15 from nitrate

## Abstract

Nitrous oxide (N<sub>2</sub>O) is a potent greenhouse gas and ozone depletion agent, with a significant natural source from marine oxygen deficient zones (ODZs). Open questions remain, however, about the microbial processes responsible for this N<sub>2</sub>O production, especially hybrid N<sub>2</sub>O production when ammonia-oxidizing archaea are present. Using <sup>15</sup>N-labeled tracer  
20 incubations, we measured the rates of N<sub>2</sub>O production from ammonium (NH<sub>4</sub><sup>+</sup>), nitrite (NO<sub>2</sub><sup>-</sup>), and nitrate (NO<sub>3</sub><sup>-</sup>) in the Eastern Tropical North Pacific ODZ, as well as the isotopic labeling of the central (α) and terminal (β) nitrogen atoms of the N<sub>2</sub>O molecule. We observed production of both doubly- and singly labeled N<sub>2</sub>O from each tracer, with the highest rates of labeled N<sub>2</sub>O production at the same depths as the near surface N<sub>2</sub>O concentration maximum. At most stations and depths, the production of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> were statistically indistinguishable, but at a few depths, there were significant differences in  
25 the labeling of the two nitrogen atoms in the N<sub>2</sub>O molecule. Implementing the rates of labeled N<sub>2</sub>O production in a time-dependent numerical model, we found that N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> dominated at most stations and depths, with rates as high as 1600±200 pM N<sub>2</sub>O/day. Hybrid N<sub>2</sub>O production, one of the mechanisms by which ammonia-oxidizing archaea produce N<sub>2</sub>O, had rates as high as 230±80 pM N<sub>2</sub>O/day that peaked in both the near surface and deep N<sub>2</sub>O concentration maxima. Based on the equal production of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> in the majority of our experiments, we infer that hybrid N<sub>2</sub>O production  
30 likely has a consistent site preference, despite drawing from two distinct substrate pools. We also found that the rates and yields of hybrid N<sub>2</sub>O production were enhanced at low dissolved oxygen concentrations ([O<sub>2</sub>]), with hybrid N<sub>2</sub>O yields as high

as 20% at depths where  $[O_2]$  was below detection (880 nM) but nitrification was still active. Finally, we identified a few incubations with  $[O_2]$  up to 20  $\mu M$  where  $N_2O$  production from  $NO_3^-$  was still active. A relatively high  $O_2$  tolerance for  $N_2O$  production via denitrification has implications for the feedbacks between marine deoxygenation and greenhouse gas cycling.

## 35 1. Introduction

Nitrous oxide ( $N_2O$ ) is one of the lesser-known greenhouse gases, yet its potential to warm the environment, on a per-molecule basis, is immense.  $N_2O$  has a global warming potential 273 times that of carbon dioxide (Smith et al., 2021), and its atmospheric mixing ratio is increasing at a rate of  $0.85 \pm 0.03$  ppb/year (Tian et al., 2020). In the ocean, hotspots of  $N_2O$  production and flux to the atmosphere occur in marine oxygen deficient zones (ODZs), where steep redox gradients allow for multiple  $N_2O$  production processes to overlap (Codispoti and Christensen, 1985). ODZs have expanded over the last 60 years (Breitburg et al., 2018; Stramma et al., 2008) and will likely continue to do so as the oceans warm (Oschlies et al., 2018), although fate of the anoxic cores of ODZs ( $[O_2] \leq 20 \mu mol/kg$ ) remains uncertain (Bianchi et al., 2018; Busecke et al., 2022; Cabré et al., 2015). Without a clear picture of  $N_2O$  cycling in these regions, it is impossible to predict how climate change will impact the marine emissions of this powerful greenhouse gas.

45

Much of the  $N_2O$  cycling in ODZs is linked to denitrification. In low-oxygen waters, denitrifying organisms produce  $N_2O$  as an intermediate during organic matter remineralization (Dalsgaard et al., 2014; Naqvi et al., 2000; Zumft, 1997). Both direct rate measurements (Frey et al., 2020; Ji et al., 2015, 2018) and natural abundance isotope measurements (Casciotti et al., 2018; Kelly et al., 2021; Monreal et al., 2022; Toyoda et al., 2023) indicate that  $N_2O$  production directly from nitrate ( $NO_3^-$ ), i.e., without exchange with extracellular nitrite ( $NO_2^-$ ) or nitric oxide (NO) pools, is the primary source of  $N_2O$  in ODZs.  $N_2O$  production from extracellular  $NO_2^-$ , meanwhile, tends to occur at lower rates (Frey et al., 2020; Ji et al., 2015, 2018). Historically,  $N_2O$  production from denitrification was thought to cease at dissolved oxygen concentrations above 2–3  $\mu M$  (Dalsgaard et al., 2014), but more recent data suggest that  $N_2O$  production from  $NO_3^-$  can occur at ambient oxygen levels as high as 30  $\mu M$  (Frey et al., 2020; Ji et al., 2018).  $N_2O$  consumption via denitrification is more sensitive to oxygen than  $N_2O$  production via denitrification, leading to an oxygen window in which denitrification is a source but not a sink of  $N_2O$  (Babbin et al., 2015; Dalsgaard et al., 2014; Farías et al., 2009; Frey et al., 2020), although the oxygen inhibition constant for  $N_2O$  consumption remains difficult to define (Sun et al., 2021a).  $N_2O$  may also be consumed through  $N_2O$  fixation, although the importance of  $N_2O$  fixation in the ocean has yet to be determined (Farías et al., 2013; Si et al., 2023).

60 Nonetheless, a significant fraction of the  $N_2O$  in the oxyclines above and below ODZs may be derived from archaeal nitrification. When  $NO_2^-$  is present, isotopic evidence continues to suggest that ammonia-oxidizing archaea can produce  $N_2O$  via a hybrid mechanism that combines nitrogen (N) derived from  $NO_2^-$  and ammonium ( $NH_4^+$ ) to form the  $N_2O$  molecule (Frame et al., 2017; Frey et al., 2020, 2023; Stieglmeier et al., 2014; Trimmer et al., 2016). New evidence indicates that

ammonia-oxidizing archaea can produce N<sub>2</sub>O both as a by-product of hydroxylamine oxidation and via hybrid N<sub>2</sub>O  
65 production, and that the ratio of these processes depends on the ratio of NH<sub>4</sub><sup>+</sup> to NO<sub>2</sub><sup>-</sup> available to the archaea (Wan et al.,  
2023b). The exact mechanism and enzymology of archaeal N<sub>2</sub>O production remains unknown (Carini et al., 2018; Stein, 2019),  
but may involve a reaction between hydroxylamine and NO, which occur as intermediates during archaeal ammonia oxidation  
(Kozłowski et al., 2016; Lancaster et al., 2018; Martens-Habbenha et al., 2015; Vajrala et al., 2013). In anaerobic conditions,  
70 ammonia-oxidizing archaea are also capable of NO dismutation to O<sub>2</sub> and N<sub>2</sub>, which may involve N<sub>2</sub>O as an intermediate  
(Kraft et al., 2022). Ammonia-oxidizing bacteria, more common in regions that are nutrient replete, produce N<sub>2</sub>O as a  
byproduct of hydroxylamine oxidation (Cohen and Gordon, 1979), and via nitrifier-denitrification as oxygen concentrations  
decline (Goreau et al., 1980; Stein and Yung, 2003; Wrage et al., 2001) and nitrite concentrations rise (Frame and Casciotti,  
2010).

75 The stable, natural abundance nitrogen and oxygen isotopes of N<sub>2</sub>O can provide quantification of – and distinction among –  
potential N<sub>2</sub>O cycling mechanisms (Kim and Craig, 1990; Rahn and Wahlen, 2000; Toyoda and Yoshida, 1999). For example,  
natural abundance N<sub>2</sub>O isotopocule studies have indicated that the high, near-surface N<sub>2</sub>O accumulations in the eastern tropical  
North Pacific (ETNP) ODZ are 80% derived from denitrification and 20% derived from nitrification (Kelly et al., 2021). The  
isotopic content of the individual N and oxygen (O) atoms in the N<sub>2</sub>O molecule are expressed in delta notation, defined as  
80  $\delta(^{15}\text{N})$  or  $\delta(^{18}\text{O}) = (\text{R}_{\text{sample}}/\text{R}_{\text{standard}} - 1)$ , where  $\text{R}_{\text{standard}}$  for  $\delta(^{15}\text{N})$  and  $\delta(^{18}\text{O})$  are the ratios <sup>15</sup>N/<sup>14</sup>N of air and <sup>18</sup>O/<sup>16</sup>O of Vienna  
Standard Mean Ocean Water (VSMOW), respectively (Kim and Craig, 1990; Rahn and Wahlen, 2000; Toyoda and Yoshida,  
1999). In addition to the bulk N and O isotope ratios in N<sub>2</sub>O, we can measure the isotopic content of the inner (α) N atom and  
an outer (β) N atom in N<sub>2</sub>O (Brenninkmeijer and Röckmann, 1999; Toyoda and Yoshida, 1999). The difference in the <sup>15</sup>N  
content of these two atoms is often referred to as the ‘site preference’ and is defined as  $\delta(^{15}\text{N}^{\text{sp}}) = \delta(^{15}\text{N}^{\alpha}) - \delta(^{15}\text{N}^{\beta})$ . In natural  
85 abundance studies,  $\delta(^{15}\text{N}^{\text{sp}})$  is particularly useful because it exhibits distinct values for different N<sub>2</sub>O production processes,  
independent of the isotopic value of the substrate (Frame and Casciotti, 2010; Sutka et al., 2003, 2004, 2006; Toyoda et al.,  
2002, 2005). This allows for partitioning between different N<sub>2</sub>O sources, and has been used extensively to quantify N<sub>2</sub>O cycling  
in the ocean (Bourbonnais et al., 2017, 2023; Casciotti et al., 2018; Farías et al., 2009; Kelly et al., 2021; Monreal et al., 2022;  
Popp et al., 2002; Toyoda et al., 2002, 2005, 2019, 2021, 2023; Westley et al., 2006; Yamagishi et al., 2007). As we elaborate  
90 upon in the discussion, however, the premise that  $\delta(^{15}\text{N}^{\text{sp}})$  exhibits a unique and consistent value depends on the assumption  
that both N atoms in N<sub>2</sub>O are derived from a singular substrate pool. Thus, hybrid N<sub>2</sub>O production may complicate traditional  
interpretations of natural abundance N<sub>2</sub>O isotopocules.

Previous studies have used <sup>15</sup>N tracer experiments to measure N<sub>2</sub>O production rates in ODZs (Frey et al., 2020, 2023; Ji et al.,  
95 2015, 2018). These studies used the accumulation of <sup>45</sup>N<sub>2</sub>O and <sup>46</sup>N<sub>2</sub>O resulting from the addition of <sup>15</sup>N-labeled substrates  
such as <sup>15</sup>N-NH<sub>4</sub><sup>+</sup> and <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> to measure N<sub>2</sub>O production rates. To our knowledge, the isotopomer measurement has never  
been applied to <sup>15</sup>N-tracer experiments to track <sup>15</sup>N from different substrates into the α and β positions of the N<sub>2</sub>O molecule.

