21 **Abstract**

22 Narrowing surface ozone disparities between urban and nonurban areas escalate health
23 risks in densely populated urban zones. A comprehensive understanding of the impact
24 of ozone photochemistry on this transition remains constrained by current knowledge
25 of aerosol effects and the availability of surface monitoring. Here we reconstructed
26 spatiotemporal gapless air quality concentrations using a novel Transformer deep
27 learning (DL) framework capable of perceiving spatiotemporal dynamics to analyze
28 ozone urban-nonurban differences. Subsequently, the photochemical effect on these
29 discrepancies was analyzed by elucidating shifts in ozone regimes inferred from an
30 interpretable machine learning method. The evaluations of model exhibited an average
31 out-of-sample cross-validation coefficient of determination of 0.96, 0.92, and 0.95 for
32 ozone, nitrogen dioxide, and fine particulate matter (PM_{2.5}), respectively. The ozone
33 sensitivity in nonurban areas, dominated by nitrogen oxide (NO_x)-limited regime, was
34 observed to shift towards increased sensitivity to volatile organic compounds (VOCs)
35 when extended to urban areas. A third ‘aerosol-inhibited’ regime was identified in the
36 Jiaodong Peninsula, where the uptake of hydroperoxyl radicals onto aerosols
37 suppressed ozone production under low NO_x levels during summertime. The reduction
38 of PM_{2.5} would increase the sensitivity of ozone to VOCs, necessitating more stringent
39 VOC emissions abatement for urban ozone mitigation. In 2020, urban ozone levels in
40 Shandong surpassed those in nonurban areas, primarily due to a more pronounced
41 decrease in the latter resulting from stronger aerosol suppression effects and lesser
42 PM_{2.5} reductions. This case study demonstrates the critical need for advanced spatially
43 resolved models and interpretable analysis in tackling ozone pollution challenges.

44

45 1. INTRODUCTION

46 Surface ozone (O_3), fine particulate matter ($PM_{2.5}$), and nitrogen dioxide (NO_2) are
47 among the most important trace gases in the atmosphere that significantly impact the
48 ecological environment and public health (Han and Naeher, 2006; Yue et al., 2017).
49 During the Action Plan on the Prevention and Control of Air Pollution (denoted as the
50 Clean Air Action, 2013-2017) (Action Plan on Air Pollution Prevention and Control (in
51 Chinese), 2023), $PM_{2.5}$ and nitrogen oxide (NO_x = nitric oxide (NO) + NO_2) emissions
52 across China decreased by 33% and 21%, respectively (Zheng et al., 2018), while
53 surface O_3 exhibited an increasing trend (Lu et al., 2018). The increase in O_3 could be
54 partially attributed to the “aerosol-inhibited” effect, where the reduction in $PM_{2.5}$ results
55 in a diminished reactive uptake of hydroperoxyl radicals (HO_2) onto aerosols (Ivatt et
56 al., 2022; Li et al., 2019). The societal benefits of reducing premature deaths and
57 economic losses from $PM_{2.5}$ reductions have been diminished by the rising O_3 (Liu et
58 al., 2022). Thus, achieving the joint attainment objectives for $PM_{2.5}$ and O_3 has been put
59 on the top priority of China’s long-term air pollution control policies.

60 The complexity of the O_3 formation is partly reflected by the nonlinear response
61 to changes in precursors (i.e. volatile organic compounds (VOCs) and NO_x), as well as
62 the presence of heterogeneous reactions in aerosols. Understanding these dynamics is
63 crucial to investigate current narrowing differences in O_3 concentrations between urban
64 and nonurban areas, which have traditionally shown higher levels in rural (Han et al.,
65 2023). The formaldehyde-to- NO_2 ratio ($HCHO/NO_2$ or FNR) serves as a theoretical

66 gauge of the relative abundance of total organic reactivity to hydroxyl radicals (OH)
67 and NO_x (Wei et al., 2022c; Sillman, 1995), and as such, it can function as a useful
68 indicator of O₃ sensitivity. Previous studies have utilized the HCHO/NO₂ from satellite
69 remote sensing to infer O₃ production regimes for guiding O₃ control policies (Jin et al.,
70 2023; Li et al., 2021a; Jin et al., 2020). However, the changes of HCHO/NO₂ threshold
71 in O₃ regimes classification modulated by meteorology and localized atmospheric
72 chemistry in space and time, and uncertainties relating column to surface, precluding
73 robust applications over larger spatial scales (Lee et al., 2023; Jin et al., 2017; Sourì et
74 al., 2023). While the observation-based model method alleviates some of these
75 limitations, constraints remain including computational demands and priori chemical
76 mechanisms (Song et al., 2022b; Chu et al., 2023). The advent of interpretable machine
77 learning models affords new opportunities to unravel intricate dependencies governing
78 O₃ formation purely from actual observational data. However, sparse ground-based
79 monitoring stations, especially in rural areas, pose great challenges to the spatially full
80 coverage of studies. Thus, the high-spatiotemporal-resolutions estimations of surface
81 air pollutants are urgently needed to improve our understanding of how these pollutants
82 are changing and interacting.

83 Recent studies have utilized spatially resolved remote sensing data to estimate the
84 continuous distribution of air pollutants in space by diverse machine learning (ML)
85 models (Lyapustin and Wang, 2022; Lamsal et al., 2022; Huang et al., 2021; Li and
86 Wu, 2021; Ren et al., 2022b), such as random forest (RF), full residual deep learning,

87 and Bayesian ensemble model. These attempts have demonstrated the tremendous
88 potential of machine learning as an alternative to atmospheric chemical models (Jung
89 et al., 2022). Nevertheless, there are still several aspects that have not been fully
90 considered. For instance, coarse-resolution maps limit the ability to characterize the
91 fine-scale variation of air pollution within urban areas, which has significant
92 implications for environmental justice disparities of disadvantaged communities
93 (Jerrett et al., 2005; Ren et al., 2022b; Dias and Tchepel, 2018). Additionally, existing
94 ML models may not fully account for the complex atmospheric chemistry and physics
95 processes that influence pollutant concentrations due to the single-pixel-based
96 processing mode (Huang et al., 2021; Requia et al., 2020; Thongthammachart et al.,
97 2022; Li et al., 2022b; Geng et al., 2021). Although several efforts have been made by
98 using the neural network with convolutional layers (Di et al., 2016), and explicitly
99 incorporating spatiotemporally weighted information to machine learning models (Wei
100 et al., 2022b), the global spatiotemporal self-correlation of multi-dimensional features
101 in the input array remained unaddressed. Meanwhile, the convolutional operations
102 extract features from all neighboring grids of the target, ignoring the fact that the
103 environmental knowledge of the target grid itself is the most significant, with the
104 adjacent features being secondary.

105 In this study, we aim to analyze the evolving dynamics of urban-nonurban O₃
106 differences between 2019 and 2020. The roles of emission discrepancies and
107 nonlinearity of O₃-NO_x-VOCs-aerosols photochemical processes in shaping these O₃

108 variations were deeply dissected. To achieve a comprehensive analysis, we employed a
109 new spatiotemporal Transformer framework that paid special attention to air mass
110 transport and dispersion affected by the spatial-temporal correlations, to reconstruct the
111 spatially gapless air quality datasets based on satellite data, ground-level observations,
112 and meteorological reanalysis. The estimations are particularly vital for regions lacking
113 dense ground-based monitors, ensuring that our understanding of O₃ dynamics in urban-
114 nonurban areas and formation regimes is not limited by geographical constraints in data
115 availability. Surface O₃ formation regimes in Shandong province were inferred by the
116 classic XGBoost model (Chen and Guestrin, 2016) coupled with Shapley Additive
117 exPlanations (SHAP) (Lundberg and Lee, 2017), which identifies the impact of
118 meteorological conditions and photochemical indicators (i.e. PM_{2.5} as a proxy for
119 aerosols, NO₂ as a proxy for NO_x, and HCHO as a proxy for VOCs) on O₃. The
120 innovative Transformer-based modeling and interpretable machine learning analysis
121 approaches are expected to enable new applications such as those of air quality
122 simulation and O₃ formation regimes studies.

123 **2. MATERIALS AND METHODS**

124 **2.1 Predictor Variables**

125 The study domain covered the Shandong province of China, which has a high
126 mortality burden of air pollution (Liu et al., 2017). The surface PM_{2.5}, O₃, and NO₂
127 concentration measurements were collected from the regulatory air quality stations of
128 the China National Environmental Monitoring Center (CNEMC, with a total of 179

129 locations) and the Shandong Provincial Eco-environmental Monitoring Center (SDEM,
130 with a total of 166 locations) (Fig. S1). The SDEM stations were included to fill the
131 spatial gaps in the county and rural areas where CNEMC stations were lacking. The
132 study area was divided into 1.22 million grid cells with a spatial resolution of 500
133 meters. We utilized a range of predictor data, including tropospheric NO₂ vertical
134 column densities (VCDs) and O₃ total VCDs measured by TROPospheric Monitoring
135 Instrument (TROPOMI) (Lamsal et al., 2022; Copernicus Sentinel-5P (processed by
136 ESA), 2020), aerosol optical depth (AOD) data and atmospheric properties obtained
137 from Moderate Resolution Imaging Spectroradiometer (MODIS) Multi-Angle
138 Implementation of Atmospheric Correction products (Lyapustin and Wang, 2022),
139 AOD estimates from Modern-Era Retrospective Analysis for Research and
140 Applications as the supplement to MODIS (2015), meteorological reanalysis obtained
141 from the fifth generation atmospheric reanalysis dataset of European Centre for
142 Medium-Range Weather Forecasts (ECMWF) (ERA5) (Hersbach et al., 2023, p.5),
143 daily dynamic industrial emissions, moonlight-adjusted nighttime lights product
144 (Román et al., 2018), vegetation index (Didan, 2021), population density (WorldPop,
145 2018), road density, land use data (Jun et al., 2014), and the shuttle radar topography
146 mission digital elevation model. The detailed information for all predictive variables
147 is listed in Table S1 and discussed in Text S1-2. Taking space-variant and seasonal
148 patterns into consideration, several spatiotemporal indicators such as geographical
149 coordinates, Euclidean spherical coordinates, year, Julian date, and helix-shaped

150 trigonometric sequences, were also included as predictor variables (Text S3) (Sun et al.,
151 2022). Geographic Information Systems techniques, including reprojection and
152 resampling, were used to consolidate all the data obtained for consistent projection and
153 spatial scale. Finally, the Light Gradient Boosting Machine was used to fill satellite data
154 gaps (Text S4) (Ke et al., 2017).

