)  $NO_2$ , and (U-Y)  
 313  $PM_{2.5}$  concentrations from observations, Air Transformer (AiT), CNEMC-trained AiT,  
 314 Random Forest (RF) and ChinaHighAirPollutants (CHAP), respectively, in 2019. The  
 315 region enclosed by the red rectangular box corresponds to the zoomed-in maps of the  
 316 satellite (© Tianditu: [www.tianditu.gov.cn](http://www.tianditu.gov.cn)) and pollutant concentrations at a city scale  
 317 for the capital city of Shandong Province, Jinan.

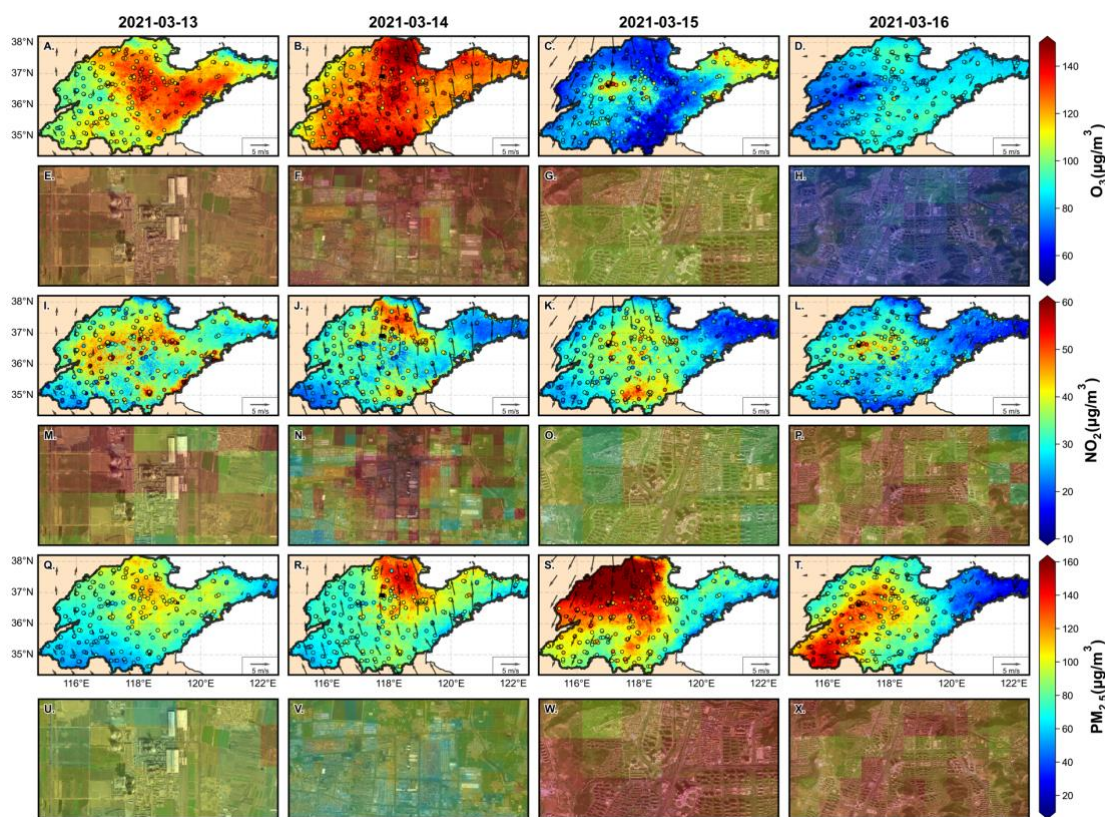

### 319 3.1.3 Typical Event Study

320 The typical example of the spatial distribution of multi-pollutant observations and  
 321 estimations of AiT is compared for validating the predictive capability of the model at  
 322 a particular pollution episode, i.e., 13-16 March 2021. During this period, an early  
 323 season dust storm, which was called the largest and strongest such storm in a decade,

324 hits northern China (Myers, 2021). As shown in **Figure 4**, our model can capture the  
325 spatial distribution of surface  $O_3$ ,  $NO_2$ , and  $PM_{2.5}$  in the time of severe atmospheric  
326 pollution. In addition, our estimations are in high concordance with measurements in  
327 terms of magnitudes and spatial variability over the entire research region. The model  
328 trained solely on CNEMC data is also capable of effectively capturing the drastic  
329 changes in air quality during the pollution episode (Figure S9). Combining wind fields  
330 to analyze  $PM_{2.5}$  distribution on the day of the dust storm, it can be found that surface  
331 wind carries a massive amount of particulate matter from Beijing, which suffered a  
332 severe dust storm, to northern Shandong. The influence was gradually diminishing in  
333 southern Shandong due to the obstruction of Mount Tai. Spatial heterogeneity within  
334 intra-urban areas was further investigated to identify the hotspots of pollution sources.  
335 The satellite images in even-numbered rows of **Figure 4** illustrate the spatial disparities  
336 of three pollutants around four typical emission sources: thermal power plants,  
337 industrial parks, overpasses, and parks. As depicted, these anthropogenic emission  
338 sources contribute to higher pollution levels, while the mountain in the park mitigates  
339 primary pollution but also increases  $O_3$  concentrations. Industrial sources emit a large  
340 number of  $NO_x$  and  $PM_{2.5}$ , leading to increased pollution of these species compared  
341 with other urban microenvironments, which in turn promotes  $O_3$  formation, particularly  
342 in downwind areas (Miller et al., 1978; Tang et al., 2020). Although the spatial gradients  
343 of pollutants on the street are not as apparent as in the dataset with 100 m resolution  
344 (Huang et al., 2021), the predicted spatial variation between various geographical

345 scenes is in satisfactory agreement given the 500 m scale of the model. Urban areas  
 346 affected by diverse dust pollution exhibit lower PM<sub>2.5</sub> concentrations compared to rural  
 347 due to the obstructive and filtering effects of artificial structures, such as buildings and  
 348 urban greenery (Figure S10), which cannot be effectively captured solely by ground-  
 349 based observations. Notably, the elevated PM<sub>2.5</sub> inhibits the formation of O<sub>3</sub> by  
 350 diminishing solar radiation flux and absorbing the HO<sub>2</sub> radical on the aerosol surface,  
 351 even in conditions characterized by similar NO<sub>2</sub> levels. As for the mapping, AiT  
 352 accurately grasps the spatial characteristics of air pollutants and delivers a coherent  
 353 spatial-temporal distribution that is consistent with the prior knowledge of atmospheric  
 354 transport.