Here, we present data showing the production of N<sub>2</sub>O isotopomers with <sup>15</sup>N in the α position (<sup>45</sup>N<sub>2</sub>O<sup>α</sup>) and <sup>15</sup>N in the β position (<sup>45</sup>N<sub>2</sub>O<sup>β</sup>) from <sup>15</sup>N-labeled NH<sub>4</sub><sup>+</sup>, NO<sub>2</sub><sup>-</sup>, and NO<sub>3</sub><sup>-</sup>. Measuring the production of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> creates an additional  
100 constraint on N<sub>2</sub>O production mechanisms and thus allows us to quantify different source process more precisely and accurately. We employed these measurements to (a) validate previous <sup>15</sup>N tracer studies of N<sub>2</sub>O production rates in the ETNP, (b) uncover that the hybrid pathway dominates production by nitrification, (c) establish the insignificance of production from solely NH<sub>4</sub><sup>+</sup> except the surface, and (d) infer a constant δ(<sup>15</sup>N<sup>sp</sup>) for hybrid N<sub>2</sub>O, despite drawing from two substrate pools. We  
105 also use these results to confirm inferences from natural abundance N<sub>2</sub>O isotopocules measured in the same system (Kelly et al., 2021).

## 2. Methods

### 2.1 Sampling sites

Experiments were performed at three stations in the eastern tropical North Pacific on the R/V *Sally Ride* in March–April 2018 (Fig. 1). Station PS1 (113° W, 10° N) was on the edge of the oxygen deficient region, station PS2 (105° W, 16° N) was near  
110 the geographic center of the ODZ, and station PS3 (102° W, 18° N) was 12 miles from the coast of Mexico (Fig. 1). Samples were collected from 30 L Niskin bottles mounted on a 12–place rosette with a conductivity–temperature–depth profiler and sensors for chlorophyll *a* fluorescence and dissolved O<sub>2</sub> (Sea–Bird SBE 43 oxygen sensor). The cruise took place during a weak La Niña event (Ocean Niño Index = -0.6°C; NOAA Climate Prediction Center).

115 Ambient [NO<sub>2</sub><sup>-</sup>] and [NH<sub>4</sub><sup>+</sup>] were measured shipboard with standard colorimetric (Grasshoff et al. 1999) and fluorometric methods (Grasshoff et al., 1999; Holmes et al., 1999), respectively. Ambient [NO<sub>3</sub><sup>-</sup>] was measured at Stanford University using a Westco SmartChem 200 Discrete Analyzer (detection limit = 83 nM, precision = 0.6 μM). Ambient [N<sub>2</sub>O] was measured via an isotope ratio mass spectrometer (IRMS) at the Stanford Stable Isotope Laboratory as part of a prior study (Kelly et al., 2021).

## Oxygen Saturation [%] @ Depth [m]=250

120

**Figure 1. Locations of the three stations sampled for this study. Stations are plotted on top of World Ocean Atlas oxygen saturation (%) at 250 m depth (World Ocean Atlas, 2013).**

### 2.2 Sample collection

Incubation depths were chosen to target prominent hydrographic features: the primary  $\text{NO}_2^-$  maximum, shallow and deep  
125 oxyclines, oxic–anoxic interfaces above and below the ODZ, secondary chlorophyll *a* maximum, and secondary  $\text{NO}_2^-$   
maximum (Table S1). Incubation samples were filled directly from Niskin bottles into 160 mL glass serum bottles (Wheaton)  
using Tygon tubing. Incubation bottles were overflowed three times before being capped and sealed bubble-free, with no  
headspace, using gray butyl rubber septa (National Scientific) and aluminum crimp seals. To minimize oxygen contamination  
during sampling, incubation bottles were overflowed in a secondary container filled with suboxic water from the same depth,  
130 and Niskin bottles were vented with carbon dioxide gas to displace the withdrawn water. The butyl rubber stoppers were  
deoxygenated in a He-flushed anaerobic chamber for ~1 week prior to sampling.

After sample collection, a 2 mL He headspace was created in each bottle by displacing 2 mL sample from the bottle with He.  
At most (all but two) anoxic depths at stations PS2 and PS3, samples were sparged with He gas for 90 minutes at a flow rate  
135 of at least 100 mL/min, equivalent to 56 volume exchanges, to remove potential oxygen contamination introduced during  
sampling. Depths with low but non-zero ambient dissolved oxygen were not purged with He gas. After sparging, 100  $\mu\text{L}$  of  
1030 ppm  $\text{N}_2\text{O}$  in He (4 nmol  $\text{N}_2\text{O}$ ) in gaseous form was introduced back into each bottle for a final concentration of 26 nM

to provide a constant background of N<sub>2</sub>O for later isotopic analysis (Fig. S4a). The isotopic content of this N<sub>2</sub>O carrier, measured independently via IRMS (Kelly et al., 2023; McIlvin and Casciotti, 2010), was  $\delta(^{15}\text{N}^{\alpha}) = -1.5 \pm 0.2 \text{ ‰}$ ,  $\delta(^{15}\text{N}^{\beta}) = 0.2 \pm 0.4 \text{ ‰}$ ,  $\delta(^{15}\text{N}^{\text{bulk}}) = -0.65 \pm 0.08 \text{ ‰}$ , and  $\delta(^{18}\text{O}) = 37.4 \pm 0.3 \text{ ‰}$ .

Time series were constructed by sacrificing triplicate bottles over a time course, rather than resampling the incubation bottles over time. A total of 27 incubation samples were thus produced at each experimental depth, comprised of triplicate samples for each of three time points and three tracers. For each station and depth, nine samples were amended with <sup>15</sup>NH<sub>4</sub>Cl (98.8 *atm%* <sup>15</sup>N, Sigma–Aldrich) to a final concentration of 0.501 μM and Na<sup>14</sup>NO<sub>2</sub> to a final concentration 1.01 μM. Nine samples were amended with Na<sup>15</sup>NO<sub>2</sub> (98.8 *atm%* <sup>15</sup>N, Sigma–Aldrich) to a final concentration of 5.00 μM and <sup>14</sup>NH<sub>4</sub>Cl to a final concentration of 0.510 μM. Finally, nine samples were amended with K<sup>15</sup>NO<sub>3</sub> (98.8 *atm%* <sup>15</sup>N, Sigma–Aldrich) to a final concentration of 1.00 μM, plus 1.01 μM Na<sup>14</sup>NO<sub>2</sub> and 0.510 μM <sup>14</sup>NH<sub>4</sub>Cl. Note that Na<sup>15</sup>NO<sub>2</sub> tracer was added at a higher concentration than the other tracers or the Na<sup>14</sup>NO<sub>2</sub> carrier; this discrepancy was due to a miscalculation that was caught midway through the cruise but the high tracer addition was retained for the sake of consistency. The NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> tracer and carrier additions were confirmed via [NO<sub>2</sub><sup>-</sup>] and [NH<sub>4</sub><sup>+</sup>] measurements of sample aliquoted from each bottle immediately before samples were measured for N<sub>2</sub>O isotopic content, using colorimetric and fluorometric techniques (Grasshoff et al., 1999; Holmes et al., 1999). The Na<sup>14</sup>NO<sub>2</sub> and <sup>14</sup>NH<sub>4</sub>Cl amendments served two purposes: 1) to provide enough total NO<sub>2</sub><sup>-</sup> for isotopic analysis of <sup>15</sup>NO<sub>2</sub><sup>-</sup> produced from <sup>15</sup>NH<sub>4</sub><sup>+</sup>, and 2) to minimize isotope dilution of the substrate pool, which can cause underestimation of rates with low substrate additions. The final *atm%* <sup>15</sup>N of the substrate pools were thus 56%–100% for <sup>15</sup>N–NH<sub>4</sub><sup>+</sup>, 65%–100% for <sup>15</sup>N–NO<sub>2</sub><sup>-</sup>, and 2%–92% for <sup>15</sup>N–NO<sub>3</sub><sup>-</sup> experiments. Three samples for each tracer were terminated immediately after tracer addition with the addition of 100 μL saturated mercuric chloride (HgCl<sub>2</sub>) solution. These also served as abiotic controls. The remaining samples were incubated at 12°C in the dark; three samples per tracer were terminated at 12 hours and at 24 hours with 100 μL saturated HgCl<sub>2</sub>. All samples were incubated at 12°C, which was chosen as an intermediate temperature that approximated subsurface conditions. After termination, samples were stored at room temperature (~20°C) in the dark until isotope analysis.

### 2.3 Chemiluminescent optode oxygen measurements

Eight 160 mL glass serum bottles were prepared with a chemiluminescent oxygen optode spot (PyroScience) affixed to the inner glass wall with silicone glue. These bottles were incubated alongside experimental bottles to monitor dissolved [O<sub>2</sub>] during incubations. At stations PS2 and PS3, two optode bottles per depth were filled, purged, amended with the N<sub>2</sub>O carrier, and incubated without the addition of tracer or HgCl<sub>2</sub>. At each timepoint, [O<sub>2</sub>] was measured in each sensor bottle for at least 10 minutes using fiber optic cables paired to the oxygen optode spot mounted inside the bottle (PyroScience). The fiber optic cables were calibrated with a 2–point measurement of: 1) a sodium sulfite solution (30 g/L in DI, or 0.24 M) and 2) surface seawater saturated with air at 12°C (270 μM [O<sub>2</sub>], based on a salinity = 35 psu and temperature = 12°C) (Garcia and Gordon, 1992). The two calibration bottles, each containing its own optode spot, were used to calibrate all four of the fiber optic cables,

effectively correcting them to the same scale. Differences in detection limit between sensor spots were accounted for by first performing this two–point calibration procedure to correct for differences between fiber optic cables, then measuring the minimum oxygen concentration measured by each sensor spot in purged seawater (purged at 100 mL/min. for 90 minutes, equal to 56 volume exchanges). Those detection limits were specific to each optode spot and varied from 146 – 880 nM [O<sub>2</sub>].

175

The optode [O<sub>2</sub>] measurements were adjusted for the detection limit specific to each sensor spot; optode [O<sub>2</sub>] for each experiment was calculated as the mean measured [O<sub>2</sub>] at each of the three timepoints. No optode measurements were made at station PS1, since this station lacked a secondary NO<sub>2</sub><sup>-</sup> maximum and thus incubations performed at low–oxygen depths were not expected to occur under functional anoxia. Optical oxygen sensors are susceptible to interference from NO, which could result in an overestimate of [O<sub>2</sub>] in experiments with especially high rates of NO production (Kraft et al., 2022). Given maximum ammonia oxidation rates of 4.68±0.07 nM N/day, the release of equivalent amounts of NO would result in an [O<sub>2</sub>] overestimate of 0.745 nM during a 24–hour incubation, based on the interference curve calculated by Kraft et al. (2022) ([O<sub>2</sub>] overestimate = 0.159×[NO]). Because of this small potential error, and the lack of relevant NO measurements, no correction was applied for NO interference.

185

Optode [O<sub>2</sub>] generally agreed with ambient [O<sub>2</sub>] measured by the Sea–Bird oxygen sensor attached to the rosette (Fig. S1). Two important exceptions were in the experiments at the base of ODZ and the deep ODZ core at station PS2, which were not purged before tracer addition. As a result, the ambient [O<sub>2</sub>] at these depths was below detection on the Sea–Bird sensor, but the optode [O<sub>2</sub>] in the incubation bottles from these depths were 17.7±0.1 μM and 19.2±0.8 μM, respectively (Fig. S1, Table S1). Additionally, two depths that were suboxic (and thus not sparged prior to tracer addition) had higher optode [O<sub>2</sub>] than ambient [O<sub>2</sub>]: in the deep oxycline at station PS2, ambient [O<sub>2</sub>] was 6.8 μM and optode [O<sub>2</sub>] was 14.8±0.2 μM; at the oxic–anoxic interface at station PS2, ambient [O<sub>2</sub>] was 6.5 μM and optode [O<sub>2</sub>] was 9.48±0.09 μM (Fig. S1, Table S1). Because of these few exceptions, we always report both optode and ambient [O<sub>2</sub>] in the following figures and text.