155 **2.2 Air Transformer**

156 AiT is an individual Transformer model that adopts an encoder-decoder
157 architecture with multidimensional self-attention computation to dynamically capture
158 the spatiotemporal autocorrelation of atmospheric pollution changes from the
159 sequences of pixels and variables for more reliable spatial maps of estimation.
160 Compared with existing image and video recognition Transformers, such as ViT
161 (Dosovitskiy et al., 2021), Timesformer (Bertasius et al., 2021), and Uniformer (Li et
162 al., 2021b), AiT is innovative in incorporating self-attention across channels after the
163 pixels-based self-attention and taking advantage of the decoder. The former can capture
164 the correlations between predictor variables. The decoder was employed to enable
165 interaction between the primary target grid and neighboring grids. Predictor variables
166 with 8 timesteps within 1000 meters of the target grid cell were fed into the model to
167 learn spatiotemporally disparities among atmospheric pollutants for predicting O₃, NO₂
168 and PM_{2.5} within the target grid point.

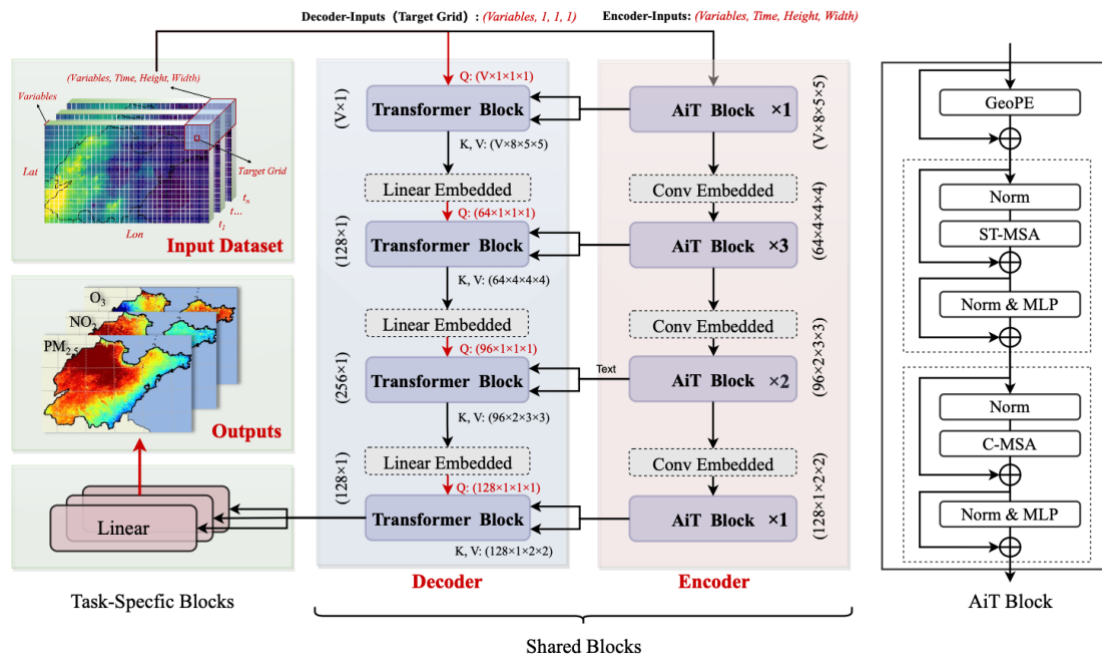

169 The overall architecture of the proposed AiT model and the dimensions of input
170 data are illustrated in Fig. 1. The encoder maps an input sequence with neighborhood

171 spatiotemporal data to a sequence with high-dimensional spatiotemporal characteristics,
 172 and the decoder generates an estimation by computing self-attention representations
 173 between the target grid and outputs of the encoder. The encoder of AiT takes as input a
 174 clip $X \in R^{V \times T \times H \times W}$ consisting of T multi-variable frames of size $H \times W$ sampled
 175 from the original dataset, where V is the number of variables and the target grid cell is
 176 located at $(\lfloor \frac{H}{2} \rfloor, \lfloor \frac{W}{2} \rfloor)$. The decoder takes as input a clip $X \in R^{V \times 1 \times 1 \times 1}$ consisting of V
 177 variables from the target grid. Several Transformer blocks with modified self-attention
 178 computation (AiT blocks) are applied to the encoder. The AiT encoder block is similar
 179 to the standard vision transformer block but specifically designed for atmospheric
 180 estimation (Dosovitskiy et al., 2021). It is a stack of two self-attention schemes,
 181 including global spatiotemporal self-attention on the pixels and channel self-attention
 182 on variable predictors. The former contains $N = HW$ effective input sequence length
 183 for the self-attention to extract spatiotemporal information. The latter computes self-
 184 attention based on V effective input sequence length to capture hidden information on
 185 variables. The decoder part is symmetric to the encoder part, but it only has a block
 186 with the spatiotemporal self-attention mechanism. We compute the matrix of self-
 187 attention outputs as:

$$188 \quad \text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}} + B\right)V \quad (1)$$

189 where Q , K , and V are the queries, keys, and values in the inputs of the particular
 190 attention, respectively. d_k is the feature dimensionality of K , and B is the geographic
 191 positional bias term. Another difference is that the attention function of the decoder is

192 computed on Q from the estimated grid data, and (K, V) from the outputs of encoder
 193 blocks under the same stage, resulting in the outputs of the last decoder block being
 194 sized 1×128 . The description of the data transformation and design details in the
 195 process of training can be found in Text S5. The multi-task learning strategy was also
 196 applied for learning representation across multiple pollutant estimation tasks (Text S6).
 197 The aggregated feature data from June 2019 to June 2021 were utilized to train and
 198 validate the model through cross-validation (CV), where the optimal model, trained
 199 based on out-of-sample CV, was used to estimate multiple pollutant concentrations
 200 during the study period, which was then employed for subsequent analysis.

201

202 **Figure 1.** Schematic diagram of the AiT model. The white box of multi-dimension
 203 inputs presents each pixel of raster data. The AiT Block is a Transformer block based
 204 on self-attention across space, time, and variables. The GeoPE, Norm, MLP, ST-MSA
 205 and C-MSA indicate respectively positional embedding, layer normalization, multi-
 206 layer perceptron, spatial-temporal multi-head self-attention and multi-channels (multi-
 207 variables) multi-head self-attention.

208 **2.3 Diagnosing O₃ Formation Sensitivity**

209 Interpretability can provide insight into how a model may be improved, bolster the
210 understanding of the process being modeled, and engender appropriate confidence
211 among researchers. SHAP is a coalitional game-theoretic approach based on Shapley
212 values (Shapley, 1988) and then assigns each variable an importance value for a
213 particular estimation. Deep SHAP, a high-speed approximation algorithm that builds on
214 the connection between Shapely values and DeepLIFT (Shrikumar et al., 2019), is
215 employed to compute the feature importance of AiT from all data with monitoring
216 labels for interpreting the prediction. The sensitivity of the O₃ formation regime was
217 deduced using a combination of the XGBoost model and SHAP interpretability method,
218 employing the GPUShap algorithm (Mitchell et al., 2020), which simulated the
219 response of surface O₃ to meteorological conditions, HCHO, NO₂ and PM_{2.5}, by
220 utilizing the continuous estimations from ERA5, AiT and TROPOMI between 2019 and
221 2020. The incorporation of meteorology in the model ameliorated the inadequacies in
222 the conventional method (HCHO-NO₂ ratio), where its thresholds for identifying O₃
223 regimes vary temporally and spatially. The positive or negative contributions of three
224 atmospheric pollutants were used to identify their promoting or inhibitory effects on O₃
225 variability. Given the unbiased property of SHAP values regarding directionality, the
226 normalized relative magnitudes of SHAP values were calculated for HCHO, NO₂, and
227 PM_{2.5}. This allowed the differentiation of the O₃ formation regimes based on the locally
228 maximal proportions of the SHAP values for each species. The ground-level monthly

229 HCHO concentrations were derived using a combination of column-to-surface
230 conversion factor (CF) simulated from the ECMWF Atmospheric Composition
231 Reanalysis 4 and the tropospheric HCHO VCDs obtained from TROPOMI (Cooper et
232 al., 2022; Su et al., 2022; Inness et al., 2019). A detailed description of the CF method
233 as used here is discussed in Text S7. To ensure consistency in resolution between
234 TROPOMI and AiT, we employed the oversampling method to downscale the
235 TROPOMI VCDs to the resolution of AiT estimation, which has been proven effective
236 in achieving finer resolution (Su et al., 2022; Cooper et al., 2022; van Donkelaar et al.,
237 2015).