355

356 **Figure 4.** The spatial distribution of ground-level O<sub>3</sub> (A-D), NO<sub>2</sub> (I-L), and PM<sub>2.5</sub> (Q-  
 357 T) concentrations from AiT and monitoring stations during 13-16 March 2021 in

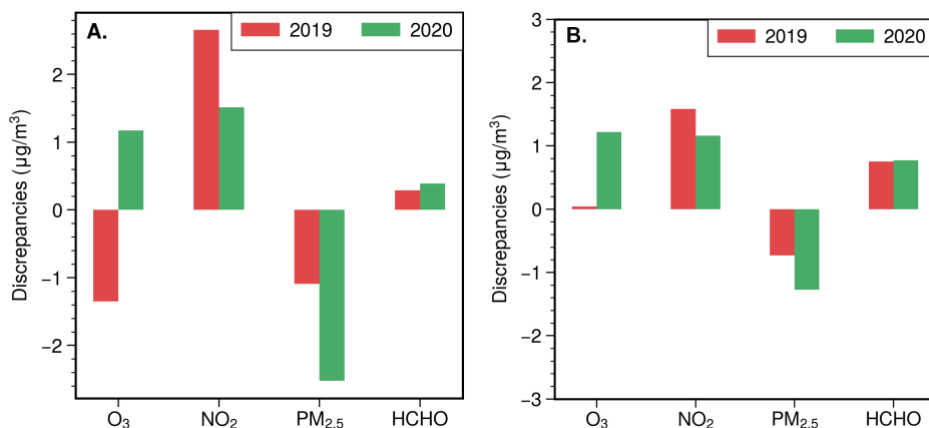

358 Shandong, China. The black arrows are the 10 m wind speed and wind direction. The  
359 even-numbered rows correspond to the concentration distribution maps of typical  
360 emission sources for the respective pollutants, accompanied by satellite images (©  
361 Tianditu: [www.tianditu.gov.cn](http://www.tianditu.gov.cn)). The upper right area of E, M, and U is a thermal power  
362 plant in Weifang City (119°250'E-119°280'E, 36°658'N-36°673'N). The center area of  
363 F, N, and V is an industrial park in Zibo city (117°725'E-117°845'E, 36°880'N-  
364 36°940'N). The center and upper right area of G, O, and W is an overpass and Wanling  
365 mountain in Jinan city (116°977'E-117°009'E, 36°590'N-36°606'N). The center area of  
366 H, P, and X is another overpass in Jinan city (116°970'E-117°030'E, 36°580'N-  
367 36°610'N).

### 368 **3.2 Urban-nonurban Difference**

369 Full-coverage pollutant estimates provide a foundational basis for assessing urban-  
370 nonurban disparities, addressing the critical issue of imbalanced site numbers between  
371 urban and rural locations. Table S4 shows the concentrations of O<sub>3</sub>, NO<sub>2</sub>, PM<sub>2.5</sub>, and  
372 HCHO over the urban and nonurban regions, delineated from an annual urban extent  
373 dataset (Zhao et al., 2022). The urban extents in Shandong Province in 2019 are  
374 depicted in Figure S11. From 2019 to 2020, surface air pollutant levels declined  
375 significantly in Shandong. The averaged concentration discrepancies of these pollutants  
376 between urban and nonurban over February to March (lockdown during COVID-19)  
377 and June to October (summertime) are shown in **Figure 5**. Surface concentrations of  
378 NO<sub>2</sub> and HCHO are higher in urban than nonurban areas, and the differences narrowed  
379 from February to October, while PM<sub>2.5</sub> is the opposite at both. Ground-level O<sub>3</sub> levels  
380 exhibited unexpected urban-nonurban disparity variations, from the lockdown period  
381 through the summer, as well as from 2019 to 2020. Compared to nonurban areas, the  
382 urban areas, which previously had lower O<sub>3</sub> levels, began to experience higher