190

## 2.4 Nitrous oxide isotopocule measurements

195 Two steps were taken to prepare incubation samples for N<sub>2</sub>O isotopocule analysis immediately prior to measurement. First, a 5 mL aliquot was removed from each sample by syringe and replaced with He gas. These aliquots were refrigerated until analysis for [NO<sub>2</sub><sup>-</sup>] and [NH<sub>4</sub><sup>+</sup>] to check tracer and carrier additions, as mentioned above. After this aliquot was removed, 100 μL of <sup>14</sup>NH<sub>4</sub>Cl, Na<sup>14</sup>NO<sub>2</sub>, or K<sup>14</sup>NO<sub>3</sub> carrier was added to each sample at final concentrations of 54 μM, 262 μM, or 27 μM, respectively, to bring <sup>15</sup>N tracer levels below 5000‰. Note that these carrier additions were *different* from the <sup>14</sup>N carrier added to each incubation alongside <sup>15</sup>N tracer; the purpose of the later carrier additions was to prevent exposure of the IRMS system to highly <sup>15</sup>N–enriched substrates.

200

Samples were measured for N<sub>2</sub>O concentrations and <sup>15</sup>N isotopocules on a custom–built purge and trap system coupled to a Thermo Finnigan DELTA V Plus IRMS, which was run in continuous flow mode and configured to measure *m/z* 30, 31, 44, 45, and 46 (McIlvin and Casciotti, 2010). These measurements were made under normal operating conditions, using an ionization energy of 124 eV, emission current of 1.50 mA, and accelerating voltage of 3 kV. Samples were analyzed alongside reference materials (B6, S2, and atmosphere–equilibrated seawater) to calibrate the IRMS for scrambling in the ion source with the pyisotopomer software package in Python (Kelly et al., 2023). The number ratios of isotopomers <sup>14</sup>N<sup>15</sup>N<sup>16</sup>O and <sup>15</sup>N<sup>14</sup>N<sup>16</sup>O were calculated as in Kelly et al., 2023, with the following modifications to account for contribution of <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O to the molecular ion number ratios 46/44 (<sup>46</sup>*R*) and 31/30 (<sup>31</sup>*R*), which, while negligible at natural abundance, becomes important in tracer experiments.

In natural abundance samples, pyisotopomer solves the following four equations to obtain <sup>15</sup>*R*<sup>α</sup> and <sup>15</sup>*R*<sup>β</sup>:

$${}^{45}R = {}^{15}R^\alpha + {}^{15}R^\beta + {}^{17}R \quad (1)$$

$${}^{46}R = ({}^{15}R^\alpha + {}^{15}R^\beta){}^{17}R + {}^{18}R + {}^{15}R^\alpha{}^{15}R^\beta \quad (2)$$

$${}^{17}R/{}^{17}R_{\text{VSMOW}} = ({}^{18}R/{}^{18}R_{\text{VSMOW}})^\beta [\Delta({}^{17}\text{O}) + 1] \quad (3)$$

$${}^{31}R = \frac{(1 - \gamma){}^{15}R^\alpha + \kappa{}^{15}R^\beta + {}^{15}R^\alpha{}^{15}R^\beta + {}^{17}R[1 + \gamma{}^{15}R^\alpha + (1 - \kappa){}^{15}R^\beta]}{1 + \gamma{}^{15}R^\alpha + (1 - \kappa){}^{15}R^\beta} \quad (4)$$

Where <sup>45</sup>*R*, <sup>46</sup>*R*, and <sup>31</sup>*R* are the molecular ion number ratios 45/44, 46/44, and 31/30. <sup>15</sup>*R*<sup>α</sup>, <sup>15</sup>*R*<sup>β</sup>, <sup>17</sup>*R* and <sup>18</sup>*R* denote the number ratios of <sup>14</sup>N<sup>15</sup>N<sup>16</sup>O, <sup>15</sup>N<sup>14</sup>N<sup>16</sup>O, <sup>14</sup>N<sub>2</sub><sup>17</sup>O, and <sup>14</sup>N<sub>2</sub><sup>18</sup>O, respectively, to <sup>14</sup>N<sub>2</sub><sup>16</sup>O. Here, Δ(<sup>17</sup>O) was assumed to be equal to 0. In these equations, the term (<sup>15</sup>*R*<sup>α</sup>)(<sup>15</sup>*R*<sup>β</sup>) represents the statistically expected contribution of <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O to the <sup>46</sup>*R* and <sup>31</sup>*R* ion number ratios, based on the probabilities of forming <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O. The probability of getting <sup>15</sup>N in N<sup>α</sup> is given by <sup>15</sup>*R*<sup>α</sup> and the probability of getting <sup>15</sup>N in N<sup>β</sup> is given by <sup>15</sup>*R*<sup>β</sup>; furthermore, the two probabilities are assumed to be independent, so the probability of getting <sup>15</sup>N in both positions would be (<sup>15</sup>*R*<sup>α</sup>)(<sup>15</sup>*R*<sup>β</sup>) (Kaiser et al., 2004). Predicting the concentration of <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O from the distribution of <sup>15</sup>N in the singly–labeled molecules (<sup>15</sup>*R*<sup>α</sup> and <sup>15</sup>*R*<sup>β</sup>) is a reasonable assumption for natural abundance samples, where the concentration of <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O is extremely low (Kantnerová et al., 2022; Magyar et al., 2016).

For <sup>15</sup>N–labeled samples, however, we cannot predict <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O from the singly labeled molecules (<sup>15</sup>*R*<sup>α</sup> and <sup>15</sup>*R*<sup>β</sup>). This is because the relationship between the formation of <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O, <sup>14</sup>N<sup>15</sup>N<sup>16</sup>O, and <sup>15</sup>N<sup>14</sup>N<sup>16</sup>O depends on production mechanism and the atom fraction of the substrate. For example, in <sup>15</sup>N–NO<sub>2</sub><sup>−</sup> experiments with denitrification occurring, there may be far more <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O molecules produced than the amount predicted from the production of <sup>14</sup>N<sup>15</sup>N<sup>16</sup>O, and <sup>15</sup>N<sup>14</sup>N<sup>16</sup>O. To account for this, we added a term to the equations for <sup>46</sup>*R* and <sup>31</sup>*R* to account for the potential of excess <sup>15</sup>N<sup>15</sup>N<sup>16</sup>O production (<sup>15</sup>N<sup>15</sup>N<sup>16</sup>O<sub>excess</sub>) in tracer experiments:

$${}^{46}R = ({}^{15}R^\alpha + {}^{15}R^\beta) {}^{17}R + {}^{18}R + ({}^{15}R^\alpha {}^{15}R^\beta)_{t_0} + {}^{15}N {}^{15}N {}^{16}O_{excess} \quad (5)$$

$${}^{31}R = \frac{(1 - \gamma) {}^{15}R^\alpha + \kappa {}^{15}R^\beta + ({}^{15}R^\alpha {}^{15}R^\beta)_{t_0} + {}^{15}N {}^{15}N {}^{16}O_{excess} + {}^{17}R [1 + \gamma {}^{15}R^\alpha + (1 - \kappa) {}^{15}R^\beta]}{1 + \gamma {}^{15}R^\alpha + (1 - \kappa) {}^{15}R^\beta} \quad (6)$$

To quantify  ${}^{15}N {}^{15}N {}^{16}O_{excess}$  in tracer samples, we assumed that any increase in  ${}^{46}R$  over the course of the experiment is due to  
 230 added  ${}^{15}N {}^{15}N {}^{16}O$ , i.e., that  $\delta({}^{18}O)$  remains constant. This should be a reasonable assumption – while denitrification  
 and  $N_2O$  consumption could cause natural abundance–level increases in  $\delta({}^{18}O)$  and thus  ${}^{46}R$  (10's of per mil),  $N_2O$  production  
 from  ${}^{15}N$ –labeled substrates are expected to cause much greater increases in  ${}^{46}R$  (100's to 1,000's of per mil). We calculated  
 the term  ${}^{15}N {}^{15}N {}^{16}O_{excess}$  by subtracting the mean  ${}^{46}R$  at  $t_0$  from the measured  ${}^{46}R$  in later timepoints using the pyisotopomer  
 template designed for tracer experiments (Kelly, 2023). Then, we used the "Tracers" function in pyisotopomer, which takes  
 235 this  ${}^{15}N {}^{15}N {}^{16}O_{excess}$  into account, to calculate  ${}^{15}R^\alpha$  and  ${}^{15}R^\beta$ .

The concentration of  ${}^{44}N_2O$  in each sample was calculated from  $m/z$  44 peak area and a linear conversion factor, divided by  
 the sample volume (McIlvin and Casciotti, 2010). The concentrations of  ${}^{45}N_2O^\alpha$ ,  ${}^{45}N_2O^\beta$ , and  ${}^{46}N_2O$  were finally calculated by  
 multiplying  ${}^{15}R^\alpha$ ,  ${}^{15}R^\beta$ , and  ${}^{46}R$  by the average  $[{}^{44}N_2O]$  across all timepoints for that tracer experiment. Average values of  
 240  $[{}^{44}N_2O]$  were used to avoid aliasing random variability in  $[{}^{44}N_2O]$  over increases in  ${}^{15}R^\alpha$ ,  ${}^{15}R^\beta$ , and  ${}^{46}R$ . The analytical precisions  
 for  $N_2O$  isotopocule measurements, based on the pooled standard deviations of reference materials run alongside samples,  
 were  $\delta({}^{15}N^\alpha) = 4.4\%$ ,  $\delta({}^{15}N^\beta) = 3.4\%$ ,  $\delta({}^{15}N^{bulk}) = 3.5\%$ , and  $\delta({}^{18}O) = 2.1\%$ . The analytical precision was poorer than that in  
 a similar natural abundance dataset (Kelly et al., 2021) due to minor  ${}^{15}N$  carry–over in some of the standards analyzed  
 immediately following highly enriched samples.

## 245 2.5 Nitrite and nitrate isotope measurements

After  $N_2O$  analysis, approximately 2 mL sample remained in each bottle, which was prepared for analysis of  $\delta({}^{15}N\text{--}NO_2^-$   
 $+NO_3^-)$ ,  $\delta({}^{15}N\text{--}NO_3^-)$ , or  $\delta({}^{15}N\text{--}NO_2^-)$ , to determine the rates of  $NH_3$  oxidation,  $NO_2^-$  oxidation, and  $NO_3^-$  reduction,  
 depending on the tracer experiment. Samples incubated with  ${}^{15}N\text{--}NH_4^+$  were prepared for  $\delta({}^{15}N\text{--}NO_2^-+NO_3^-)$  analysis using  
 the denitrifier method (Casciotti et al., 2002; Sigman et al., 2001), with updates from McIlvin and Casciotti (2011), to determine  
 250 rates of  $NH_3$  oxidation. These samples were run on a Thermo–Finnigan DELTA<sup>PLUS</sup> XP IRMS alongside a process blank and  
 reference materials USGS32, USGS34, and USGS35 (Böhlke et al., 2003) to obtain  $\delta({}^{15}N\text{--}NO_2^-+NO_3^-)$ .