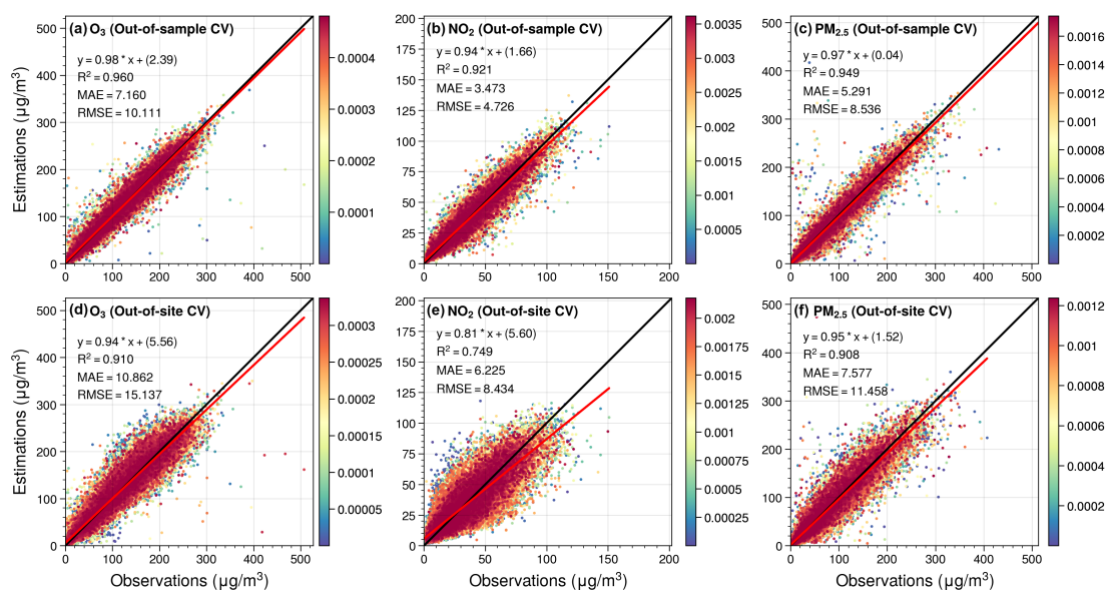

238 **3. RESULTS AND DISCUSSION**

239 **3.1 Performance Evaluation for the AiT**

240 **3.1.1 Cross-validation Metrics**

241 We evaluated the AiT performance using the 10-fold CV approach (Text S8), with
242 correlation coefficient (R^2) measuring the extent to which model simulations explain
243 variability in atmospheric pollutants, and root mean square errors (RMSE) and mean
244 absolute errors (MAE) evaluating the bias/error of the estimates. As shown in Fig. 2,
245 out-of-sample CV daily ground-level O_3 , NO_2 , and $PM_{2.5}$ estimations are highly
246 consistent with ground observations ($R^2 = 0.96, 0.92, 0.95$), indicating low uncertainties,
247 with RMSE of 10.1, 4.7, and 8.5 $\mu g/m^3$ and MAE of 7.2, 3.5, and 5.3 $\mu g/m^3$ for the
248 2018-2021 period. The linear regression comparing the O_3 predictions versus
249 observations yields a slope of 0.98 and an intercept of 2.39, which demonstrates that

250 there is no systematic bias in the estimations. Meanwhile, as shown in Fig. S3, our AiT
 251 model performs well at the individual-site scale with high CV-RMSE for O₃, NO₂, and
 252 PM_{2.5} (10.5 ± 8.6 , 4.7 ± 1.1 , and $8.3 \pm 2.8 \mu\text{g}/\text{m}^3$). In general, the AiT model is robust
 253 for multi-pollutant simultaneous estimations.

254

255 **Figure 2.** Out-of-sample cross-validation (a-c) and out-of-site cross-validation (d-f) of
 256 daily ground-level O₃, NO₂ and PM_{2.5} concentration in the validation set.

257 The spatial generalization ability of the AiT is then examined by the out-of-site CV
 258 evaluation method (Fig. 2). The daily spatial variations of O₃, NO₂, and PM_{2.5} at
 259 locations without ground measurements can be well estimated by our model (i.e., CV-
 260 R² = 0.91, 0.75, 0.91), representing a core contribution of such studies. We also probe
 261 the model performance for each site separately based on spatial CV estimations (Fig.
 262 S4). This general model yields an RMSE of 15.2 ± 8.8 , 8.1 ± 2.7 , and $11.1 \pm 2.8 \mu\text{g}/\text{m}^3$,
 263 respectively. Furthermore, we trained the AiT model using data exclusively from
 264 CNEMC and assessed its generalizability by validating it with data from SDEM. The

265 model demonstrates strong performance with high our-of-sample CV R^2 values in the
266 validation dataset of CNEMC (Fig. S5), and when evaluated with SDEM data, it
267 exhibits only an acceptable degradation in predictive accuracy (Fig. S6, R^2 for O_3 , NO_2 ,
268 and $PM_{2.5}$: 0.90, 0.73, 0.79). Meanwhile, our framework utilizes multi-task learning to
269 enhance computational efficiency through a single iteration and leverages the
270 interactions among multiple pollutants to optimize the performance at individual
271 pollutant levels (Table S2). In summary, AiT provides relatively stable estimations in
272 areas without available ground-level monitoring and reliably extends ground
273 monitoring from the site scale to the full-coverage spatial scale with high spatial
274 resolution.

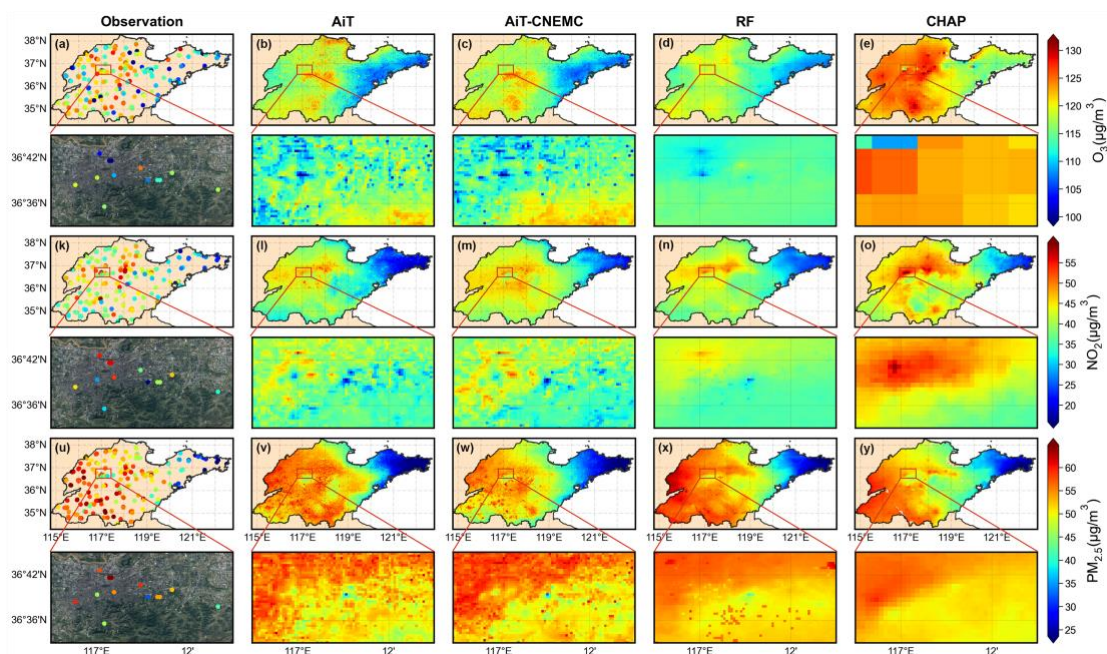

275 **3.1.2 Compared with Other ML Models**

276 Since ground-level air quality measurements across the target regions are
277 extremely limited at a 500 m spatial resolution, representing only roughly two-
278 thousandths of the total grid cells, we seek implicit approaches to validate our estimated
279 near surface pollutant concentrations. We compared the model performance with
280 previous studies that applied different ML methods to estimate these three air pollutants
281 individually and found out that our cross-validation results are comparable or even
282 better than those (Table S3). We also created a new dataset in our study by applying the
283 classic RF algorithm which is the most common ML model for estimating atmospheric
284 pollution in recent years (Wei et al., 2022a; Requia et al., 2020; Xiao et al., 2018; Geng
285 et al., 2021; Lu et al., 2021) with the same variables as AiT. The statistical comparisons

286 between AiT and RF are also shown in Table S3. We then compared the spatial
287 distribution of our results with estimations from CHAP, AiT-CNEMC, and RF.