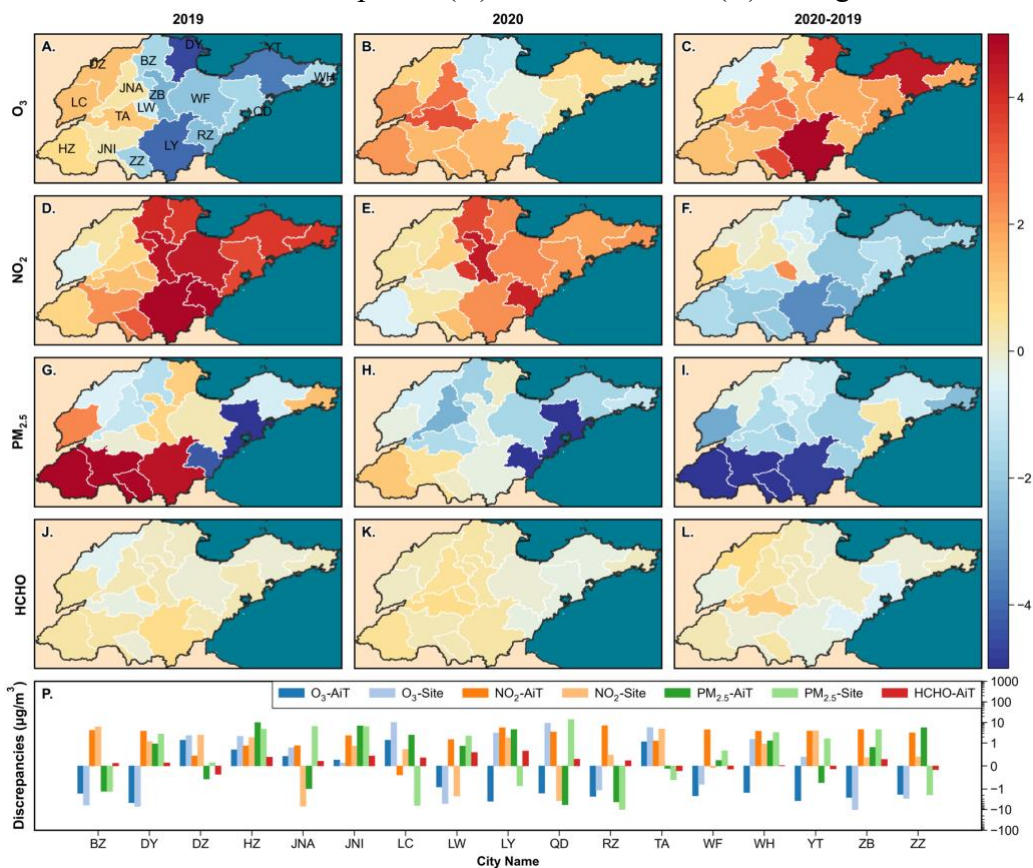

383 concentrations, attributed to a more rapid decline of ozone in nonurban regions. **Figure**  
384 **6** revealed that urban-nonurban differences in O<sub>3</sub> and PM<sub>2.5</sub> varied across various cities  
385 during the lockdown period in 2019, while the higher NO<sub>2</sub> pollution in urban areas  
386 remained consistent. In summer, only a handful of urban areas exhibit lower levels of  
387 ozone concentration, where NO<sub>2</sub> and PM<sub>2.5</sub> levels surpass those in nonurban regions,  
388 attributable to a more pronounced titration effect of NO and a slower rate of  
389 photochemistry reactions (Figure S12) (Sicard et al., 2016, 2020; Zhang et al., 2004).  
390 Comparative urban-nonurban differences from 2019 to 2020 indicate an accelerated  
391 reduction of ozone and HCHO in non-urban areas, while NO<sub>2</sub> and PM<sub>2.5</sub> levels in urban  
392 have seen a more significant decrease due to the decline in anthropogenic activities,  
393 particularly the suspension of emissions from pollution sources located in urban areas.  
394 Upon comparing the results of urban-nonurban disparities of our data with monitoring  
395 data and the CHAP dataset, we have identified potential overestimations or  
396 underestimations across various cities in monitoring data, likely resulting from the  
397 limited number of non-urban sites (**Figure 6P**, S13). The notable disparity between the  
398 number of urban and non-urban sites in cities such as JNA, LC, LY, QD, and YT results  
399 in a pattern of urban-nonurban differences that contrasts markedly with the observed in  
400 AiT (Table S5). The urban-nonurban difference calculated by the CHAP generally  
401 aligns with our findings (Figure S14). Nevertheless, it is worth noting that the coarse  
402 resolution of O<sub>3</sub> (10 km) has led to a significant overestimation. These results highlight  
403 the invaluable of high-resolution and gapless data for studying urban-nonurban

404 disparities.

405

406 **Figure 5.** The discrepancies of  $\text{O}_3$ ,  $\text{NO}_2$ , and  $\text{PM}_{2.5}$  between urban and non-urban from  
407 2019 to 2020 for the lockdown period (A) and summertime (B) averaged concentration.

408

409 **Figure 6.** The urban-nonurban disparities of  $\text{O}_3$ ,  $\text{NO}_2$ ,  $\text{PM}_{2.5}$ , and HCHO calculated by  
410 AiT across cities with administrative divisions in Shandong, China during lockdown  
411 periods in 2019 (A, D, G, J) and 2020 (B, E, H, K), and the changes of differences  
412 between 2019 and 2020 (C, F, I, L). P is the comparison between the results of  
413 monitoring station data and the AiT dataset in 2019. The red color represents a greater  
414 decline in air pollutants in nonurban areas, while the blue color indicates a more

415 significant reduction in urban areas in the third column of the figure. (YT: Yantai, BZ:

417 Weifang, ZB: Zibo, LC: Liaocheng, LW: Laiwu, TA: Taian, LY: Linyi, RZ: Rizhao, JNI:  
418 Jining, HZ: Hezhe, ZZ: Zaozhuang)