Samples incubated with  ${}^{15}N\text{--}NO_2^-$  were first treated with 5% sulfamic acid (weight–by–volume, or 10 mM final concentration)  
 to remove  ${}^{15}N\text{--}NO_2^-$  (Granger and Sigman, 2009), then prepared with the denitrifier method for  $\delta({}^{15}N\text{--}NO_3^-)$  analysis  
 255 (Casciotti et al., 2002; McIlvin and Casciotti, 2011; Sigman et al., 2001) to determine rates of  $NO_2^-$  oxidation. For these

analyses, reference materials USGS32, USGS34, and USGS35 (Böhlke et al., 2003) were also treated with 5% sulfamic acid and prepared with the denitrifier method alongside samples. Incubations with low ambient  $[\text{NO}_3^-]$  had high  $t_0$   $\delta(^{15}\text{N})$  values ( $>1000$  ‰; Fig. S2). This is likely because  $\text{NO}_3^-$  is produced when sulfamic acid is added to  $\text{NO}_2^-$  (Granger and Sigman, 2009), so the sulfamic treatment probably chemically converted some  $^{15}\text{N}\text{-NO}_2^-$  tracer to  $^{15}\text{N}\text{-NO}_3^-$ ; additionally,  $^{15}\text{N}\text{-NO}_3^-$  is a possible contaminant of the  $^{15}\text{N}\text{-NO}_2^-$  tracer solutions. Regardless, this would have shifted all three timepoints equally, and thus should not introduce a bias into the slope of  $\delta(^{15}\text{N}\text{-NO}_3^-)$  with time and the rates calculated there from.

Finally, samples incubated with  $^{15}\text{N}\text{-NO}_3^-$  were prepared for  $\delta(^{15}\text{N}\text{-NO}_2^-)$  isotopic analysis with the azide method (McIlvin and Altabet, 2005) to determine rates of  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$ . The 2 mL of remaining sample was transferred into 20 mL vials, where it was prepared alongside reference materials RSIL-N23, -N7373 and -N10219 (Casciotti et al., 2007). Reference materials were diluted from 200 mM working stocks into 3 mL  $\text{NO}_2^-$ -free seawater in 5 and 10 nmol quantities of  $\text{NO}_2^-$  to correct for the contribution of a consistent blank to a range of sample sizes. The analytical precisions for  $\delta(^{15}\text{N}\text{-NO}_x^-)$ ,  $\delta(^{15}\text{N}\text{-NO}_3^-)$ , and  $\delta(^{15}\text{N}\text{-NO}_2^-)$  were 0.9 ‰, 1.2 ‰, and 0.4 ‰, respectively. The  $\delta(^{15}\text{N})$  analytical precision for the denitrifier and azide methods is typically better (McIlvin and Altabet, 2005; Sigman et al., 2001), but tracer measurements tend to have lower analytical precision than natural abundance measurements.

The rates of  $\text{NH}_4^+$  and  $\text{NO}_2^-$  oxidation were calculated using a weighted least squares linear regression through product  $^{15}\text{N}$  vs. incubation time (Fig. S3). Each sample was weighted by its uncertainty, which was calculated based on the slope and intercept of the calibration curve, blank peak area, and sample peak area (Appendix A). Although using this uncertainty calculation is complex, it allows for the assessment of relative error, and for the inclusion of low-peak area samples that had high enough  $\delta(^{15}\text{N})$  enrichments such that the relative error remained below 10% (and in most cases, 1%). A weighted least squares regression was used in place of an ordinary least squares regression to prevent samples with high uncertainties from biasing the slope estimate (e.g., two samples in Fig. S3b). Then, the rate was calculated by:

$$\text{rate (nM N/day)} = \frac{m(^{15}F_{\text{product}})[P]}{^{15}F_{\text{substrate}}} \quad (7)$$

where  $m(^{15}F_{\text{product}})$  is the slope of the atom fraction of  $^{15}\text{N}$  in the product vs. incubation time,  $[P]$  is the mean product concentration (e.g.,  $\text{NO}_3^-$  in a  $\text{NO}_2^-$  oxidation experiment), and  $^{15}F_{\text{substrate}}$  is the atom fraction of  $^{15}\text{N}$  in the substrate (e.g.,  $\text{NO}_2^-$  in a  $\text{NO}_2^-$  oxidation experiment). Our method of estimating individual uncertainties was developed to deal with low  $\text{NH}_3$  oxidation rates, which generated low peak areas in  $\delta(^{15}\text{N}\text{-NO}_3^-)$  samples. Since the rates of  $\text{NO}_3^-$  reduction were generally much higher than the rates of  $\text{NH}_3$  oxidation (Table S2), a parallel method was not needed to estimate individual uncertainties in samples measured with the azide method, i.e.  $\delta(^{15}\text{N}\text{-NO}_2^-)$  measurements, so rates of  $\text{NO}_3^-$  reduction were with an ordinary least squares regression in eqn. (7) instead of a weighted least squares regression.

## 2.6 Modeling N<sub>2</sub>O production mechanisms

A time-dependent model was constructed to infer the rates and mechanisms of N<sub>2</sub>O production from the measured isotopocule time courses in each incubation experiment. While it is possible to calculate rates of hybrid and bacterial N<sub>2</sub>O production with linear regressions of <sup>45</sup>N<sub>2</sub>O and <sup>46</sup>N<sub>2</sub>O with time (Trimmer et al., 2016), these calculations cannot take into account <sup>15</sup>N transfer  
290 between substrates, and more importantly, produce separate rate estimates for separate tracer experiments. They also do not leverage the additional information provided by N<sub>2</sub>O isotopomers. We sought to solve for a common set of N<sub>2</sub>O production rate constants across the three parallel tracer experiments at a given station and depth, wherein the only differences between each tracer experiment were the starting concentrations of <sup>14</sup>N and <sup>15</sup>N in NH<sub>4</sub><sup>+</sup>, NO<sub>2</sub><sup>-</sup>, and NO<sub>3</sub><sup>-</sup> (Fig. 2). The model encoded four different N<sub>2</sub>O producing pathways: 1) **production from solely NH<sub>4</sub><sup>+</sup>**, which includes N<sub>2</sub>O from hydroxylamine oxidation  
295 (referred to as Pathway 1 in Wan et al., 2023), hybrid production using cellular NO<sub>2</sub><sup>-</sup> (referred to as Pathway 2 in Wan et al., 2023) and nitrifier-denitrification using cellular NO<sub>2</sub><sup>-</sup>; 2) **hybrid production** using extracellular NO<sub>2</sub><sup>-</sup> (referred to as Pathway 3 in Wan et al., 2023); 3) **production from NO<sub>2</sub><sup>-</sup>**, i.e. denitrification or nitrifier-denitrification using extracellular NO<sub>2</sub><sup>-</sup>; and 4) **production from NO<sub>3</sub><sup>-</sup>**, i.e. denitrification using cellular NO<sub>2</sub><sup>-</sup> (Fig. 2). Using this model, the relative importance of each of these pathways was determined at each incubation depth based on the production of <sup>15</sup>N-labeled N<sub>2</sub>O isotopocules in parallel  
300 experiments supplied with different <sup>15</sup>N substrates.

Pathway name	Includes N <sub>2</sub> O production from...	Corresponding process in Wan et al. (2023)
Production from solely NH <sub>4</sub> <sup>+</sup>	Hydroxylamine oxidation	Pathway 1
	Hybrid production using cellular NO <sub>2</sub> <sup>-</sup>	Pathway 2
	Nitrifier–denitrification using cellular NO <sub>2</sub> <sup>-</sup>	N/A
Hybrid production	Hybrid production using extracellular NO <sub>2</sub> <sup>-</sup>	Pathway 3
Production from NO <sub>2</sub> <sup>-</sup>	Denitrification or nitrifier–denitrification using extracellular NO <sub>2</sub> <sup>-</sup>	N/A
Production from NO <sub>3</sub> <sup>-</sup>	Denitrification using cellular NO <sub>2</sub> <sup>-</sup>	N/A

Figure 2. Schematic of the forward–running model used to solve for rates of N<sub>2</sub>O production. Horizontal arrows represent processes whose rates are solved for, while vertical arrows represent processes whose rates are prescribed based on our experimental results. The model solves for 2<sup>nd</sup>–order rate constants for four N<sub>2</sub>O–producing processes: 1) production from solely NH<sub>4</sub><sup>+</sup> (yellow horizontal arrows), which includes N<sub>2</sub>O from hydroxylamine oxidation (Wan et al., 2023 Pathway 1), hybrid production using cellular NO<sub>2</sub><sup>-</sup> (Wan et al., 2023 Pathway 2), and nitrifier–denitrification using cellular NO<sub>2</sub><sup>-</sup>; 2) hybrid production using NH<sub>4</sub><sup>+</sup> and extracellular NO<sub>2</sub><sup>-</sup> (green arrows, Wan et al., 2023 Pathway 3); 3) production from NO<sub>2</sub><sup>-</sup>, i.e. denitrification or nitrifier–denitrification using extracellular NO<sub>2</sub><sup>-</sup> (blue hatched horizontal arrows); and 4) production from NO<sub>3</sub><sup>-</sup>, i.e. denitrification or nitrifier–denitrification using cellular NO<sub>2</sub><sup>-</sup> (indigo horizontal arrows). The model also solves for *f*, the proportion of N<sup>α</sup> derived from NO<sub>2</sub><sup>-</sup> during hybrid N<sub>2</sub>O production. NH<sub>3</sub> oxidation (yellow vertical arrows), NO<sub>2</sub><sup>-</sup> oxidation (blue hatched vertical arrows), and NO<sub>3</sub><sup>-</sup> reduction to NO<sub>2</sub><sup>-</sup> (indigo vertical arrows) are modeled as first–order rates to account for <sup>15</sup>N transfer between substrate pools, as described in the main text. Finally, N<sub>2</sub>O consumption (black dashed arrow) is modeled as first–order to N<sub>2</sub>O. It is assumed that while the distribution of <sup>15</sup>N in each tracer experiment at a given station and depth is different, the overall rates and mechanisms of N<sub>2</sub>O production are the same regardless of which substrate is labeled. The model is optimized against the observed <sup>46</sup>N<sub>2</sub>O, <sup>45</sup>N<sub>2</sub>O, <sup>45</sup>N<sub>2</sub>Oβ, and <sup>44</sup>N<sub>2</sub>O at each timepoint in each tracer experiment (black box).

The concentration of each nitrogen species was modeled as:

$$N_{t+1} = N_t + \Delta t \left( \sum_{n=1}^i J_n^{source} - \sum_{n=1}^k J_n^{sink} \right) \quad (8)$$

where  $N_t$  is the concentration of a given N species (e.g.,  $\text{NH}_4^+$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ , or  $\text{N}_2\text{O}$ ) at time  $t$ ,  $N_{t+1}$  is its concentration at time  $t+1$ ,  $\Delta t$  represents the model timestep (days),  $\sum_{n=1}^i J_n^{source}$  is the sum of  $i$  individual source processes of that species (nM/day), and  $\sum_{n=1}^k J_n^{sink}$  is the sum of  $k$  individual sink processes of that species (nM/day).