288 Figure 3 shows the spatial maps of near-surface air pollutants with partially
289 zoomed satellite images for monitoring sites, AiT, CNEMC-trained AiT, RF, and CHAP
290 in 2019 (see Fig. S7 for 2020). We found that the estimated NO₂ and PM_{2.5} from the
291 AiT share a similar spatial distribution to those estimated by RF and CHAP. However,
292 enlarged city-level urban regions in Fig. 3 reveal that AiT estimates fine structures and
293 intra-urban disparities in near-surface multi-pollutant concentrations, which cannot be
294 captured by either RF or CHAP products. This spatial gradient is also captured by AiT
295 trained with CNEMC data, revealing the reliability of the deep learning model structure.
296 In general, while RF and CHAP can only identify the hotspots of air pollutants at a
297 regional scale, the spatial distribution of air pollutants estimated by AiT shows much
298 more detailed differences with high spatial and temporal variability across the city scale.
299 The differences of near-surface annual averaged pollutants between 2019 and 2020 for
300 measured and multi-estimated data are presented in Fig. S8. The reductions or increases
301 of O₃, NO₂, and PM_{2.5} in distinct locations can be simulated by our model, which is
302 relatively consistent with the changes of measurements. The zoomed maps in Fig. S8
303 show the differences in three pollutant concentrations at the city scale of the capital of
304 Shandong Province, Jinan. It can be found that the change in pollutant levels in 2020
305 compared to 2019 exhibits substantial regional variations and intra-urban heterogeneity,
306 with some areas experiencing an increase while others a decrease. Compared to the

307 estimations of RF and CHAP, our results successfully capture the complex distribution
 308 of air pollution in reality and reveal that the decline in PM_{2.5} is primarily concentrated
 309 in suburban areas, while an increase is pronounced in some regions of urban during
 310 2020. Notably, this spatial trend may be consistent with underlying emission patterns
 311 and meteorological conditions.

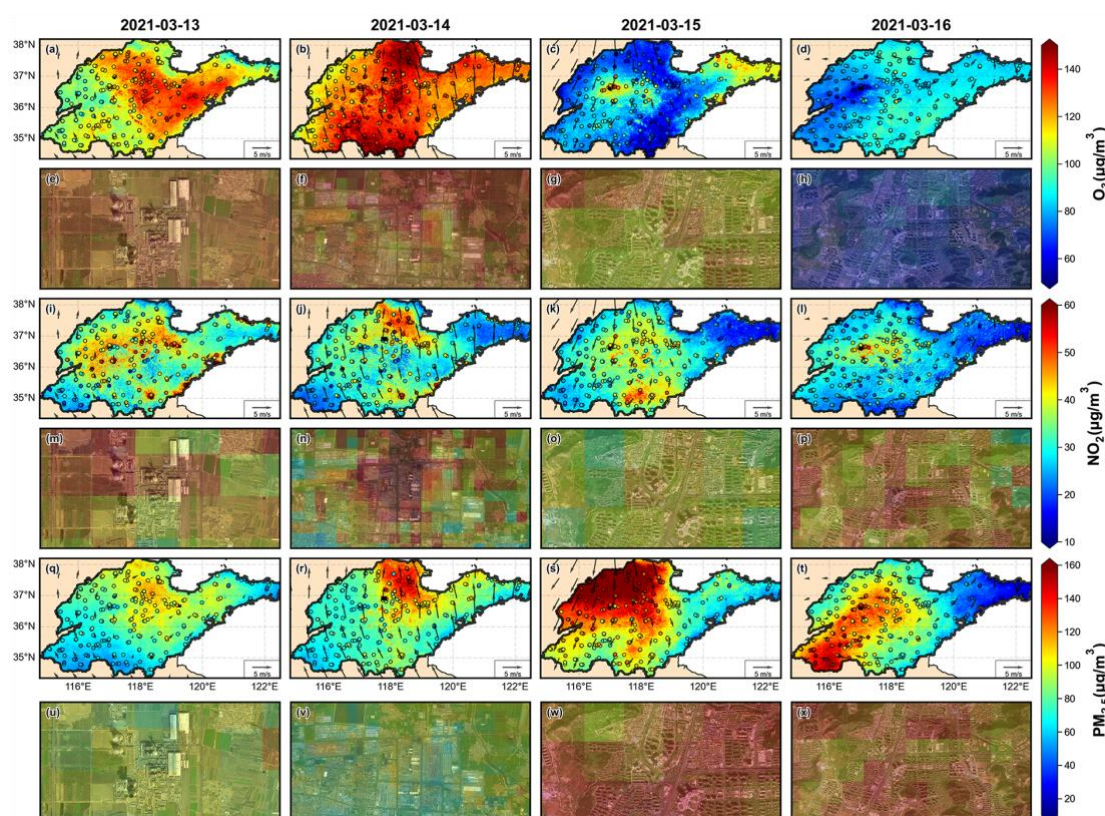

312
 313 **Figure 3.** Spatial distribution of the annual mean (a-e) O₃, (k-o) NO₂, and (u-y) PM_{2.5}
 314 concentrations from observations, Air Transformer (AiT), CNEMC-trained AiT,
 315 Random Forest (RF) and ChinaHighAirPollutants (CHAP), respectively, in 2019. The
 316 region enclosed by the red rectangular box corresponds to the zoomed-in maps of the
 317 satellite (© Tianditu: www.tianditu.gov.cn) and pollutant concentrations at a city scale
 318 for the capital city of Shandong Province, Jinan.

319 3.1.3 Typical Event Study

320 The typical example of the spatial distribution of multi-pollutant observations and
 321 estimations of AiT is compared for validating the predictive capability of the model at
 322 a particular pollution episode, i.e., 13-16 March 2021. During this period, an early

323 season dust storm, which was called the largest and strongest such storm in a decade,
324 hits northern China (Myers, 2021). As shown in Fig. 4, our model can capture the spatial
325 distribution of surface O₃, NO₂, and PM_{2.5} in the time of severe atmospheric pollution.
326 In addition, our estimations are in high concordance with measurements in terms of
327 magnitudes and spatial variability over the entire research region. The model trained
328 solely on CNEMC data is also capable of effectively capturing the drastic changes in
329 air quality during the pollution episode (Fig. S9). Combining wind fields to analyze
330 PM_{2.5} distribution on the day of the dust storm, it can be found that surface wind carries
331 a massive amount of particulate matter from Beijing, which suffered a severe dust storm,
332 to northern Shandong. The influence was gradually diminishing in southern Shandong
333 due to the obstruction of Mount Tai. Spatial heterogeneity within intra-urban areas was
334 further investigated to identify the hotspots of pollution sources. The satellite images in
335 even-numbered rows of Fig. 4 illustrate the spatial disparities of three pollutants around
336 four typical emission sources: thermal power plants, industrial parks, overpasses, and
337 parks. As depicted, these anthropogenic emission sources contribute to higher pollution
338 levels, while the mountain in the park mitigates primary pollution but also increases O₃
339 concentrations. Industrial sources emit a large number of NO_x and PM_{2.5}, leading to
340 increased pollution of these species compared with other urban microenvironments,
341 which in turn promotes O₃ formation, particularly in downwind areas (Miller et al.,
342 1978; Tang et al., 2020). Although the spatial gradients of pollutants on the street are
343 not as apparent as in the dataset with 100 m resolution (Huang et al., 2021), the

344 predicted spatial variation between various geographical scenes is in satisfactory
 345 agreement given the 500 m scale of the model. Urban areas affected by diverse dust
 346 pollution exhibit lower PM_{2.5} concentrations compared to rural due to the obstructive
 347 and filtering effects of artificial structures, such as buildings and urban greenery (Fig.
 348 S10), which cannot be effectively captured solely by ground-based observations.
 349 Notably, the elevated PM_{2.5} inhibits the formation of O₃ by diminishing solar radiation
 350 flux and absorbing the HO₂ radical on the aerosol surface, even in conditions
 351 characterized by similar NO₂ levels. As for the mapping, AiT accurately grasps the
 352 spatial characteristics of air pollutants and delivers a coherent spatial-temporal
 353 distribution that is consistent with the prior knowledge of atmospheric transport.

354

355 **Figure 4.** The spatial distribution of ground-level O₃ (a-d), NO₂ (i-l), and PM_{2.5} (q-t)
 356 concentrations from AiT and monitoring stations during 13-16 March 2021 in

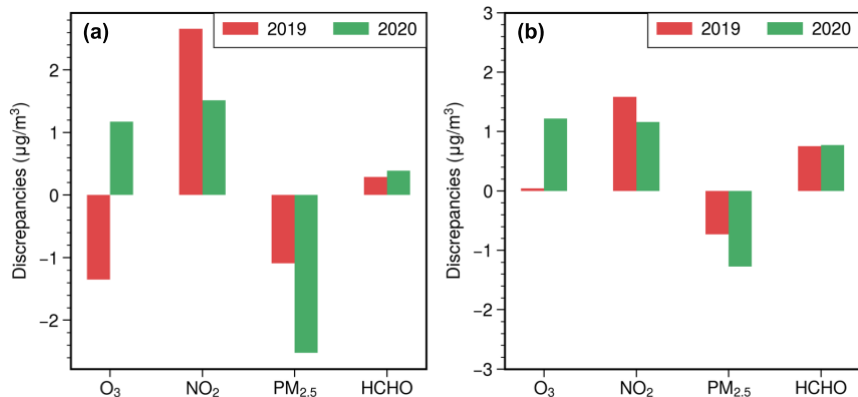

357 Shandong, China. The black arrows are the 10 m wind speed and wind direction. The
358 even-numbered rows correspond to the concentration distribution maps of typical
359 emission sources for the respective pollutants, accompanied by satellite images (©
360 Tianditu: www.tianditu.gov.cn). The upper right area of e, m, and u is a thermal power
361 plant in Weifang City (119°250' E-119°280' E, 36°658' N-36°673' N). The center area
362 of f, n, and v is an industrial park in Zibo city (117°725' E-117°845' E, 36°880' N-
363 36°940' N). The center and upper right area of g, o, and w is an overpass and Wanling
364 mountain in Jinan city (116°977' E-117°009' E, 36°590' N-36°606' N). The center area
365 of h, p, and x is another overpass in Jinan city (116°970' E-117°030' E, 36°580' N-
366 36°610' N).