### 419 3.3 Photochemical Regimes

#### 420 3.3.1 Ozone-NO<sub>x</sub>-VOCs-Aerosols Sensitivity

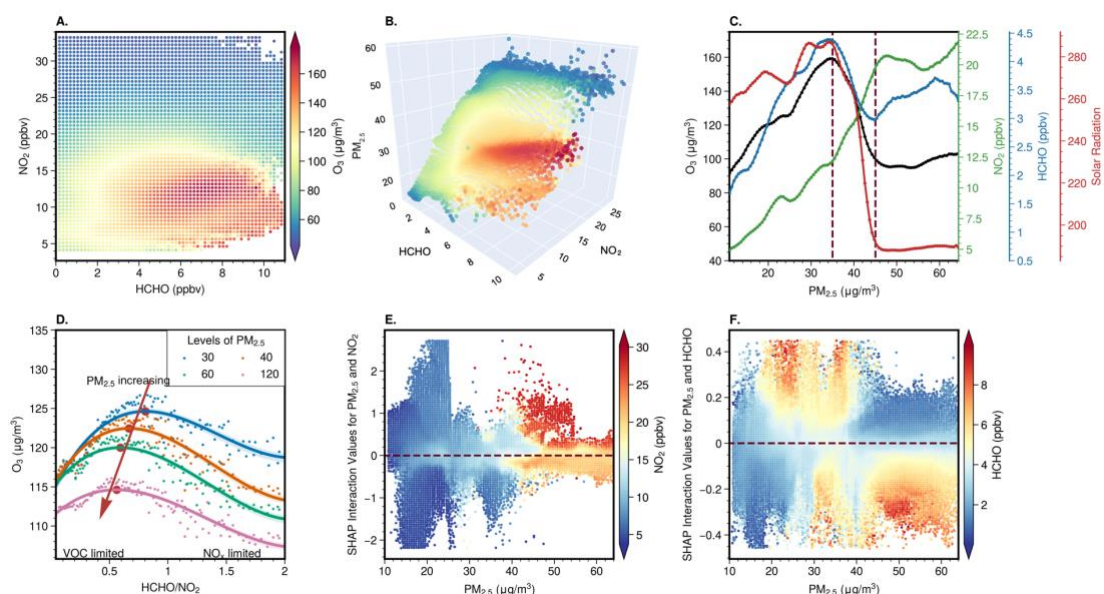

421 Figure S15 shows the seasonal maps of O<sub>3</sub>, PM<sub>2.5</sub>, and NO<sub>2</sub> estimations from AIT,  
422 and satellite-derived surface HCHO. Based on these data, we first capture the well-  
423 established non-linearities in O<sub>3</sub>-VOC-NO<sub>x</sub> chemistry by a conceptual framework  
424 similar to classic O<sub>3</sub> isopleths typically generated with models (Pusede et al., 2015; Ren  
425 et al., 2022a). **Figure 7A** depicts O<sub>3</sub> concentration as a function of HCHO and NO<sub>2</sub>,  
426 which was derived solely from ground-level estimation. The result indicates that the O<sub>3</sub>  
427 regimes can be qualitatively identified based on the nonlinear interaction between  
428 surface O<sub>3</sub>, HCHO, and NO<sub>2</sub>. In the regime characterized by high NO<sub>2</sub> and low HCHO,  
429 the elevated consumption of HO<sub>x</sub>, predominantly driven by the OH + NO<sub>2</sub> termination  
430 reaction, results in the suppression of NO<sub>x</sub> on O<sub>3</sub>, indicating the prevalence of VOC-  
431 limited chemistry. Conversely, when HCHO levels are high and NO<sub>2</sub> levels are  
432 relatively low, O<sub>3</sub> increases with NO<sub>2</sub> and exhibits insensitivity to HCHO due to  
433 abundant peroxy radicals (HO<sub>2</sub> + organic peroxy (RO<sub>2</sub>) radicals, RO<sub>x</sub>) self-reactions,  
434 suggesting NO<sub>x</sub>-limited (VOC-saturated) chemistry. In cases where high HCHO and  
435 NO<sub>2</sub>, the O<sub>3</sub> increases with both HCHO and NO<sub>2</sub>, reaching a peak. While **Figure 7A**  
436 resembles this overall O<sub>3</sub>-VOC-NO<sub>x</sub>, the blurry transition between two different  
437 regimes and the role of PM<sub>2.5</sub> is uncertain which may be influenced by meteorological

438 conditions, chemical and depositional loss of O<sub>3</sub>, errors of estimations, and “aerosol-  
439 inhibited”. Increasing PM<sub>2.5</sub> levels could suppress O<sub>3</sub> formation even under high HCHO  
440 and NO<sub>2</sub> conditions (**Figure 7B**), which could be induced by enhanced reactive uptake  
441 of HO<sub>2</sub> onto aerosol particles and weaker photochemical reaction resulting from the  
442 scattering and absorption of solar radiation by anthropogenic aerosols. The relationship  
443 between PM<sub>2.5</sub> and O<sub>3</sub> in Shandong demonstrates the distinct stages of O<sub>3</sub> chemistry, as  
444 depicted in **Figure 7C**. When PM<sub>2.5</sub> was below the maximum turning point (MTP1, 35  
445 µg/m<sup>3</sup>), a linear and positive correlation between O<sub>3</sub> and PM<sub>2.5</sub> was observed due to the  
446 common dependence on precursors in the initial stage (Zhang et al., 2022). As PM<sub>2.5</sub>  
447 increased beyond the MTP1, a sharp reduction in HCHO and O<sub>3</sub> was observed,  
448 accompanied by a decline in surface short-wave radiation, reflecting their formation as  
449 photo-oxidation products of OVOCs and NO<sub>x</sub>. When PM<sub>2.5</sub> exceeded the minimum  
450 transition point (MTP2, 45 µg/m<sup>3</sup>), a phase was observed with stagnant radiation  
451 intensity and relatively higher NO<sub>2</sub> levels compared to HCHO. This regime is typically  
452 associated with a VOC-limited regime, where an increase in HCHO and a decrease in  
453 NO<sub>2</sub> concentration could promote O<sub>3</sub> production. However, our findings demonstrated  
454 an opposite impact of HCHO and NO<sub>2</sub> on O<sub>3</sub> when PM<sub>2.5</sub> exceeded MTP2. **Figure 7D**  
455 shows the changes in the quantitative relationships between HCHO/NO<sub>2</sub> (FNR) and O<sub>3</sub>  
456 by artificially changing PM<sub>2.5</sub> and precursors levels for XGBoost, in which the peak of  
457 curves marks the transitional threshold of O<sub>3</sub> regimes from VOC to NO<sub>x</sub> sensitive. It  
458 can be seen that attenuated PM<sub>2.5</sub> pollution could increase the sensitivity of O<sub>3</sub> to VOCs

459 and decrease the sensitivity to  $\text{NO}_x$ , which causes the shift in  $\text{O}_3$  regimes from  $\text{NO}_x$ -  
460 limited to VOC-limited. With the recent reduction in  $\text{NO}_x$  emissions in China, the  
461 anticipated transition of the  $\text{O}_3$  production regime in urban areas towards being more  
462  $\text{NO}_x$ -limited has been impeded by the heightened VOC sensitivity resulting from  
463 decreased  $\text{PM}_{2.5}$  levels. Our results are consistent with the findings of Li et al. regarding  
464  $\text{O}_x$ - $\text{NO}_x$  relationship in response to changing  $\text{PM}_{2.5}$  (Li et al., 2022a), and with the  
465 findings of Dyson et al. on the impact of  $\text{HO}_2$  aerosol uptake on  $\text{O}_3$  production (Dyson  
466 et al., 2023). The SHAP interaction plots in **Figures 7E** and **F** illustrate that the  
467 influence of  $\text{NO}_2$  and HCHO on  $\text{O}_3$  formation is not constant and is influenced by the  
468 levels of  $\text{PM}_{2.5}$ . Typically, at a certain level of  $\text{PM}_{2.5}$ , a lower NO concentration results  
469 in a stronger inhibitory effect on  $\text{O}_3$  production. This could be due to aerosols exerting  
470 stronger suppression through the  $\text{HO}_2$  sink at lower  $\text{NO}_x$  levels. As the concentration of  
471  $\text{PM}_{2.5}$  increases, often accompanied by a concurrent increase in  $\text{NO}_2$  as a key precursor,  
472 there is a greater need for higher levels of  $\text{NO}_2$  to be converted into nitrous acid ( $\text{HONO}$ )  
473 through the heterogeneous uptake by aerosols. This process produces more OH radicals,  
474 which facilitate photochemical  $\text{O}_3$  formation, thereby offsetting the increased inhibitory  
475 effect of the  $\text{HO}_2$  sink. Under high  $\text{PM}_{2.5}$  concentrations, an increase in  $\text{NO}_2$  along with  
476 a decrease in HCHO enhances their effect on promoting  $\text{O}_3$  formation. This  
477 enhancement could be caused by increased titration of  $\text{O}_3$  by NO, resulting from weaker  
478 conversion of NO to  $\text{NO}_x$  through the  $\text{RO}_x$  radical. Meanwhile, the impact of HCHO  
479 shifts from promoting to suppressing as  $\text{PM}_{2.5}$  pollution intensifies. It further illustrates