The pattern of  $\text{N}_2\text{O}$  isotopocule production for a given process was set by the total rate  $J$  of  $\text{N}_2\text{O}$  production for that process, multiplied by the probability of forming each isotopocule from a given pair of substrates. The probabilities of forming each isotopocule were based on the atom fractions of the two substrates from which the nitrogen atoms in  $\text{N}_2\text{O}$  are derived:

$$P({}^{46}\text{N}_2\text{O}) = ({}^{15}\text{F}_1)({}^{15}\text{F}_2) \quad (9)$$

$$P({}^{45}\text{N}_2\text{O}^\alpha) = f({}^{15}\text{F}_1)(1 - {}^{15}\text{F}_2) + (1 - f)(1 - {}^{15}\text{F}_1)({}^{15}\text{F}_2) \quad (10)$$

$$P({}^{45}\text{N}_2\text{O}^\beta) = (1 - f)({}^{15}\text{F}_1)(1 - {}^{15}\text{F}_2) + f(1 - {}^{15}\text{F}_1)({}^{15}\text{F}_2) \quad (11)$$

$$P({}^{44}\text{N}_2\text{O}) = (1 - {}^{15}\text{F}_1)(1 - {}^{15}\text{F}_2) \quad (12)$$

where  $P({}^{46}\text{N}_2\text{O})$ ,  $P({}^{45}\text{N}_2\text{O}^\alpha)$ ,  $P({}^{45}\text{N}_2\text{O}^\beta)$ , and  $P({}^{44}\text{N}_2\text{O})$  are the probabilities of forming each isotopocule,  ${}^{15}\text{F}_1$  is the atom fraction of  ${}^{15}\text{N}$  in substrate 1,  ${}^{15}\text{F}_2$  is the atom fraction of  ${}^{15}\text{N}$  in substrate 2, and  $f$  is the proportion of  $\text{N}^\alpha$  derived from substrate 1;  $1 - f$  is the proportion of  $\text{N}^\alpha$  derived from substrate 2. Assuming a 1:1 pairing of substrates 1 and 2,  $f$  also represents the proportion of  $\text{N}^\beta$  derived from substrate 2, and  $1 - f$  represents the proportion of  $\text{N}^\beta$  derived from substrate 1. Processes that derive both nitrogen atoms from the same substrate pool are a special case of eqns. (9–12), where  ${}^{15}\text{F}_1 = {}^{15}\text{F}_2$ . Measuring bulk  ${}^{45}\text{N}_2\text{O}$  production instead of individual isotopomers (Trimmer et al., 2016) is also a special case of eqns. (9–12), where  $P({}^{45}\text{N}_2\text{O}) = P({}^{45}\text{N}_2\text{O}^\alpha) + P({}^{45}\text{N}_2\text{O}^\beta)$  and  $f$  cancels out.

To represent each  $\text{N}_2\text{O}$ -producing  $J$  term in the model, the rates of  $\text{N}_2\text{O}$  production were modeled as second order:

$$J_i = k_i[\text{substrate}_1][\text{substrate}_2] \quad (13)$$

where  $J_i$  is the rate of  $\text{N}_2\text{O}$  production process  $i$  in nM N/day,  $k_i$  is a second-order rate constant for that process,  $[\text{substrate}_1]$  is the concentration of substrate 1 for process  $i$ , and  $[\text{substrate}_2]$  is the concentration of substrate 2 for process  $i$ . Each rate constant  $k_i$  was optimized in the model for each station and depth. Again,  $\text{N}_2\text{O}$  production processes that draw both nitrogen atoms from the same substrate are a special case, where  $[\text{substrate}_1] = [\text{substrate}_2]$ .  $J$  was multiplied by  $1/2$  to convert the rate from nM

N/day to nM N<sub>2</sub>O/day, which was then multiplied by eqns. (9–12) to obtain the rates of production of each isotopocule (note that rates are reported in pM/day). For example, the rate of hybrid <sup>46</sup>N<sub>2</sub>O production was represented as:

$$J_{hybrid}^{46N2O} = 1/2 (k_{hybrid} [NH_4^+][NO_2^-]) (\overset{15}{F}_{NH_4^+}) (\overset{15}{F}_{NO_2^-}) \quad (14)$$

where  $J_{hybrid}^{46N2O}$  is the rate of <sup>46</sup>N<sub>2</sub>O production via hybrid production in nM N<sub>2</sub>O/day.

To relate the  $J$  terms to consumption of the substrate pools (NH<sub>4</sub><sup>+</sup>, NO<sub>2</sub><sup>-</sup>, and NO<sub>3</sub><sup>-</sup>),  $J$  draws upon the <sup>15</sup>N and <sup>14</sup>N substrate pools according to the atom fractions of <sup>15</sup>N in each substrate:

$$J_i^{15} = J_i \cdot \overset{15}{F}_{substrate} \text{ and } J_i^{14} = J_i \cdot (1 - \overset{15}{F}_{substrate}) \quad (15)$$

where  $J_i^{15}$  and  $J_i^{14}$  are the rates of consumption of the <sup>15</sup>N and <sup>14</sup>N substrate pools by N<sub>2</sub>O producing process  $i$ ,  $J_i$  is the rate in nM N/day calculated in eqn. (13) for N<sub>2</sub>O production process  $i$ , and  $\overset{15}{F}_{substrate}$  is the atom fraction of <sup>15</sup>N in the given substrate pool (NH<sub>4</sub><sup>+</sup>, NO<sub>2</sub><sup>-</sup>, and NO<sub>3</sub><sup>-</sup>). Essentially, eqn. (15) relates how each rate  $J_i$  draws from the <sup>15</sup>N and <sup>14</sup>N substrate pools, while eqns. (9–12) determine the <sup>15</sup>N and <sup>14</sup>N distribution in the product N<sub>2</sub>O. For example, the rate of <sup>15</sup>NH<sub>4</sub><sup>+</sup> consumption by hybrid N<sub>2</sub>O production was represented as:

$$J_{hybrid}^{15NH4^+} = (k_{hybrid} [NH_4^+][NO_2^-]) (\overset{15}{F}_{NH_4^+}) \quad (16)$$

where  $J_{hybrid}^{15NH4^+}$  is the rate of <sup>15</sup>N–NH<sub>4</sub><sup>+</sup> consumption via hybrid production in nM N/day. Eqn. (16) does not contain the factor of 1/2 in eqn. (14) because the units are nM N/day, not nM N<sub>2</sub>O/day. Rates of <sup>15</sup>N and <sup>14</sup>N transfer between substrate pools via NH<sub>3</sub> oxidation, NO<sub>2</sub><sup>-</sup> oxidation, and NO<sub>3</sub><sup>-</sup> reduction were also included in the model. The model solves for N<sub>2</sub>O production rates, given a set of NH<sub>3</sub> oxidation, NO<sub>2</sub><sup>-</sup> oxidation, and NO<sub>3</sub><sup>-</sup> reduction rates calculated in Sect. 2.5, eqn. (7) (Table S2). These rates were represented in the model as first-order:

$$J^{15} = \frac{k}{\alpha} [\overset{15}{N}] \text{ and } J^{14} = k [\overset{15}{N}] \quad (17)$$

Where  $J^{15}$  and  $J^{14}$  represent the rates of <sup>15</sup>N and <sup>14</sup>N transformation via NH<sub>3</sub> oxidation, NO<sub>2</sub><sup>-</sup> oxidation, or NO<sub>3</sub><sup>-</sup> reduction,  $k$  is a first-order rate constant derived from measured rates,  $\alpha$  is a fractionation factor (Table S3), [<sup>15</sup>N] is the concentration of the <sup>15</sup>N species, and [<sup>14</sup>N] is the concentration of the <sup>14</sup>N species. N<sub>2</sub>O consumption was modeled as first-order to the concentration of each isotopocule, based on the [O<sub>2</sub>]-corrected rates of N<sub>2</sub>O consumption measured on the same cruise (Sun et al., 2021a).

The model was optimized against isotopocule data at each timestep, in each tracer experiment (Fig. S4). The parameters being optimized (inputs to the cost function) were the 2<sup>nd</sup>-order rate constants  $k_i$  for N<sub>2</sub>O production from solely NH<sub>4</sub><sup>+</sup>, N<sub>2</sub>O production from NO<sub>2</sub><sup>-</sup> via denitrification or nitrifier–denitrification, N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> via denitrification, hybrid N<sub>2</sub>O production using extracellular NO<sub>2</sub><sup>-</sup>, and  $f$  (Fig. 2). In the model, these are all separate processes that operate independently.

The model was optimized using the Nelder–Mead Simplex algorithm (Nelder and Mead, 1965), implemented in the Scipy optimization library (Virtanen et al., 2020), which has been used successfully for natural abundance  $\text{N}_2\text{O}$  isotopocule models (Monreal et al., 2022). Model error was estimated by optimizing the model at each station and depth with 100 combinations of model parameters, randomly varying the initial concentrations of each  $^{15}\text{N}$  and  $^{14}\text{N}$  substrate and rate constants for  $\text{NH}_3$  oxidation,  $\text{NO}_2^-$  oxidation, and  $\text{NO}_3^-$  oxidation by up to 25%.

To ground truth the model, rates of  $\text{N}_2\text{O}$  production obtained from the model were compared to the measured net rates of  $^{46}\text{N}_2\text{O}$  production (Fig. S5). For processes drawing both nitrogen atoms from the same substrate pool (i.e., not hybrid production), the modeled rates of  $\text{N}_2\text{O}$  production from each substrate should correspond roughly to the net rate of  $^{46}\text{N}_2\text{O}$  production from the same  $^{15}\text{N}$ -labeled substrate. Higher modeled rates of  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  corresponded generally to higher net rates of  $^{46}\text{N}_2\text{O}$  production from  $^{15}\text{N}\text{-NH}_4^+$  (Fig. S5a). Since the model cannot produce negative rates, negative net rates of  $^{46}\text{N}_2\text{O}$  production from  $^{15}\text{N}\text{-NH}_4$  corresponded to modeled  $\text{N}_2\text{O}$  production rates equal to zero (Fig. S5a). Modeled rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  and  $\text{NO}_3^-$  via denitrification also corresponded to higher measured rates of  $^{46}\text{N}_2\text{O}$  production from  $^{15}\text{N}\text{-NO}_2^-$  and  $^{15}\text{N}\text{-NO}_3^-$ , respectively (Fig. S5b, c).