367 **3.2 Urban-nonurban Difference**

368 Full-coverage pollutant estimates provide a foundational basis for assessing urban-
369 nonurban disparities, addressing the critical issue of imbalanced site numbers between
370 urban and rural locations. Table S4 shows the concentrations of O₃, NO₂, PM_{2.5}, and
371 HCHO over the urban and nonurban regions, delineated from an annual urban extent
372 dataset (Zhao et al., 2022). The urban extents in Shandong Province in 2019 are
373 depicted in Fig. S11. From 2019 to 2020, surface air pollutant levels declined
374 significantly in Shandong. The averaged concentration discrepancies of these pollutants
375 between urban and nonurban over February to March (lockdown during COVID-19)
376 and June to October (summertime) are shown in Fig. 5. Surface concentrations of NO₂
377 and HCHO are higher in urban than nonurban areas, and the differences narrowed from
378 February to October, while PM_{2.5} is the opposite at both. Ground-level O₃ levels
379 exhibited unexpected urban-nonurban disparity variations, from the lockdown period
380 through the summer, as well as from 2019 to 2020. Compared to nonurban areas, the
381 urban areas, which previously had lower O₃ levels, began to experience higher

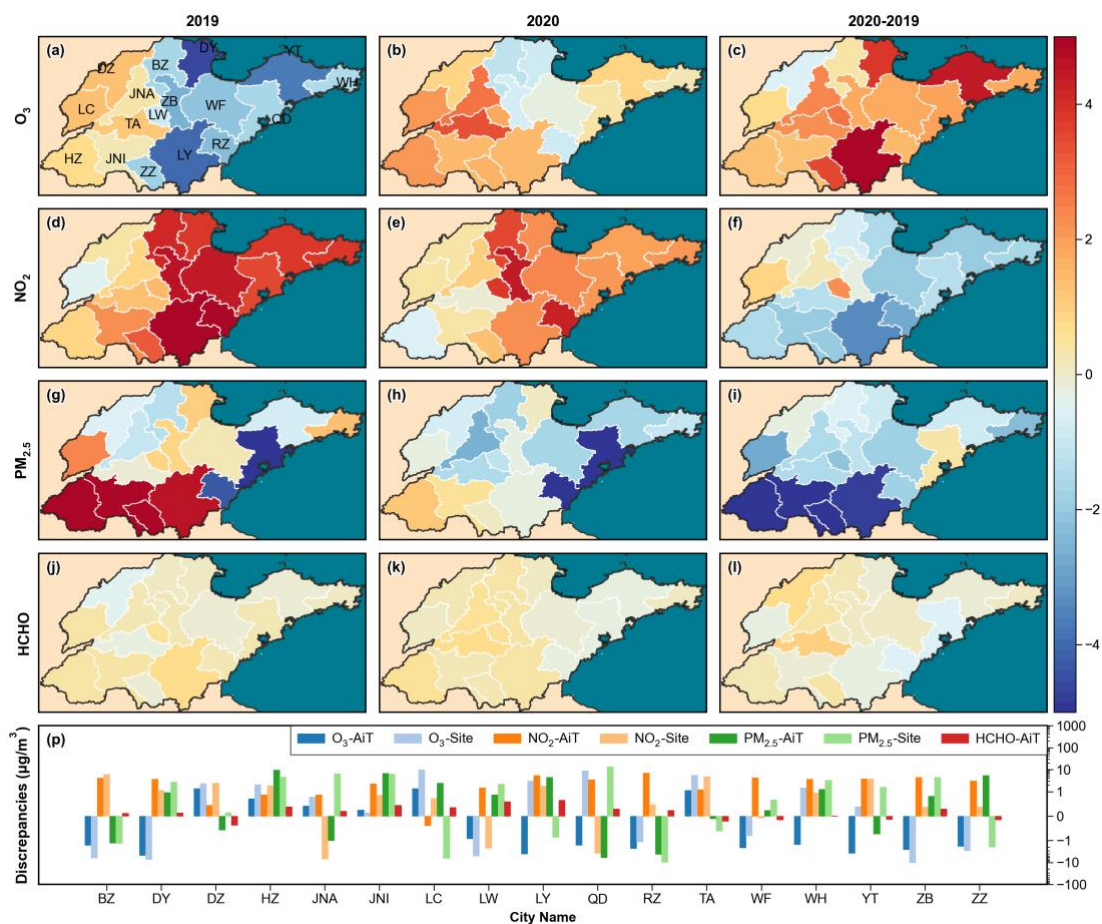

382 concentrations, attributed to a more rapid decline of ozone in nonurban regions. Figure
383 6 revealed that urban-nonurban differences in O₃ and PM_{2.5} varied across various cities
384 during the lockdown period in 2019, while the higher NO₂ pollution in urban areas
385 remained consistent. In summer, only a handful of urban areas exhibit lower levels of
386 ozone concentration, where NO₂ and PM_{2.5} levels surpass those in nonurban regions,
387 attributable to a more pronounced titration effect of NO and a slower rate of
388 photochemistry reactions (Fig. S12) (Sicard et al., 2016, 2020; Zhang et al., 2004).
389 Comparative urban-nonurban differences from 2019 to 2020 indicate an accelerated
390 reduction of ozone and HCHO in non-urban areas, while NO₂ and PM_{2.5} levels in urban
391 have seen a more significant decrease due to the decline in anthropogenic activities,
392 particularly the suspension of emissions from pollution sources located in urban areas.
393 Upon comparing the results of urban-nonurban disparities of our data with monitoring
394 data and the CHAP dataset, we have identified potential overestimations or
395 underestimations across various cities in monitoring data, likely resulting from the
396 limited number of non-urban sites (Figs. 6p and S13). The notable disparity between
397 the number of urban and non-urban sites in cities such as JNA, LC, LY, QD, and YT
398 results in a pattern of urban-nonurban differences that contrasts markedly with the
399 observed in AiT (Table S5). The urban-nonurban difference calculated by the CHAP
400 generally aligns with our findings (Fig. S14). Nevertheless, it is worth noting that the
401 coarse resolution of O₃ (10 km) has led to a significant overestimation. These results
402 highlight the invaluable of high-resolution and gapless data for studying urban-

403 nonurban disparities.

404

405 **Figure 5.** The discrepancies of O_3 , NO_2 , and $\text{PM}_{2.5}$ between urban and non-urban from
406 2019 to 2020 for the lockdown period (a) and summertime (b) averaged concentration.

407

408 **Figure 6.** The urban-nonurban disparities of O_3 , NO_2 , $\text{PM}_{2.5}$, and HCHO calculated by
409 AiT across cities with administrative divisions in Shandong, China during lockdown
410 periods in 2019 (a, d, g, j) and 2020 (b, e, h, k), and the changes of differences between
411 2019 and 2020 (c, f, i, l). P is the comparison between the results of monitoring station
412 data and the AiT dataset in 2019. The red color represents a greater decline in air

413 pollutants in nonurban areas, while the blue color indicates a more significant reduction
414 in urban areas in the third column of the figure. (YT: Yantai, BZ: Binzhou, DY:

418 **3.3 Photochemical Regimes**

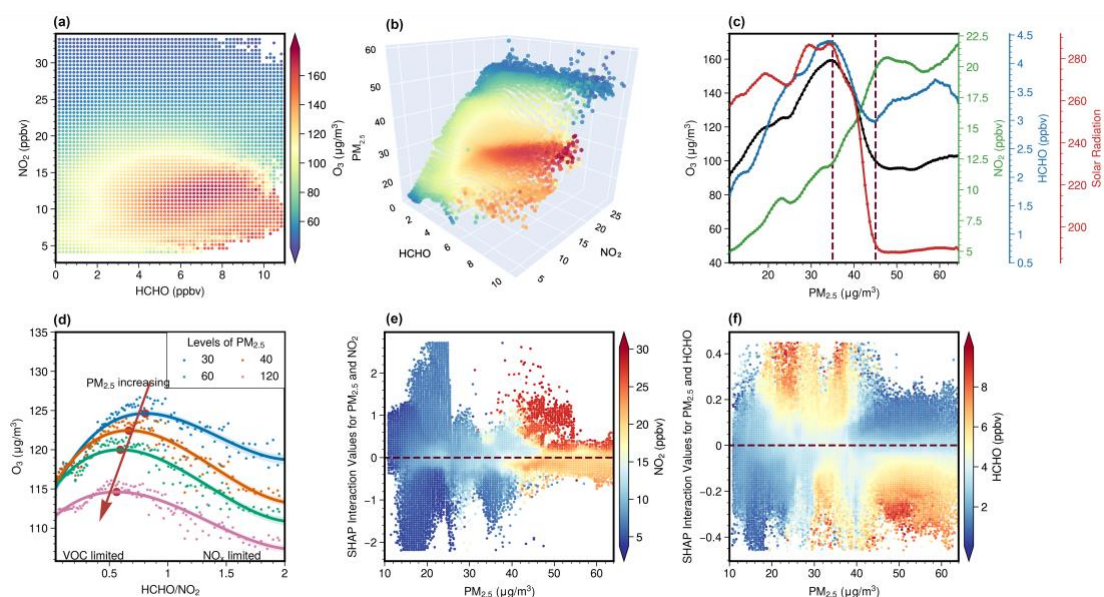

419 **3.3.1 Ozone-NO_x-VOCs-Aerosols Sensitivity**

420 Figure S15 shows the seasonal maps of O₃, PM_{2.5}, and NO₂ estimations from AiT,
421 and satellite-derived surface HCHO. Based on these data, we first capture the well-
422 established non-linearities in O₃-VOC-NO_x chemistry by a conceptual framework
423 similar to classic O₃ isopleths typically generated with models (Pusede et al., 2015; Ren
424 et al., 2022a). Figure 7a depicts O₃ concentration as a function of HCHO and NO₂,
425 which was derived solely from ground-level estimation. The result indicates that the O₃
426 regimes can be qualitatively identified based on the nonlinear interaction between
427 surface O₃, HCHO, and NO₂. In the regime characterized by high NO₂ and low HCHO,
428 the elevated consumption of HO_x, predominantly driven by the OH + NO₂ termination
429 reaction, results in the suppression of NO_x on O₃, indicating the prevalence of VOC-
430 limited chemistry. Conversely, when HCHO levels are high and NO₂ levels are
431 relatively low, O₃ increases with NO₂ and exhibits insensitivity to HCHO due to
432 abundant peroxy radicals (HO₂ + organic peroxy (RO₂) radicals, RO_x) self-reactions,
433 suggesting NO_x-limited (VOC-saturated) chemistry. In cases where high HCHO and
434 NO₂, the O₃ increases with both HCHO and NO₂, reaching a peak. While Fig. 7a
435 resembles this overall O₃-VOC-NO_x, the blurry transition between two different

436 regimes and the role of PM_{2.5} is uncertain which may be influenced by meteorological
437 conditions, chemical and depositional loss of O₃, errors of estimations, and “aerosol-
438 inhibited”. Increasing PM_{2.5} levels could suppress O₃ formation even under high HCHO
439 and NO₂ conditions (Fig. 7b), which could be induced by enhanced reactive uptake of
440 HO₂ onto aerosol particles and weaker photochemical reaction resulting from the
441 scattering and absorption of solar radiation by anthropogenic aerosols. The relationship
442 between PM_{2.5} and O₃ in Shandong demonstrates the distinct stages of O₃ chemistry, as
443 depicted in Fig. 7c. When PM_{2.5} was below the maximum turning point (MTP1, 35
444 μg/m³), a linear and positive correlation between O₃ and PM_{2.5} was observed due to the
445 common dependence on precursors in the initial stage (Zhang et al., 2022). As PM_{2.5}
446 increased beyond the MTP1, a sharp reduction in HCHO and O₃ was observed,
447 accompanied by a decline in surface short-wave radiation, reflecting their formation as
448 photo-oxidation products of OVOCs and NO_x. When PM_{2.5} exceeded the minimum
449 transition point (MTP2, 45 μg/m³), a phase was observed with stagnant radiation
450 intensity and relatively higher NO₂ levels compared to HCHO. This regime is typically
451 associated with a VOC-limited regime, where an increase in HCHO and a decrease in
452 NO₂ concentration could promote O₃ production. However, our findings demonstrated
453 an opposite impact of HCHO and NO₂ on O₃ when PM_{2.5} exceeded MTP2. Figure 7d
454 shows the changes in the quantitative relationships between HCHO/NO₂ (FNR) and O₃
455 by artificially changing PM_{2.5} and precursors levels for XGBoost, in which the peak of
456 curves marks the transitional threshold of O₃ regimes from VOC to NO_x sensitive. It

457 can be seen that attenuated PM_{2.5} pollution could increase the sensitivity of O₃ to VOCs
458 and decrease the sensitivity to NO_x, which causes the shift in O₃ regimes from NO_x-
459 limited to VOC-limited. With the recent reduction in NO_x emissions in China, the
460 anticipated transition of the O₃ production regime in urban areas towards being more
461 NO_x-limited has been impeded by the heightened VOC sensitivity resulting from
462 decreased PM_{2.5} levels. Our results are consistent with the findings of Li et al. regarding
463 O_x-NO_x relationship in response to changing PM_{2.5} (Li et al., 2022a), and with the
464 findings of Dyson et al. on the impact of HO₂ aerosol uptake on O₃ production (Dyson
465 et al., 2023). The SHAP interaction plots in Fig. 7e and f illustrate that the influence of
466 NO₂ and HCHO on O₃ formation is not constant and is influenced by the levels of PM_{2.5}.
467 Typically, at a certain level of PM_{2.5}, a lower NO concentration results in a stronger
468 inhibitory effect on O₃ production. This could be due to aerosols exerting stronger
469 suppression through the HO₂ sink at lower NO_x levels. As the concentration of PM_{2.5}
470 increases, often accompanied by a concurrent increase in NO₂ as a key precursor, there
471 is a greater need for higher levels of NO₂ to be converted into nitrous acid (HONO)
472 through the heterogeneous uptake by aerosols. This process produces more OH radicals,
473 which facilitate photochemical O₃ formation, thereby offsetting the increased inhibitory
474 effect of the HO₂ sink. Under high PM_{2.5} concentrations, an increase in NO₂ along with
475 a decrease in HCHO enhances their effect on promoting O₃ formation. This
476 enhancement could be caused by increased titration of O₃ by NO, resulting from weaker
477 conversion of NO to NO_x through the RO_x radical. Meanwhile, the impact of HCHO

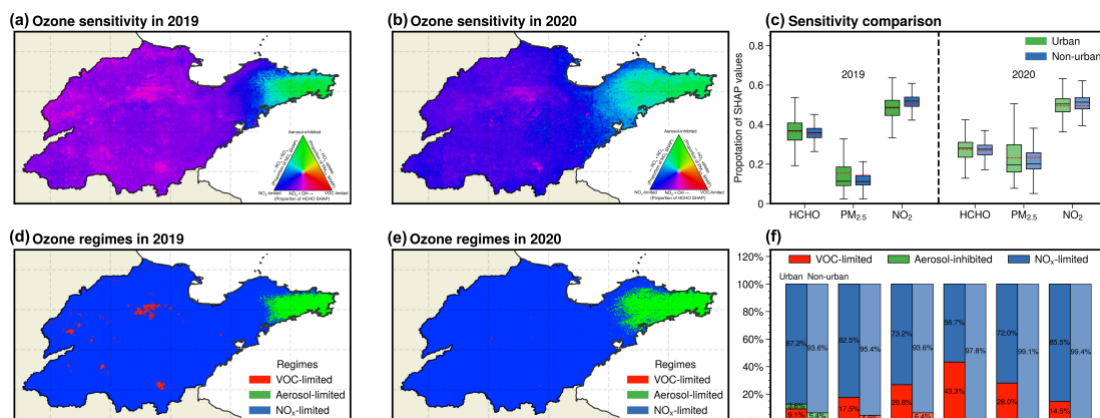

478 shifts from promoting to suppressing as PM_{2.5} pollution intensifies. It further illustrates
 479 that the scavenging of HO₂ on aerosols can cause the shift in O₃ regimes from being
 480 VOC-limited to NO_x-limited and the threshold approach is restricted by aerosols and
 481 meteorology for determining the constantly changing O₃ formation regimes over time
 482 and space.

483
 484 **Figure 7.** (a) O₃ concentrations as a function of surface HCHO and NO₂. (b) O₃
 485 concentrations as a function of surface HCHO, NO₂, and PM_{2.5}. Both A and B utilize a
 486 shared color bar to indicate O₃ concentrations, enhancing comparability. (c)
 487 Relationship between O₃, and NO₂, HCHO, and surface short-wave radiation flux. The
 488 paired O₃, HCHO, NO₂, and solar radiation are divided into 100 bins based on PM_{2.5}
 489 and then the averaged concentrations (y-axis) are calculated for each PM_{2.5} bin (x-axis).
 490 (d) Changes in HCHO/NO₂-O₃ relationship in response to changing PM_{2.5} by XGBoost
 491 model. The solid lines are fitted with four-order polynomial curves, and the shading
 492 indicates 95% confidence intervals. (e-f) The interaction SHAP values reveal an
 493 interesting hidden relationship between pairwise variables (PM_{2.5} and NO₂, HCHO) and
 494 O₃.