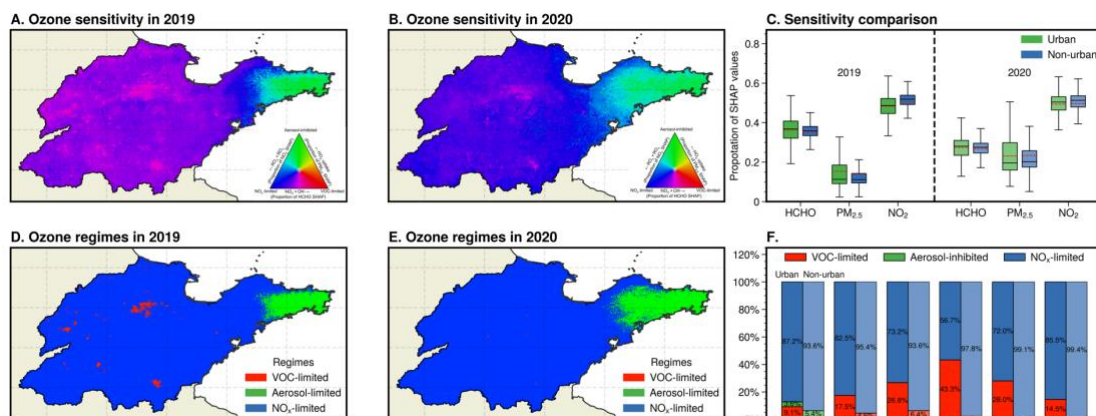

480 that the scavenging of HO<sub>2</sub> on aerosols can cause the shift in O<sub>3</sub> regimes from being  
 481 VOC-limited to NO<sub>x</sub>-limited and the threshold approach is restricted by aerosols and  
 482 meteorology for determining the constantly changing O<sub>3</sub> formation regimes over time  
 483 and space.

484 **Figure 7.** (A) O<sub>3</sub> concentrations as a function of surface HCHO and NO<sub>2</sub>. (B) O<sub>3</sub>  
 485 concentrations as a function of surface HCHO, NO<sub>2</sub>, and PM<sub>2.5</sub>. Both A and B utilize a  
 486 shared color bar to indicate O<sub>3</sub> concentrations, enhancing comparability. (C)  
 487 Relationship between O<sub>3</sub>, and NO<sub>2</sub>, HCHO, and surface short-wave radiation flux. The  
 488 paired O<sub>3</sub>, HCHO, NO<sub>2</sub>, and solar radiation are divided into 100 bins based on PM<sub>2.5</sub>  
 489 and then the averaged concentrations (y-axis) are calculated for each PM<sub>2.5</sub> bin (x-axis).  
 490 (D) Changes in HCHO/NO<sub>2</sub>-O<sub>3</sub> relationship in response to changing PM<sub>2.5</sub> by XGBoost  
 491 model. The solid lines are fitted with four-order polynomial curves, and the shading  
 492 indicates 95% confidence intervals. (E-F) The interaction SHAP values reveal an  
 493 interesting hidden relationship between pairwise variables (PM<sub>2.5</sub> and NO<sub>2</sub>, HCHO) and  
 494 O<sub>3</sub>.  
 495 O<sub>3</sub>.

496 Unraveling the intricate interplay of O<sub>3</sub> with meteorology, aerosols, and precursors  
 497 that govern O<sub>3</sub> formation over extensive spatial domains has long confounded robust  
 498 interpretation. These multiscale processes were elucidated using an interpretable ML  
 499 model, which can quantify the positive or negative contributions of individual processes.

500 As depicted in Figure S16, the performance of the XGBoost model is robust, evidenced  
501 by a high  $R^2$  value of 0.99 coupled with a low RMSE of  $3.24 \mu\text{g}/\text{m}^3$  and MAE of  $2.33$   
502  $\mu\text{g}/\text{m}^3$ . Figure S17 elucidates that meteorological variations, chiefly surface short-wave  
503 radiation flux modulating photochemical reaction kinetics, primarily dictate the  
504 heterogeneous geographic distribution of  $\text{O}_3$  at the regional scale, with lower levels  
505 over the Jiaodong Peninsula. Meanwhile, local atmospheric chemical processes  
506 predominate the city-scale variability of  $\text{O}_3$ . HCHO facilitated  $\text{O}_3$  formation in urban  
507 areas yet suppressed it in rural regions across areas with high ozone, where most  $\text{NO}_2$   
508 promoted  $\text{O}_3$  production overall, indicating VOC- $\text{NO}_x$  synergistic control on  $\text{O}_3$  in cities  
509 and a  $\text{NO}_x$ -limited regime in rural areas during summertime. The contribution of  $\text{NO}_2$   
510 and  $\text{PM}_{2.5}$  exhibits analogous seasonal variability, promoting  $\text{O}_3$  formation under low  
511 pollution conditions while inhibiting  $\text{O}_3$  when pollution levels are high (Figures S15  
512 and 18). The elevated  $\text{NO}_2$  levels in autumn led to a negative contribution to  $\text{O}_3$ ,  
513 whereas the facilitating effect of  $\text{PM}_{2.5}$  was enhanced. This stems from the relatively  
514 moderate  $\text{PM}_{2.5}$  concentrations slightly affecting photochemical reaction rates, while  
515 the increased  $\text{NO}_2$  amplified the reactive uptake of  $\text{NO}_2$  by  $\text{PM}_{2.5}$ , generating more OH  
516 radicals that promote  $\text{O}_3$  formation (Lin et al., 2023; Tan et al., 2022). In winter,  $\text{PM}_{2.5}$   
517 pollution exceeding  $75 \mu\text{g}/\text{m}^3$  suppressed  $\text{O}_3$  formation through scattering and  
518 absorbing solar radiation that activates atmospheric chemical processes, which  
519 counteracted the promoting effect of high  $\text{PM}_{2.5}$  through the conversion of  $\text{NO}_2$  to  
520 HONO.