### 3 Results

#### 3.1 Depth distributions of oxygen, nitrite, and nitrous oxide

Station PS1, which was at the edge of the ODZ, represented a “background” station with no secondary  $\text{NO}_2^-$  maximum and a less pronounced minimum in  $[\text{N}_2\text{O}]$  below the oxycline (Fig. S6; Kelly et al., 2021). At station PS1, the oxic–anoxic interface – defined in this study as the depth just above the ODZ – occurred at the base of the mixed layer, at 100 m depth (Fig. S6). Station PS2 was near the geographic center of the oxygen–deficient region and had a secondary  $\text{NO}_2^-$  maximum of 2.2  $\mu\text{M}$ , indicating functional anoxia (Fig. S6). The oxic–anoxic interface at Station PS2 occurred at 92 m depth (Fig. S6). Below the oxic–anoxic interface,  $[\text{N}_2\text{O}]$  declined to  $4.5\pm 0.3$  nM before increasing again at the base of the secondary  $\text{NO}_2^-$  maximum and reaching a local maximum around 800 m depth. Station PS3 was approximately 12 miles from the coast of Mexico and had a shallow oxic–anoxic interface that moved up and down on timescales of days: on April 10<sup>th</sup>, the oxic–anoxic interface occurred at 40 m depth; two days later, the oxic–anoxic interface had deepened to 62 m depth. Experiments were performed at the oxic–anoxic interface on both days and are designated with abbreviations “Interface” and “Interface2” in the experimental metadata (Table S1). The chemical profiles from April 11<sup>th</sup> (Fig. S6), on which the near–surface  $[\text{N}_2\text{O}]$  maximum occurred at 61 m (Kelly et al., 2021), are displayed along with the rate data in this study. Station PS3 had a pronounced secondary  $\text{NO}_2^-$  maximum of 2.8  $\mu\text{M}$  at 161 m depth (Fig. S6) and an  $\text{NH}_4^+$  maximum of 400 nM at 15 m depth (not shown). On April 11<sup>th</sup>,  $[\text{N}_2\text{O}]$  reached a maximum of  $195\pm 13$  nM at the oxic–anoxic interface and declined below this depth. Below 600 m depth,  $[\text{N}_2\text{O}]$  began to increase again to  $44\pm 3$  nM. At every station, a deep, secondary chlorophyll *a* maximum was observed near the oxic–anoxic interface, where photosynthetically active radiation was much reduced and  $[\text{NO}_3^-]$  was abundant (Travis et al.,

2023). This secondary chlorophyll *a* maximum tended to develop between the depths of the oxic–anoxic interface and secondary  $\text{NO}_2^-$  maximum (Travis et al., 2023).

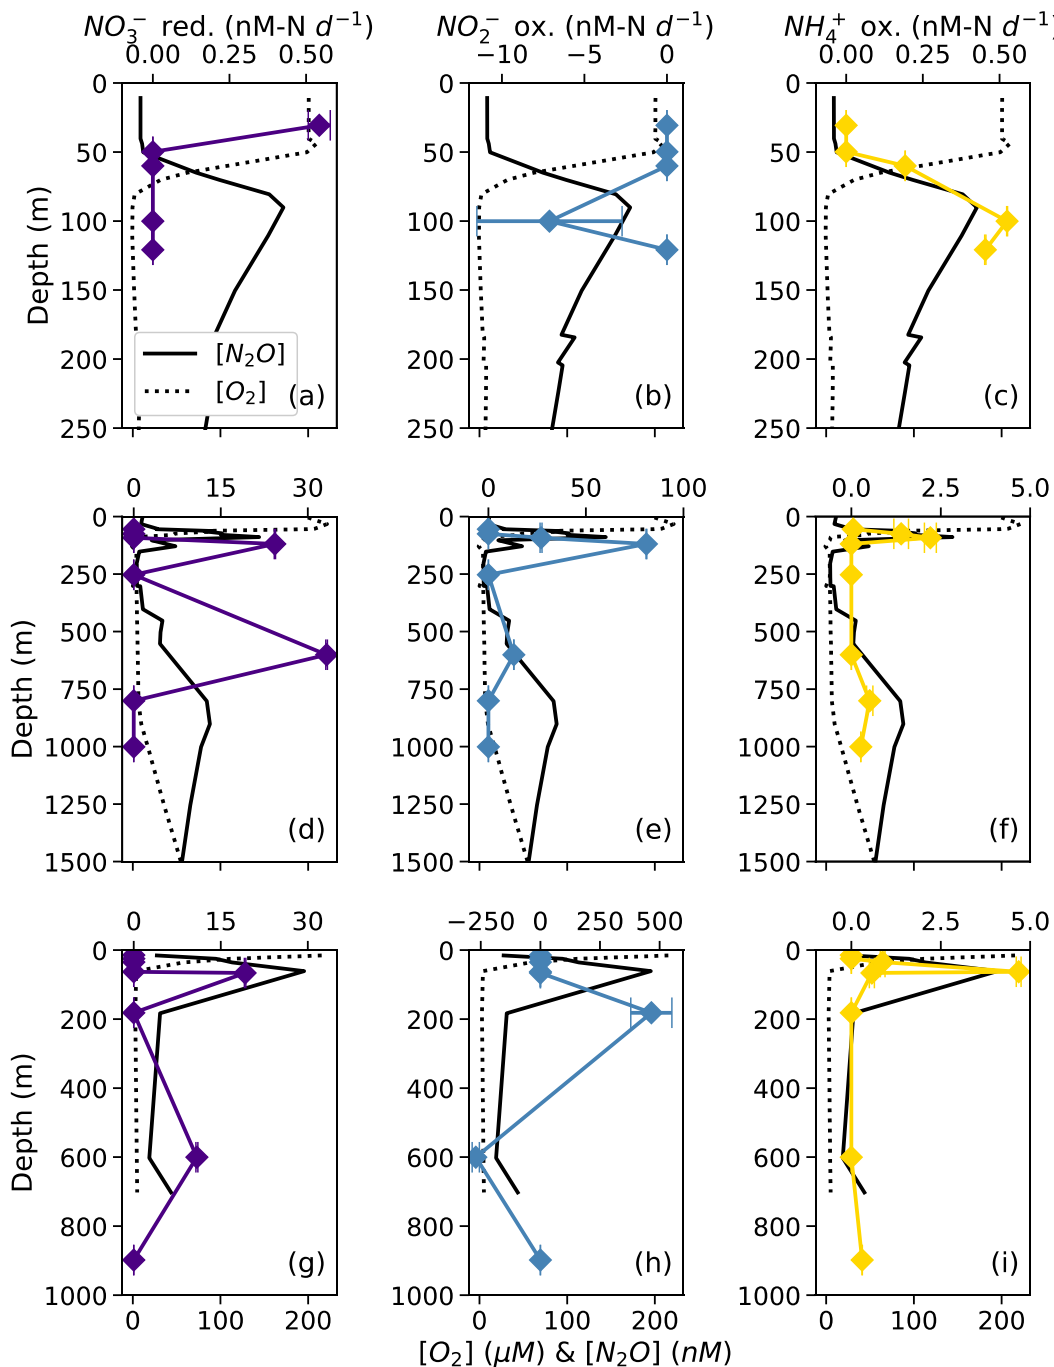

### 3.2 Nitrification and nitrate reduction rates

400  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$  occurred at rates ranging from  $0.54 \pm 0.04$  to  $33.2 \pm 0.1$  nM N/day (Table S2). There was a small, significant rate of  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$  in apparently aerobic waters near the surface at station PS1 (Fig. 3a). The highest rates of  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$  occurred in the deep, anoxic waters at station PS2 ( $33.24 \pm 0.01$  nM N/day; Fig. 3d) and in the secondary chlorophyll maximum at station PS3 ( $19.2 \pm 0.1$  nM N/day; Fig. 3g).

405  $\text{NO}_2^-$  oxidation rates ranged from  $13.05 \pm 0.08$  nM N/day to  $465 \pm 86$  nM N/day (Table S2). The highest rates of  $\text{NO}_2^-$  oxidation occurred within apparently oxygen deficient waters, at  $81.0 \pm 0.2$  nM N/day in the secondary chlorophyll *a* maximum at station PS2 and at  $465 \pm 86$  nM N/day in the secondary  $\text{NO}_2^-$  maximum at station PS3 (Fig. 3e, h; Table S2). Note that these are potential rates, since the  $^{15}\text{N}$  addition was generally much greater than the ambient concentration (Lipschultz, 2008). In some cases,  $\text{NO}_2^-$  oxidation rates appeared negative due to a decrease in  $^{15}\text{N}$ – $\text{NO}_3^-$  vs. incubation time (Fig. 3b, h), which was likely  
410 an artifact of the elevated  $t_0 \delta(^{15}\text{N})$  values in some of our  $^{15}\text{N}$ – $\text{NO}_2^-$  treatments (discussed above). We chose, however, not to left censor the data.