495 Unraveling the intricate interplay of O₃ with meteorology, aerosols, and precursors
 496 that govern O₃ formation over extensive spatial domains has long confounded robust
 497 interpretation. These multiscale processes were elucidated using an interpretable ML

498 model, which can quantify the positive or negative contributions of individual processes.
499 As depicted in Fig. S16, the performance of the XGBoost model is robust, evidenced
500 by a high R^2 value of 0.99 coupled with a low RMSE of $3.24 \mu\text{g}/\text{m}^3$ and MAE of 2.33
501 $\mu\text{g}/\text{m}^3$. Figure S17 elucidates that meteorological variations, chiefly surface short-wave
502 radiation flux modulating photochemical reaction kinetics, primarily dictate the
503 heterogeneous geographic distribution of O_3 at the regional scale, with lower levels
504 over the Jiaodong Peninsula. Meanwhile, local atmospheric chemical processes
505 predominate the city-scale variability of O_3 . HCHO facilitated O_3 formation in urban
506 areas yet suppressed it in rural regions across areas with high ozone, where most NO_2
507 promoted O_3 production overall, indicating VOC- NO_x synergistic control on O_3 in cities
508 and a NO_x -limited regime in rural areas during summertime. The contribution of NO_2
509 and $\text{PM}_{2.5}$ exhibits analogous seasonal variability, promoting O_3 formation under low
510 pollution conditions while inhibiting O_3 when pollution levels are high (Figs. S15 and
511 18). The elevated NO_2 levels in autumn led to a negative contribution to O_3 , whereas
512 the facilitating effect of $\text{PM}_{2.5}$ was enhanced. This stems from the relatively moderate
513 $\text{PM}_{2.5}$ concentrations slightly affecting photochemical reaction rates, while the
514 increased NO_2 amplified the reactive uptake of NO_2 by $\text{PM}_{2.5}$, generating more OH
515 radicals that promote O_3 formation (Lin et al., 2023; Tan et al., 2022). In winter, $\text{PM}_{2.5}$
516 pollution exceeding $75 \mu\text{g}/\text{m}^3$ suppressed O_3 formation through scattering and
517 absorbing solar radiation that activates atmospheric chemical processes, which
518 counteracted the promoting effect of high $\text{PM}_{2.5}$ through the conversion of NO_2 to

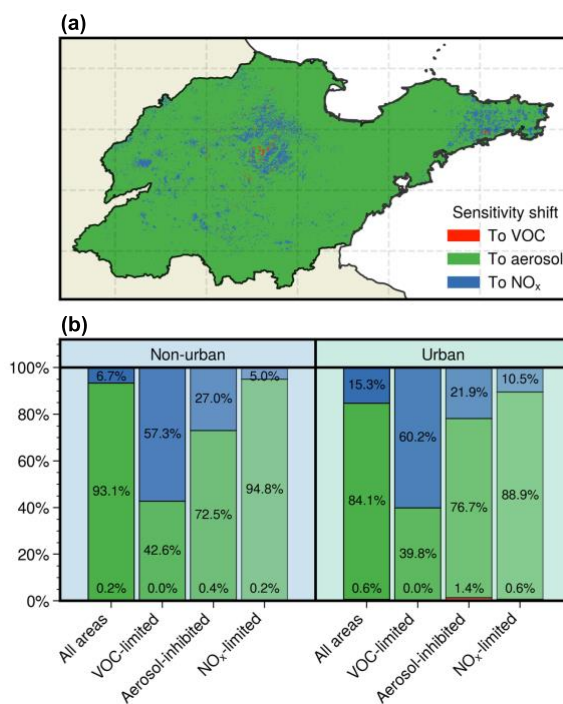

520

521 **Figure 8.** Comparison of geographical distribution for ozone formation regimes
 522 between 2019 and 2020 in the summertime. All surface daily O₃, PM_{2.5}, and NO₂
 523 estimations from Air Transformer (AiT) are averaged over each month from May to
 524 October 2019-2020 for matching monthly HCHO derived from TROPOMI (500 * 500
 525 m). (a, b) Geographical distribution of fractional contribution of chemical factors
 526 representing O₃ formation regimes. The ternary phase diagram in the legend depicts the
 527 normalized fraction of SHAP values for O₃ attributed to HCHO, NO₂, and PM_{2.5} at the
 528 surface, representing VOC-limited (red), aerosol-inhibited (green), and NO_x-limited
 529 (blue) regimes, respectively. (c) Statistical Changes in the fractional contribution of
 530 chemical factors. (d, e) Geographical distribution of O₃ chemical regimes. (f)
 531 Proportion of three O₃ chemical regimes across urban and nonurban areas in 2019 in
 532 Shandong (SD), and individual cities (BZ: Binzhou, ZB: Zibo, LC: Liaocheng, LY:
 533 Linyi, JNI: Jining).

534 Figure 8a-c shows surface distribution and changes of the relative proportions of
 535 SHAP values on three pollutants for inferring O₃ photochemical regimes. Moving along
 536 an urban-to-rural gradient, reactions dominated by RO_x radical self-reactions are
 537 continuously enhanced with increasing NO_x SHAP values, resulting in the majority of
 538 rural Shandong being situated in NO_x-limited regimes. Furthermore, the overall ozone
 539 production regimes in Shandong exhibited a transition toward more NO_x-limited from
 540 2019 to 2020, with regions dominated by NO_x-limited shifting toward being aerosol-

541 inhibited in the Jiaodong Peninsula. The aerosol-inhibited regime differs from either of
542 the two classically applied tropospheric O₃ policy-control regimes. It is attributed to the
543 predominant heterogeneous HO₂ uptake by aqueous aerosols, despite comparatively
544 low PM_{2.5} levels during summertime. The marine environment engenders liquid aerosol
545 particles with HO₂ uptake coefficients exceeding those of dry aerosols by orders of
546 magnitude (Song et al., 2022a). Concurrently, lower ambient NO_x levels minimize the
547 promotive effects of aerosols on ozone formation (Tan et al., 2022; Kohno et al., 2022).
548 This result is consistent with the findings of Dyson et al. (Dyson et al., 2023), which
549 concluded that the contribution of HO₂ sinks onto aerosols on total HO₂ could increase
550 for areas with low NO levels. The attenuated responsiveness of O₃ formation to VOCs
551 induced by the uptake of HO₂ results in enhanced sensitivity of NO_x at the northwest
552 boundary region of the Jiaodong Peninsula. Collectively, these processes delineate an
553 aerosol-inhibited ozone production regime in this coastal region, reflecting the
554 sensitivity of O₃ photochemistry to the HO₂ sink. In several cities, including Binzhou,
555 Zibo, Liaocheng, Linyi, and Jining, a greater proportion of urban areas, as compared to
556 their nonurban counterparts, exhibited a VOC-limited regime in 2019, as indicated by
557 the prevalence of red regions in Fig. 8d. The percentage of urban areas in these cities
558 under a VOC-limited regime ranges from 15% to 43%, in stark contrast to non-urban
559 areas where such a regime is typically rare (Fig. 8f). The comparison of O₃ sensitivities
560 from 2019 to 2020 shows a regional shift towards increased sensitivity to aerosol and
561 NO_x, along with a decreased VOC sensitivity as a result of NO_x reduction (Fig. 8a-c).

562 This shift has led to the majority of areas in Shandong being dominated by a NO_x-
 563 limited regime in 2020, with an expanded aerosol-inhibited regime region in the
 564 Jiaodong Peninsula (Fig. 8e). Additionally, the discrepancy in O₃ formation sensitivity
 565 between urban and non-urban areas has been diminishing during this period (Fig. 8c).
 566 As illustrated in Fig. 9, while the ozone regime transitions towards NO_x-limited, there
 567 is a marked shift towards greater aerosol sensitivity across nearly 90% of areas, leading
 568 to a 1.6% increase in aerosol-inhibited grids. Compared to nonurban regions, a higher
 569 number of grids in urban areas demonstrate a shift towards NO_x sensitivity. Conversely,
 570 urban areas that were predominantly aerosol-inhibited in 2019 showed a lower
 571 sensitivity shift towards NO_x.

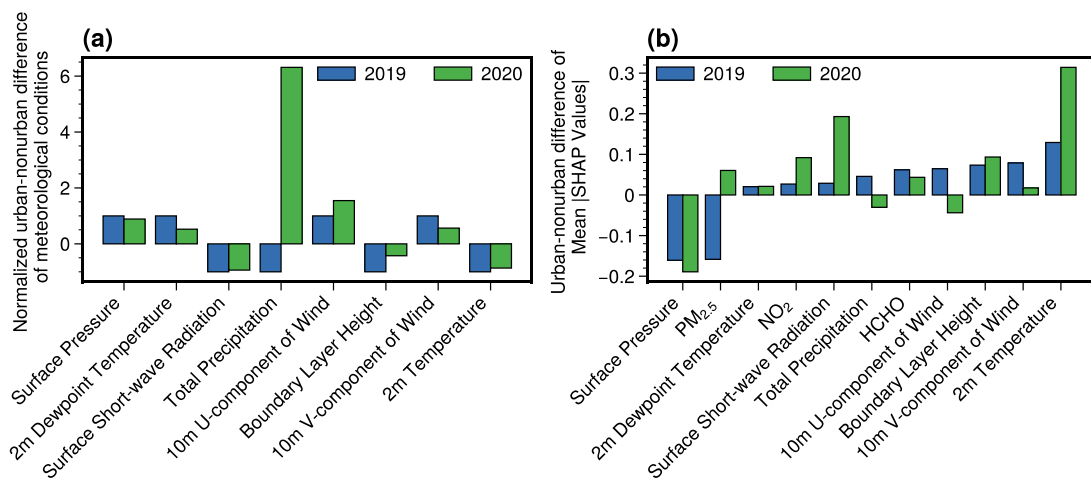

572
 573 **Figure 9.** Geographical distribution of changes in ozone sensitivity from 2019 to 2020
 574 in summertime (a). Comparison of ozone sensitivity changes across areas dominated
 575 by different chemical regimes in 2019 between urban and non-urban areas (b).