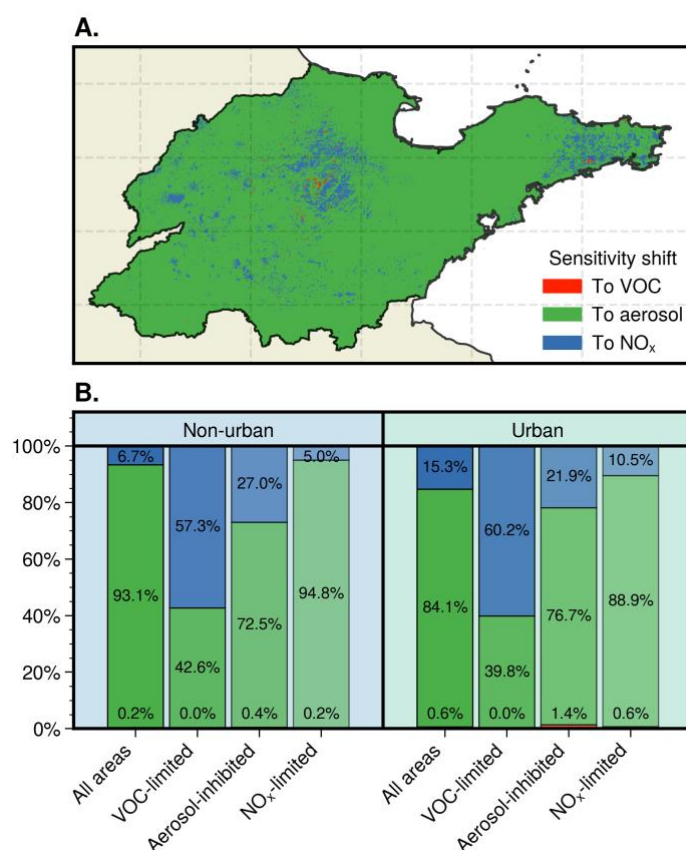

521

522 **Figure 8.** Comparison of geographical distribution for ozone formation regimes  
 523 between 2019 and 2020 in the summertime. All surface daily O<sub>3</sub>, PM<sub>2.5</sub>, and NO<sub>2</sub>  
 524 estimations from Air Transformer (AiT) are averaged over each month from May to  
 525 October 2019-2020 for matching monthly HCHO derived from TROPOMI (500 \* 500  
 526 m). (A, B) Geographical distribution of fractional contribution of chemical factors  
 527 representing O<sub>3</sub> formation regimes. The ternary phase diagram in the legend depicts the  
 528 normalized fraction of SHAP values for O<sub>3</sub> attributed to HCHO, NO<sub>2</sub>, and PM<sub>2.5</sub> at the  
 529 surface, representing VOC-limited (red), aerosol-inhibited (green), and NO<sub>x</sub>-limited  
 530 (blue) regimes, respectively. (C) Statistical Changes in the fractional contribution of  
 531 chemical factors. (D, E) Geographical distribution of O<sub>3</sub> chemical regimes. (F)  
 532 Proportion of three O<sub>3</sub> chemical regimes across urban and nonurban areas in 2019 in  
 533 Shandong (SD), and individual cities (BZ: Binzhou, ZB: Zibo, LC: Liaocheng, LY:  
 534 Linyi, JINI: Jining).

535 **Figure 8A-C** shows surface distribution and changes of the relative proportions of  
 536 SHAP values on three pollutants for inferring O<sub>3</sub> photochemical regimes. Moving along  
 537 an urban-to-rural gradient, reactions dominated by RO<sub>x</sub> radical self-reactions are  
 538 continuously enhanced with increasing NO<sub>x</sub> SHAP values, resulting in the majority of  
 539 rural Shandong being situated in NO<sub>x</sub>-limited regimes. Furthermore, the overall ozone  
 540 production regimes in Shandong exhibited a transition toward more NO<sub>x</sub>-limited from  
 541 2019 to 2020, with regions dominated by NO<sub>x</sub>-limited shifting toward being aerosol-  
 542 inhibited in the Jiaodong Peninsula. The aerosol-inhibited regime differs from either of

543 the two classically applied tropospheric O<sub>3</sub> policy-control regimes. It is attributed to the  
544 predominant heterogeneous HO<sub>2</sub> uptake by aqueous aerosols, despite comparatively  
545 low PM<sub>2.5</sub> levels during summertime. The marine environment engenders liquid aerosol  
546 particles with HO<sub>2</sub> uptake coefficients exceeding those of dry aerosols by orders of  
547 magnitude (Song et al., 2022a). Concurrently, lower ambient NO<sub>x</sub> levels minimize the  
548 promotive effects of aerosols on ozone formation (Tan et al., 2022; Kohno et al., 2022).  
549 This result is consistent with the findings of Dyson et al. (Dyson et al., 2023), which  
550 concluded that the contribution of HO<sub>2</sub> sinks onto aerosols on total HO<sub>2</sub> could increase  
551 for areas with low NO levels. The attenuated responsiveness of O<sub>3</sub> formation to VOCs  
552 induced by the uptake of HO<sub>2</sub> results in enhanced sensitivity of NO<sub>x</sub> at the northwest  
553 boundary region of the Jiaodong Peninsula. Collectively, these processes delineate an  
554 aerosol-inhibited ozone production regime in this coastal region, reflecting the  
555 sensitivity of O<sub>3</sub> photochemistry to the HO<sub>2</sub> sink. In several cities, including Binzhou,  
556 Zibo, Liaocheng, Linyi, and Jining, a greater proportion of urban areas, as compared to  
557 their nonurban counterparts, exhibited a VOC-limited regime in 2019, as indicated by  
558 the prevalence of red regions in **Figure 8D**. The percentage of urban areas in these cities  
559 under a VOC-limited regime ranges from 15% to 43%, in stark contrast to non-urban  
560 areas where such a regime is typically rare (**Figure 8F**). The comparison of O<sub>3</sub>  
561 sensitivities from 2019 to 2020 shows a regional shift towards increased sensitivity to  
562 aerosol and NO<sub>x</sub>, along with a decreased VOC sensitivity as a result of NO<sub>x</sub> reduction  
563 (**Figure 8A-C**). This shift has led to the majority of areas in Shandong being dominated