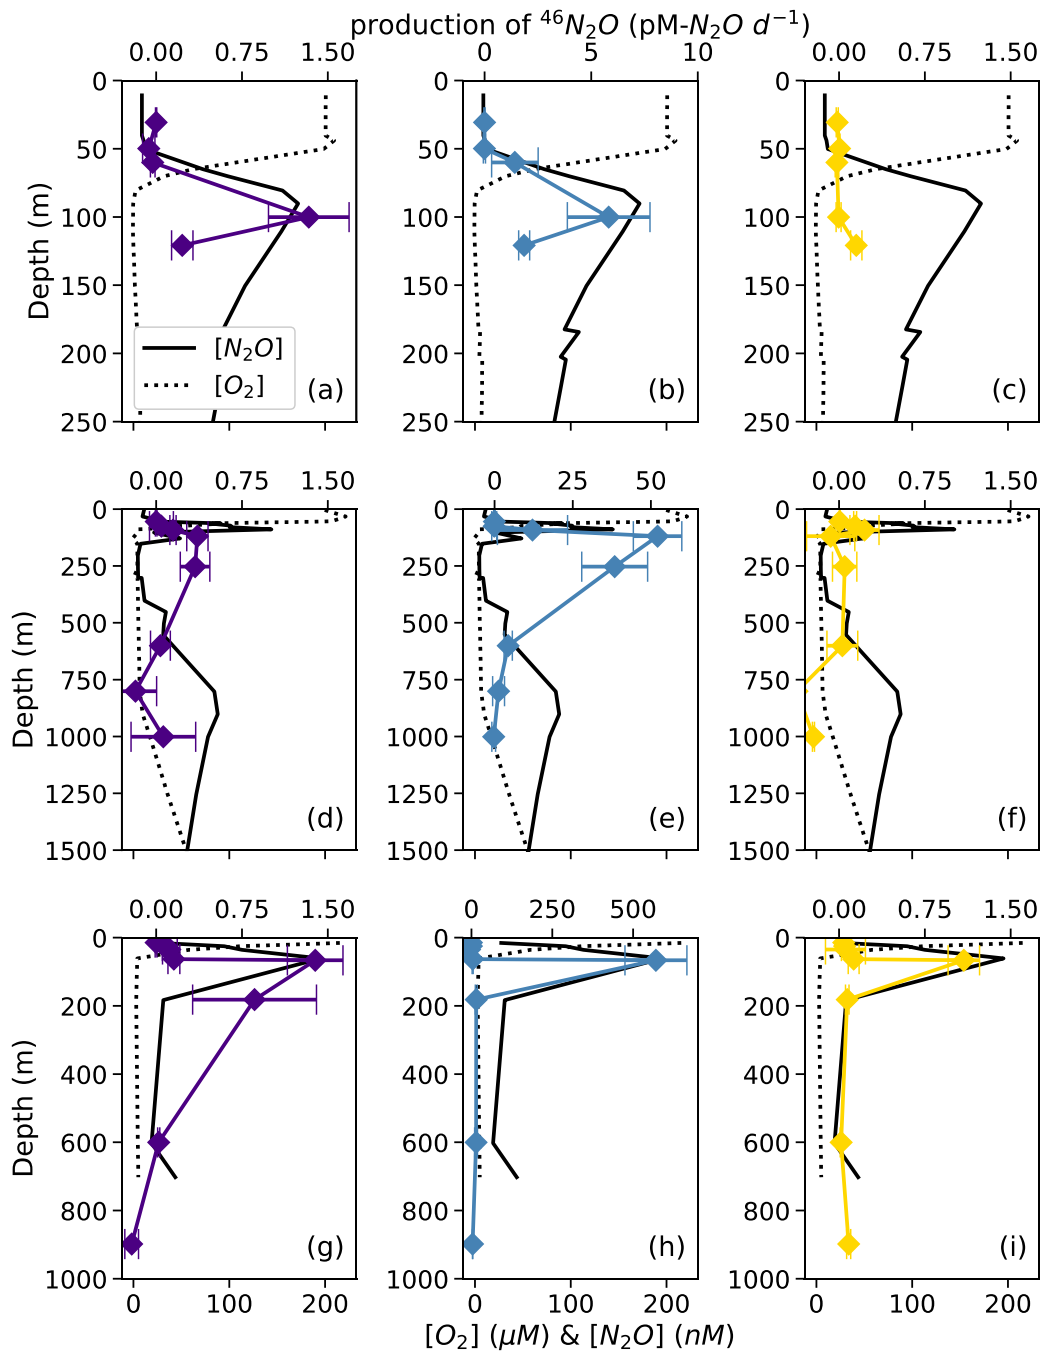

$\text{NH}_3$  oxidation to  $\text{NO}_2^-$  occurred at small, but significant rates ranging from  $0.19 \pm 0.0004$  nM N/day to  $4.68 \pm 0.07$  nM N/day (Table S2). At every station, rates of  $\text{NH}_3$  oxidation peaked near the base of the mixed layer, at the same depth as the near–  
415 surface  $[\text{N}_2\text{O}]$  maximum (Fig. 3c, f, i). At station PS2,  $\text{NH}_3$  oxidation showed a secondary peak at the same depth as the deep  $[\text{N}_2\text{O}]$  maximum (Fig. 3f). At station PS3, there was also a small, significant rate of  $\text{NH}_3$  oxidation ( $0.303 \pm 0.005$  nM N/day) at 898 m, which was close to the bottom depth (Fig. 3i). Rates of  $\text{NH}_3$  oxidation were generally lower than  $\text{NO}_2^-$  oxidation and undetectable in oxygen deficient waters (Fig. 3c, f, i).

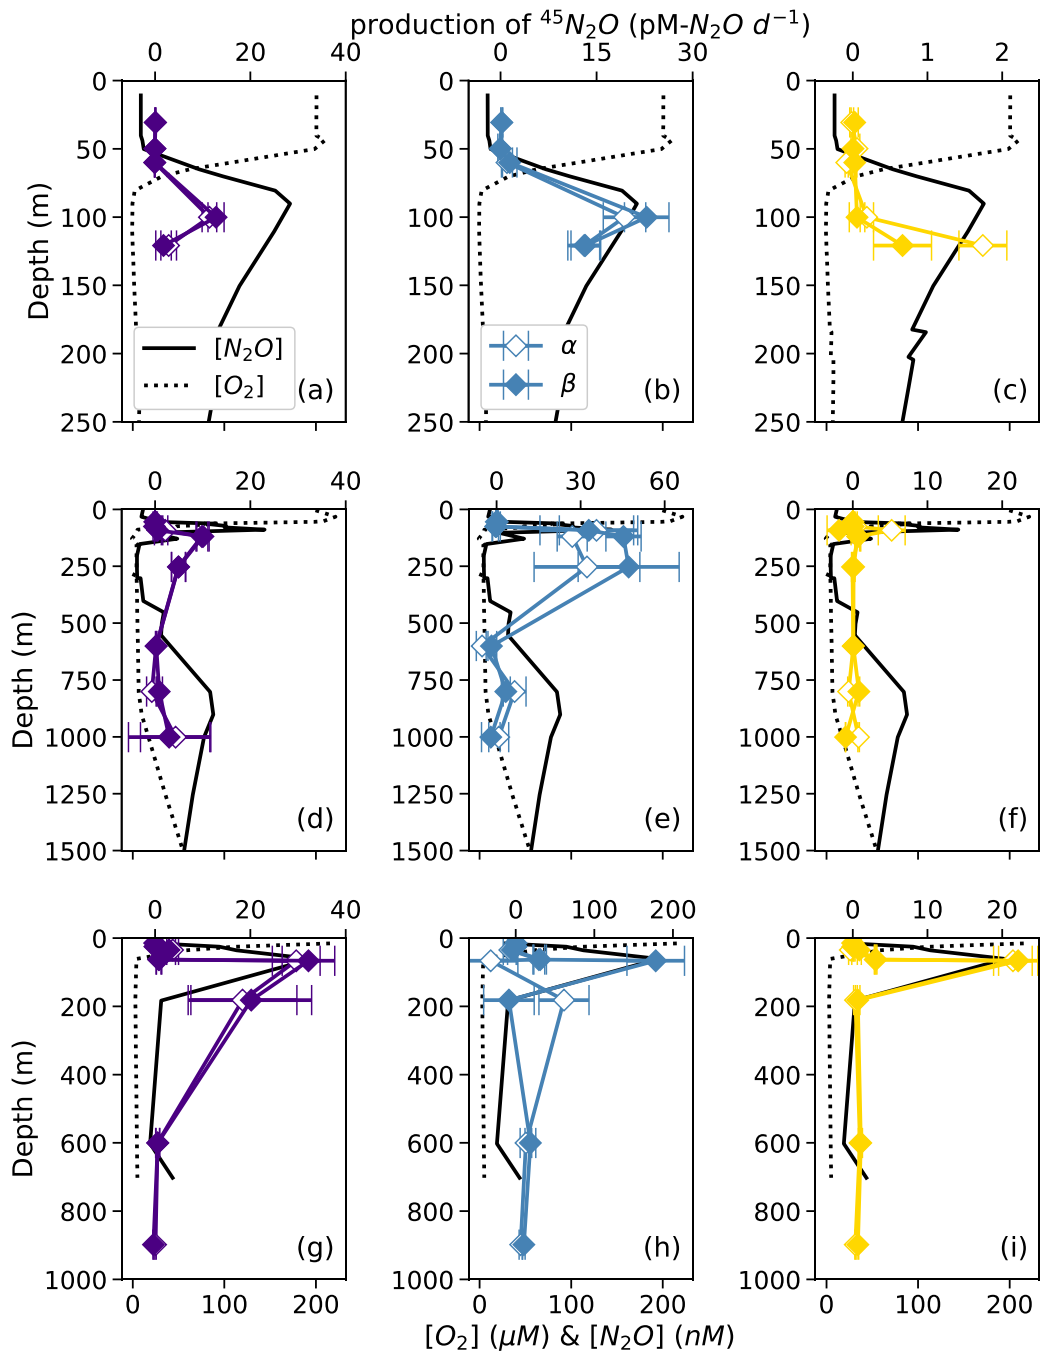

420

**Figure 3.** Rates of  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$  (a, d, g, indigo),  $\text{NO}_2^-$  oxidation to  $\text{NO}_3^-$  (b, e, h, blue),  $\text{NH}_3$  oxidation to  $\text{NO}_2^- + \text{NO}_3^-$  (c, f, i, yellow) at stations PS1 (a–c), PS2 (d–f), and PS3 (g–i). Rates are plotted over depth profiles of dissolved  $[\text{O}_2]$  (dashed lines) and  $[\text{N}_2\text{O}]$  (solid lines, from Kelly et al., 2021). Error bars represent rate error, calculated from the error of the slope of product  $^{15}\text{N}$  vs. time. Note the different x-axis scales for rate measurements (top) and  $[\text{O}_2]$  and  $[\text{N}_2\text{O}]$  (bottom).

**Figure 4.** Net  $^{46}\text{N}_2\text{O}$  production from  $^{15}\text{N}\text{-NO}_3^-$  (a, d, g, indigo),  $^{15}\text{N}\text{-NO}_2^-$  (b, e, h, blue), and  $^{15}\text{N}\text{-NH}_4^+$  (c, f, i, yellow) at stations PS1 (a–c), PS2 (d–f), and PS3 (g–i).  $\text{N}_2\text{O}$  production rates are plotted over depth profiles of dissolved  $[\text{O}_2]$  (dashed lines) and  $[\text{N}_2\text{O}]$  (solid lines, from Kelly et al., 2021). Error bars are calculated from linear regression slope error of  $^{46}\text{N}_2\text{O}$  vs. incubation time. Note the different x-axis scales for  $^{46}\text{N}_2\text{O}$  production (top) and  $[\text{O}_2]$  and  $[\text{N}_2\text{O}]$  (bottom).

430

**Figure 5.** Net  $^{45}\text{N}_2\text{O}^\alpha$  (open symbols) and  $^{45}\text{N}_2\text{O}^\beta$  (closed symbols) production from  $^{15}\text{N-NO}_3^-$  (a, d, g, indigo),  $^{15}\text{N-NO}_2^-$  (b, e, h, blue), and  $^{15}\text{N-NH}_4^+$  (c, f, i, yellow) at stations PS1 (a–c), PS2 (d–f), and PS3 (g–i).  $\text{N}_2\text{O}$  production rates are plotted over depth profiles of dissolved  $[\text{O}_2]$  (dashed lines) and  $[\text{N}_2\text{O}]$  (solid lines, from Kelly et al., 2021). Error bars are calculated from linear regression slope error of  $^{45}\text{N}_2\text{O}$  vs. incubation time. Note the different x-axis scales for  $^{45}\text{N}_2\text{O}$  production (top) and  $[\text{O}_2]$  and  $[\text{N}_2\text{O}]$  (bottom).

### 435 3.3 Net production rates of $^{45}\text{N}_2\text{O}^\alpha$ , $^{45}\text{N}_2\text{O}^\beta$ , and $^{46}\text{N}_2\text{O}$ (measured net rates)

At each station, the observed rates of net  $^{46}\text{N}_2\text{O}$  (Fig. 4),  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  (Fig. 5) production from  $^{15}\text{N-NH}_4^+$ ,  $^{15}\text{N-NO}_2^-$ , and  $^{15}\text{N-NO}_3^-$  all peaked at or just below the oxic–anoxic interface, where the near surface  $[\text{N}_2\text{O}]$  maximum was found. There were also relatively higher rates of net  $^{46}\text{N}_2\text{O}$  production from  $^{15}\text{N-NO}_2^-$  and  $^{15}\text{N-NO}_3^-$  within the secondary  $\text{NO}_2^-$  maximum (253 m) at station PS2 (Fig. 4d–e). Relatively high rates of net  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  production also occurred in the secondary  
 440  $\text{NO}_2^-$  maximum at stations PS2 (253m; Fig. 5d–e) and PS3 (182 m; Fig. 5g–h). The net rates of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  production varied in concert at almost every station and depth, with a few exceptions (Fig. 5).