576 3.3.2 Impact on Urban-nonurban Differences

577 We further explore the reversed O₃ differences by separating the individual
578 contributions of climate and anthropogenic changes using an interpretable machine
579 learning model (Fig. 10). The results demonstrate that atmospheric chemical processes
580 and meteorological conditions commonly dominate the discrepancies in O₃ levels
581 between urban and non-urban areas. From 2019 to 2020, meteorological shifts remained
582 uniform across urban and non-urban regions, marked by lowered surface pressure,
583 boundary layer height, and short-wave radiation, alongside heightened precipitation.
584 This, coupled with decreased precursor levels, contributed to a decline in O₃ pollution.
585 As shown in Fig. 10 and S19, the diminished reduction in boundary layer height and
586 radiation flux across urban areas, compared to nonurban areas in 2020, decelerated the
587 expected decline of O₃ concentrations, leading to urban O₃ levels exceeding those of
588 nonurban areas. Concurrently, a narrowing difference in temperatures between urban
589 and nonurban areas, despite an overall cooling from 2019 to 2020, favored O₃ formation
590 in urban regions during the summertime. Additionally, PM_{2.5} emerged as the principal
591 anthropogenic factor inverting the urban-nonurban O₃ disparity over the course of 2019
592 to 2020. Its contribution to ozone shifted from being lower in urban areas to exceeding
593 that in nonurban areas, revealing that the decreased reactive uptake of HO₂ from
594 aerosols induced by a more substantial reduction in PM_{2.5} in urban areas made the larger
595 contribution to O₃ production (Ivatt et al., 2022; Li et al., 2017). Moreover, the response
596 of O₃ to the changes in its precursors and PM_{2.5} was determined by the O₃ formation

597 regimes. The variations in O₃ sensitivity also corroborate the above finding. In rural
 598 areas, where there was a lesser reduction in PM_{2.5} concentration, the sensitivity
 599 increasingly favored aerosol suppression across more than 93% of the assessed grids
 600 (Fig. 9). This enhanced suppression effect of aerosols in rural areas leads to a more
 601 significant O₃ reduction compared to urban locales. The reduction of NO_x in nonurban
 602 areas demonstrated a more effective reduction in O₃ levels, which predominantly
 603 shifted towards a NO_x-limited regime in 2020. Although urban areas also showed a shift
 604 towards being a NO_x-limited regime, they exhibited relatively higher sensitivity to
 605 VOCs (Fig. 8). The urban areas, characterized by elevated NO_x emissions, exhibited a
 606 higher sensitivity to VOCs, and the fraction of aerosol-inhibited areas increased from
 607 2019 to 2020, resulting in the control benefits of urban O₃ pollution in 2020 are partially
 608 offset by the nonlinear response of O₃ to a greater reduction in NO₂ and PM_{2.5}, and a
 609 smaller decrease in HCHO relative to nonurban areas. Consequently, O₃ exhibits a
 610 lower reduction in urban areas as a result of the aforementioned changes.

611
 612 **Figure 10.** Comparison of urban-nonurban disparities in meteorological conditions (a),

613 and mean absolute SHAP values (b) between 2019 and 2020 across Shandong, China
614 during the summertime.

615 **4. CONCLUSIONS**

616 The purpose of the current study was to diagnose the non-linearity of O₃-NO_x-
617 VOCs-aerosols chemistry using an interpretable ML model based on spatially resolved
618 multi-pollutant estimations for determining the causes of changing differences in O₃
619 levels between urban and non-urban areas. Our study represents the first attempt to
620 develop an advanced DL model that reconstructs the concentrations of multiple
621 pollutants and subsequently infers the aerosol-inhibited regime from observations. This
622 innovative approach provides further support for investigating the impact of precursor
623 emissions and aerosol on the urban-nonurban differences in O₃ levels.

624 Given the non-linearity of ozone formation and its increasing regional differences,
625 precise estimations of ground-level O₃, NO₂, HCHO, and PM_{2.5} are crucial for deducing
626 the chemical regimes governing ozone pollution and its urban-nonurban disparities. The
627 evaluation of the model's performance indicates that it can be readily extended to any
628 other domain thanks to its unified architecture. Anyone can easily utilize the model to
629 estimate ground-level pollutants, intelligently considering spatial-temporal
630 neighborhood information based on their customized input data. The model further
631 improved spatial resolution to sub-km levels using TROPOMI and MODIS retrievals
632 via spatiotemporal autocorrelation downscaling of AiT. The "black box" nature of AiT
633 can be made more physically interpretable by SHAP, enabling the evaluation of the
634 significance of each input variable (Fig. S20). The season trends show the highest

635 contribution, followed by emission proxies and meteorological conditions. Meanwhile,
636 the results between AiT trained with all data and that trained exclusively with CNEMC
637 data across various spatiotemporal scales underscore the promising prospect for
638 improving the model's generalization ability with more ground-level monitoring data
639 and the growing space of methods.

640 We conclude that with the effective reduction of PM_{2.5} pollution, the sensitivity of
641 O₃ to VOCs will increase, necessitating further intensification of VOC emissions
642 regulation by government agencies. Three distinct chemical regimes were assessed by
643 tracking NO_x, VOCs, and aerosols with surface NO₂, HCHO, and PM_{2.5}. In the
644 Jiaodong Peninsula of Shandong Province, coastal areas with relatively few primary
645 pollutants are widely found to be under an aerosol suppression regime, illustrating that
646 ozone regime inference based on machine learning can serve as an alternative to
647 determining the aerosol suppression regime through the rate of radical termination in
648 atmospheric chemical models. The O₃ regime in other areas of Shandong generally
649 transited from the NO_x-sensitive regime in nonurban to a more VOC-sensitive regime
650 in urban areas. We estimate that substantial reductions in anthropogenic emissions of
651 PM_{2.5} and NO₂ are the main drivers of the reversal of the traditional discrepancy in O₃
652 levels between urban and non-urban areas. In essence, due to the lower efforts in
653 reducing PM_{2.5} in nonurban settings, the aerosol-mediated suppression of ozone
654 became more pronounced, resulting in lower ozone levels in rural areas relative to urban
655 centers. This shift underlines the intricate balance between emission reduction and

656 ozone formation mechanisms, suggesting that nuanced understanding and targeted
657 interventions are necessary to manage and mitigate the health and environmental
658 impacts of such disparities. To preclude exacerbated O₃ pollution resulting from the
659 shift of many regions from VOC-limited to NO_x-limited regimes and the decline in
660 heterogeneous HO₂ uptake induced by PM_{2.5} reduction in urban areas, emission policies
661 aimed at decreasing NO_x to reduce O₃ levels will only be effective with stringent VOC
662 emission abatement when PM_{2.5} is concurrently decreased. The integration of high-
663 resolution pollutant estimations with an interpretable machine learning model offers a
664 promising avenue for advancing our understanding of ozone pollution dynamics and
665 developing effective air quality management strategies.

666 Although our study endeavors to establish O₃ formation regimes involving NO_x,
667 VOCs, and aerosols, and the method identifies an aerosol-inhibited regime from a
668 statistical perspective, it is subject to certain uncertainties due to the relatively poor data
669 quality of HCHO and the unsegregated multiple impacts of aerosols, such as N₂O₅
670 uptake, NO₂ uptake, HO₂ uptake, and light extinction (Tan et al., 2022). We have made
671 efforts to integrate all required surface pollutant concentrations into a unified model,
672 while the absence of ground-level HCHO monitoring data compelled us to tap into an
673 alternative methodology. The retrieval error of surface HCHO and the system error
674 between its retrieval approach and the AiT model degrade the ability of ML to identify
675 the O₃ sensitivity. Meanwhile, the notion of ozone regimes is only appreciated in
676 photochemically active environments where the RO_x-HO_x cycle is active (Souri et al.,

677 2023). The definition of NO_x-limited or VOC-limited regimes is meaningless in
678 nighttime chemistry, where NO-O₃-NO₂ partitioning is the primary driver. The surface
679 daytime pollutant estimations with finer resolutions in space and time based on a unified
680 modeling framework will offer an unprecedented view to characterize the near-surface
681 O₃ formation regimes. Notwithstanding the relatively limited duration of the study, this
682 work offers valuable insights into the current state and causes of urban-nonurban
683 disparities in O₃ pollution. Future efforts should conduct a more detailed long-term
684 evaluation of urban-nonurban disparities in global O₃ levels and the impact of formation
685 mechanisms to further our understanding of air pollution and its mitigation.

686 **Competing Interests**

687 The authors declare that they have no conflict of interest.

688 **Acknowledgments**

689 The work was financially supported by the National Natural Science Foundation
690 of China (project No. 22236004) and Taishan Scholars (No. ts201712003).

691 **Code and Data Availability**

692 The Air Transformer deep learning framework is available on GitHub
693 (<https://github.com/myles-tcl/Air-Transformer>), which provides the scripts for
694 spatiotemporal data extraction, normalization, model training, and estimating of multi-
695 pollutants. The sources of input data in the Air Transformer can be found in Table S1.
696 The estimation of the Air Transformer can be downloaded from Zenodo:
697 <https://zenodo.org/records/10071408> (Tao, 2023).