564 by a NO<sub>x</sub>-limited regime in 2020, with an expanded aerosol-inhibited regime region in  
 565 the Jiaodong Peninsula (**Figure 8E**). Additionally, the discrepancy in O<sub>3</sub> formation  
 566 sensitivity between urban and non-urban areas has been diminishing during this period  
 567 (**Figure 8C**). As illustrated in **Figure 9**, while the ozone regime transitions towards  
 568 NO<sub>x</sub>-limited, there is a marked shift towards greater aerosol sensitivity across nearly  
 569 90% of areas, leading to a 1.6% increase in aerosol-inhibited grids. Compared to  
 570 nonurban regions, a higher number of grids in urban areas demonstrate a shift towards  
 571 NO<sub>x</sub> sensitivity. Conversely, urban areas that were predominantly aerosol-inhibited in  
 572 2019 showed a lower sensitivity shift towards NO<sub>x</sub>.

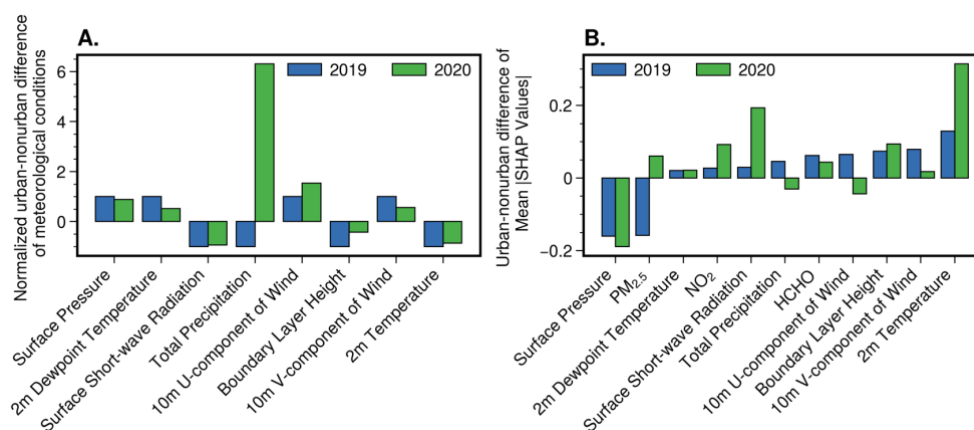

573  
 574 **Figure 9.** Geographical distribution of changes in ozone sensitivity from 2019 to 2020  
 575 in summertime (A). Comparison of ozone sensitivity changes across areas dominated  
 576 by different chemical regimes in 2019 between urban and non-urban areas (B).

### 577 3.3.2 Impact on Urban-nonurban Differences

578 We further explore the reversed O<sub>3</sub> differences by separating the individual  
579 contributions of climate and anthropogenic changes using an interpretable machine  
580 learning model (**Figure 10**). The results demonstrate that atmospheric chemical  
581 processes and meteorological conditions commonly dominate the discrepancies in O<sub>3</sub>  
582 levels between urban and non-urban areas. From 2019 to 2020, meteorological shifts  
583 remained uniform across urban and non-urban regions, marked by lowered surface  
584 pressure, boundary layer height, and short-wave radiation, alongside heightened  
585 precipitation. This, coupled with decreased precursor levels, contributed to a decline in  
586 O<sub>3</sub> pollution. As shown in **Figures 10** and S19, the diminished reduction in boundary  
587 layer height and radiation flux across urban areas, compared to nonurban areas in 2020,  
588 decelerated the expected decline of O<sub>3</sub> concentrations, leading to urban O<sub>3</sub> levels  
589 exceeding those of nonurban areas. Concurrently, a narrowing difference in  
590 temperatures between urban and nonurban areas, despite an overall cooling from 2019  
591 to 2020, favored O<sub>3</sub> formation in urban regions during the summertime. Additionally,  
592 PM<sub>2.5</sub> emerged as the principal anthropogenic factor inverting the urban-nonurban O<sub>3</sub>  
593 disparity over the course of 2019 to 2020. Its contribution to ozone shifted from being  
594 lower in urban areas to exceeding that in nonurban areas, revealing that the decreased  
595 reactive uptake of HO<sub>2</sub> from aerosols induced by a more substantial reduction in PM<sub>2.5</sub>  
596 in urban areas made the larger contribution to O<sub>3</sub> production (Ivatt et al., 2022; Li et al.,  
597 2017). Moreover, the response of O<sub>3</sub> to the changes in its precursors and PM<sub>2.5</sub> was

598 determined by the O<sub>3</sub> formation regimes. The variations in O<sub>3</sub> sensitivity also  
 599 corroborate the above finding. In rural areas, where there was a lesser reduction in PM<sub>2.5</sub>  
 600 concentration, the sensitivity increasingly favored aerosol suppression across more than  
 601 93% of the assessed grids (**Figure 9**). This enhanced suppression effect of aerosols in  
 602 rural areas leads to a more significant O<sub>3</sub> reduction compared to urban locales. The  
 603 reduction of NO<sub>x</sub> in nonurban areas demonstrated a more effective reduction in O<sub>3</sub>  
 604 levels, which predominantly shifted towards a NO<sub>x</sub>-limited regime in 2020. Although  
 605 urban areas also showed a shift towards being a NO<sub>x</sub>-limited regime, they exhibited  
 606 relatively higher sensitivity to VOCs (**Figure 8**). The urban areas, characterized by  
 607 elevated NO<sub>x</sub> emissions, exhibited a higher sensitivity to VOCs, and the fraction of  
 608 aerosol-inhibited areas increased from 2019 to 2020, resulting in the control benefits of  
 609 urban O<sub>3</sub> pollution in 2020 are partially offset by the nonlinear response of O<sub>3</sub> to a  
 610 greater reduction in NO<sub>2</sub> and PM<sub>2.5</sub>, and a smaller decrease in HCHO relative to  
 611 nonurban areas. Consequently, O<sub>3</sub> exhibits a lower reduction in urban areas as a result  
 612 of the aforementioned changes.

613

614 **Figure 10.** Comparison of urban-nonurban disparities in meteorological conditions (A),  
615 and mean absolute SHAP values (B) between 2019 and 2020 across Shandong, China  
616 during the summertime.

#### 617 **4. CONCLUSIONS**

618 The purpose of the current study was to diagnose the non-linearity of O<sub>3</sub>-NO<sub>x</sub>-  
619 VOCs-aerosols chemistry using an interpretable ML model based on spatially resolved  
620 multi-pollutant estimations for determining the causes of changing differences in O<sub>3</sub>  
621 levels between urban and non-urban areas. Our study represents the first attempt to  
622 develop an advanced DL model that reconstructs the concentrations of multiple  
623 pollutants and subsequently infers the aerosol-inhibited regime from observations. This  
624 innovative approach provides further support for investigating the impact of precursor  
625 emissions and aerosol on the urban-nonurban differences in O<sub>3</sub> levels.

626 Given the non-linearity of ozone formation and its increasing regional differences,  
627 precise estimations of ground-level O<sub>3</sub>, NO<sub>2</sub>, HCHO, and PM<sub>2.5</sub> are crucial for deducing  
628 the chemical regimes governing ozone pollution and its urban-nonurban disparities. The  
629 evaluation of the model's performance indicates that it can be readily extended to any  
630 other domain thanks to its unified architecture. Anyone can easily utilize the model to  
631 estimate ground-level pollutants, intelligently considering spatial-temporal  
632 neighborhood information based on their customized input data. The model further  
633 improved spatial resolution to sub-km levels using TROPOMI and MODIS retrievals  
634 via spatiotemporal autocorrelation downscaling of AiT. The "black box" nature of AiT  
635 can be made more physically interpretable by SHAP, enabling the evaluation of the

636 significance of each input variable (Figure S20). The season trends show the highest  
637 contribution, followed by emission proxies and meteorological conditions. Meanwhile,  
638 the results between AiT trained with all data and that trained exclusively with CNEMC  
639 data across various spatiotemporal scales underscore the promising prospect for  
640 improving the model's generalization ability with more ground-level monitoring data  
641 and the growing space of methods.

642 We conclude that with the effective reduction of PM<sub>2.5</sub> pollution, the sensitivity of  
643 O<sub>3</sub> to VOCs will increase, necessitating further intensification of VOC emissions  
644 regulation by government agencies. Three distinct chemical regimes were assessed by  
645 tracking NO<sub>x</sub>, VOCs, and aerosols with surface NO<sub>2</sub>, HCHO, and PM<sub>2.5</sub>. In the  
646 Jiaodong Peninsula of Shandong Province, coastal areas with relatively few primary  
647 pollutants are widely found to be under an aerosol suppression regime, illustrating that  
648 ozone regime inference based on machine learning can serve as an alternative to  
649 determining the aerosol suppression regime through the rate of radical termination in  
650 atmospheric chemical models. The O<sub>3</sub> regime in other areas of Shandong generally  
651 transited from the NO<sub>x</sub>-sensitive regime in nonurban to a more VOC-sensitive regime  
652 in urban areas. We estimate that substantial reductions in anthropogenic emissions of  
653 PM<sub>2.5</sub> and NO<sub>2</sub> are the main drivers of the reversal of the traditional discrepancy in O<sub>3</sub>  
654 levels between urban and non-urban areas. In essence, due to the lower efforts in  
655 reducing PM<sub>2.5</sub> in nonurban settings, the aerosol-mediated suppression of ozone  
656 became more pronounced, resulting in lower ozone levels in rural areas relative to urban

657 centers. This shift underlines the intricate balance between emission reduction and  
658 ozone formation mechanisms, suggesting that nuanced understanding and targeted  
659 interventions are necessary to manage and mitigate the health and environmental  
660 impacts of such disparities. To preclude exacerbated O<sub>3</sub> pollution resulting from the  
661 shift of many regions from VOC-limited to NO<sub>x</sub>-limited regimes and the decline in  
662 heterogeneous HO<sub>2</sub> uptake induced by PM<sub>2.5</sub> reduction in urban areas, emission policies  
663 aimed at decreasing NO<sub>x</sub> to reduce O<sub>3</sub> levels will only be effective with stringent VOC  
664 emission abatement when PM<sub>2.5</sub> is concurrently decreased. The integration of high-  
665 resolution pollutant estimations with an interpretable machine learning model offers a  
666 promising avenue for advancing our understanding of ozone pollution dynamics and  
667 developing effective air quality management strategies.

668       Although our study endeavors to establish O<sub>3</sub> formation regimes involving NO<sub>x</sub>,  
669 VOCs, and aerosols, and the method identifies an aerosol-inhibited regime from a  
670 statistical perspective, it is subject to certain uncertainties due to the relatively poor data  
671 quality of HCHO and the unsegregated multiple impacts of aerosols, such as N<sub>2</sub>O<sub>5</sub>  
672 uptake, NO<sub>2</sub> uptake, HO<sub>2</sub> uptake, and light extinction (Tan et al., 2022). We have made  
673 efforts to integrate all required surface pollutant concentrations into a unified model,  
674 while the absence of ground-level HCHO monitoring data compelled us to tap into an  
675 alternative methodology. The retrieval error of surface HCHO and the system error  
676 between its retrieval approach and the AiT model degrade the ability of ML to identify  
677 the O<sub>3</sub> sensitivity. Meanwhile, the notion of ozone regimes is only appreciated in

678 photochemically active environments where the  $\text{RO}_x\text{-HO}_x$  cycle is active (Souri et al.,  
679 2023). The definition of  $\text{NO}_x$ -limited or VOC-limited regimes is meaningless in  
680 nighttime chemistry, where  $\text{NO-O}_3\text{-NO}_2$  partitioning is the primary driver. The surface  
681 daytime pollutant estimations with finer resolutions in space and time based on a unified  
682 modeling framework will offer an unprecedented view to characterize the near-surface  
683  $\text{O}_3$  formation regimes. Notwithstanding the relatively limited duration of the study, this  
684 work offers valuable insights into the current state and causes of urban-nonurban  
685 disparities in  $\text{O}_3$  pollution. Future efforts should conduct a more detailed long-term  
686 evaluation of urban-nonurban disparities in global  $\text{O}_3$  levels and the impact of formation  
687 mechanisms to further our understanding of air pollution and its mitigation.