For example, in the secondary  $\text{NO}_2^-$  maximum (182 m) at station PS3, in the  $^{15}\text{N-NO}_2^-$  experiment, the production of  $^{45}\text{N}_2\text{O}^\alpha$  was  $60\pm 30$  pM  $\text{N}_2\text{O}/\text{day}$  ( $p = 0.09$ ) and there was no significant production of  $^{45}\text{N}_2\text{O}^\beta$  (Fig. 5h). In the parallel  $^{15}\text{N-NH}_4^+$   
 445 experiment, the production of  $^{45}\text{N}_2\text{O}^\beta$  was  $0.7\pm 0.3$  pM  $\text{N}_2\text{O}/\text{day}$  ( $p = 0.06$ ) and there was no significant production of  $^{45}\text{N}_2\text{O}^\alpha$ . At this station and depth,  $f$  (the proportion of  $\text{N}^\alpha$  derived from  $\text{NO}_2^-$ ) was equal to  $0.9\pm 0.2$  (Table S4). The second experiment in which labeling was unequal occurred at the oxic–anoxic interface (92 m) at station PS2, where in the  $^{15}\text{N-NH}_4^+$  experiment, the production of  $^{45}\text{N}_2\text{O}^\alpha$  was  $5\pm 2$  pM  $\text{N}_2\text{O}/\text{day}$  ( $p = 0.02$ ) and there was no significant production of  $^{45}\text{N}_2\text{O}^\beta$  (Fig. 5f). Here,  $f$  was equal to  $0.2\pm 0.1$ . Finally, at the mid–oxycline depth (25 m) at station PS3, in the  $^{15}\text{N-NH}_4^+$  experiment, the production  
 450 of  $^{45}\text{N}_2\text{O}^\alpha$  was  $0.23\pm 0.8$  pM  $\text{N}_2\text{O}/\text{day}$  ( $p = 0.02$ ) and there was no significant production of  $^{45}\text{N}_2\text{O}^\beta$ . Here,  $f$  was statistically indistinguishable from 0.

At many stations and depths, the net production of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  exceeded the values expected from  $^{46}\text{N}_2\text{O}$  production for a process that draws both nitrogen atoms from the same substrate pool (Fig. S7). This expected value is calculated from  
 455 the atom fraction of  $^{15}\text{N}$  in the substrate and a binomial distribution of the isotopocules of  $\text{N}_2\text{O}$  during  $\text{N}_2\text{O}$  production (Trimmer et al., 2016):

$$p_{\text{expected}}^{45} = \frac{p^{46}}{(\frac{15}{15}F)^2} 2(\frac{15}{15}F)(1 - \frac{15}{15}F) = \frac{p^{46}}{\frac{15}{15}F} 2(1 - \frac{15}{15}F) \quad (18)$$

where  $p_{\text{expected}}^{45}$  is the expected production of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  from a process that draws both nitrogen atoms from the same substrate pool,  $p^{46}$  is the net production rate of  $^{46}\text{N}_2\text{O}$ , and  $^{15}F$  is the atom fraction of  $^{15}\text{N}$  in the substrate pool (for example,  $\text{NO}_2^-$  in a  $^{15}\text{N-NO}_2^-$  experiment). Then, excess production of  $^{45}\text{N}_2\text{O}$  is any  $^{45}\text{N}_2\text{O}$  production above and beyond this expected  
 460 rate:

$$p_{\text{excess}}^{45} = p^{45} - p_{\text{expected}}^{45} = p^{45} - \frac{p^{46}}{\frac{15}{15}F} 2(1 - \frac{15}{15}F) \quad (19)$$

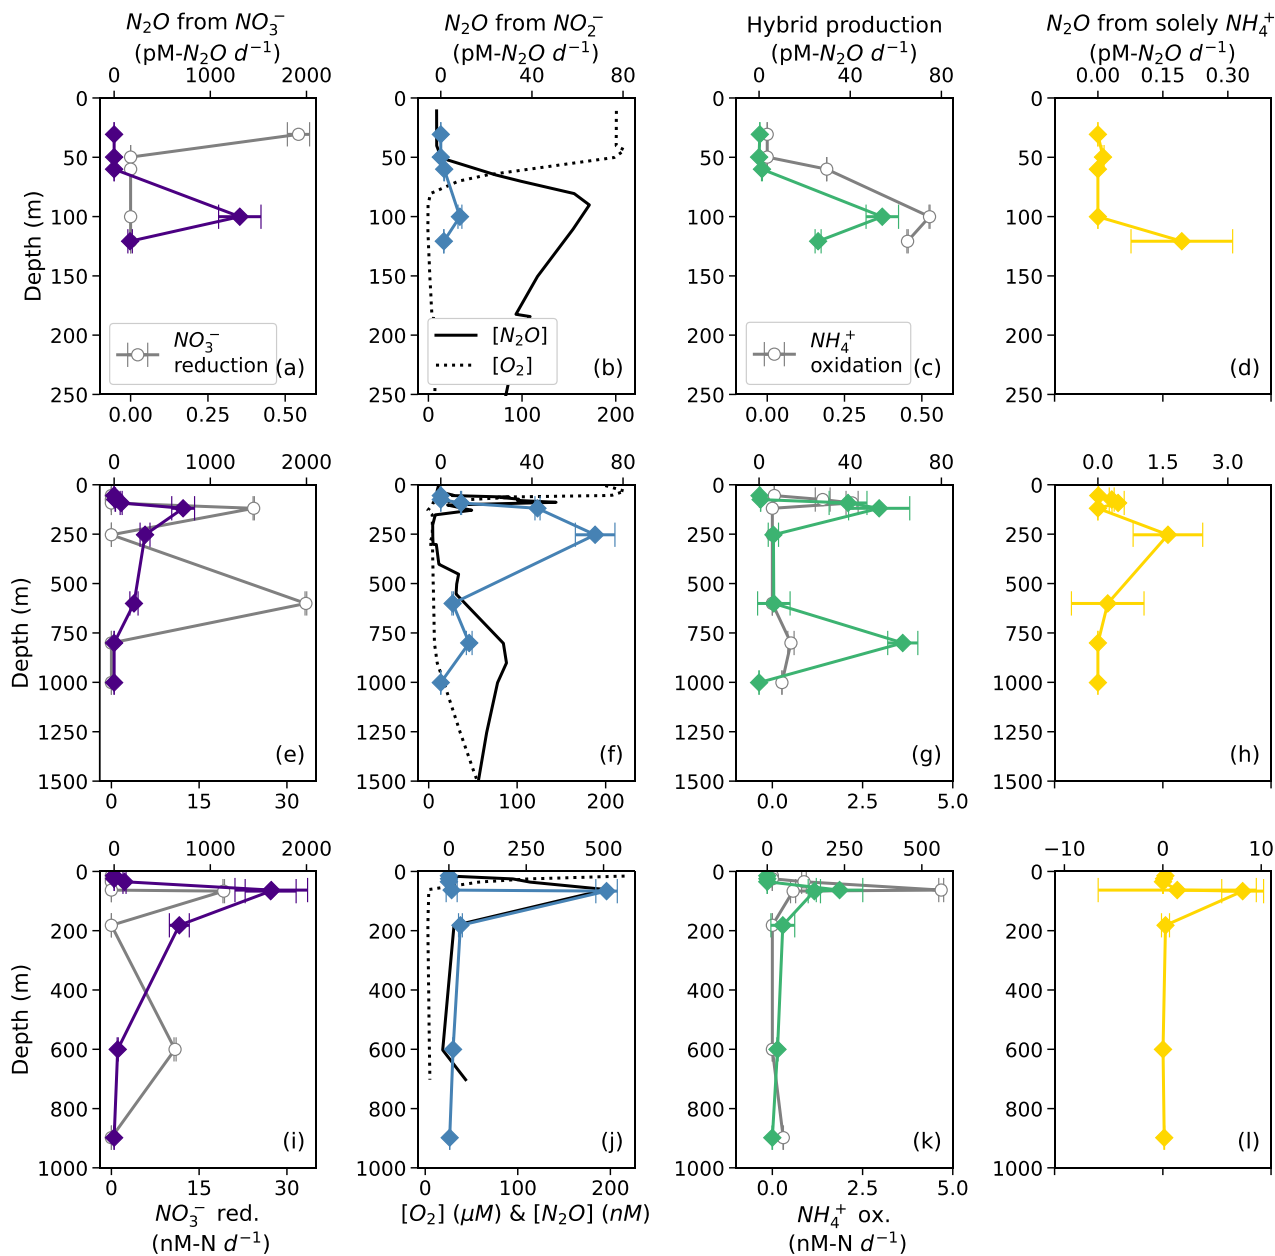

where  $p_{excess}^{45}$  is excess production of  $^{45}\text{N}_2\text{O}$  above and beyond that expected for a process drawing both nitrogen atoms from the same pool and  $p^{45}$  is the measured net production of  $^{45}\text{N}_2\text{O}$ . The equations for  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  are the same as eqn. (19), except for the factor of 2. In many of the  $^{15}\text{N}\text{-NH}_4^+$  experiments, there was significant excess  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  production (Fig. S7a). Similarly, there was significant excess  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  production in many of the  $^{15}\text{N}\text{-NO}_2^-$  experiments, although this was harder to discern due to the wider range of atom fractions in these experiments (Fig. S7b). In a few experiments, excess  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  production diverged.

### 3.4 $\text{N}_2\text{O}$ production mechanisms and yields (model results)

Based on model results, the rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  (denitrification using cellular  $\text{NO}_2^-$ , Fig. 2) were the highest among the  $\text{N}_2\text{O}$  production processes measured in this study. In suboxic to anoxic depths, the rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  were orders of magnitude higher than all the other  $\text{N}_2\text{O}$  production rates (Fig. 6).  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  reached its maximum value ( $1600\pm 400$  pM  $\text{N}_2\text{O}/\text{day}$ , Table S4) at the depth of the near surface  $[\text{N}_2\text{O}]$  maximum at every station (Fig. 6a, e, i), where there were also high rates of  $\text{NO}_3^-$  reduction to  $\text{NO}_2^-$  at stations PS2 and PS3 (Fig. 6e, i).  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  (denitrification using extracellular  $\text{NO}_2^-$ ; Fig. 2) exhibited lower rates, with a maximum of  $510\pm 30$  pM  $\text{N}_2\text{O}/\text{day}$  (Table S4). At stations PS1 and PS3,  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  peaked at the depth of the near surface  $[\text{N}_2\text{O}]$  maximum (Fig. 6b, j); at station PS2,  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  was observed in the near surface  $[\text{N}_2\text{O}]$  maximum but peaked in the secondary  $\text{NO}_2^-$  maximum (253 m, Fig. 6f).

Hybrid  $\text{N}_2\text{O}$  production occurred at a similar rate as  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$ , ranging from  $0.061\pm 0.005$  pM  $\text{N}_2\text{O}/\text{day}$  to  $230\pm 80$  pM  $\text{N}_2\text{O}/\text{day}$ . Hybrid  $\text{N}_2\text{O}$  production peaked within the near surface  $[\text{N}_2\text{O}]$  maximum at all stations (Fig. 6c, g, k). At station PS2, hybrid  $\text{N}_2\text{O}$  production exhibited the highest rates at the same depths as  $\text{NH}_3$  oxidation, with a secondary peak in the deep  $[\text{N}_2\text{O}]$  maximum (Fig. 6g). At station PS3, hybrid  $\text{N}_2\text{O}$  production, like  $\text{NH}_3$  oxidation, exhibited a small, significant rate at 898 m, which was very close to the bottom depth at station PS3 (Table S4).

$\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  occurred at the smallest rates overall, ranging from  $0.010\pm 0.004$  pM  $\text{N}_2\text{O}/\text{day}$  to  $8\pm 2$  pM  $\text{N}_2\text{O}/\text{day}$  (Table S4).  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  peaked around the near-surface  $[\text{N}_2\text{O}]$  maximum at each station (Fig. 6d, h, l), as well as in the secondary  $\text{NO}_2^-$  maximum at station PS2 (Fig. 6h).

490 **Figure 6.**  $N_2O$  production from  $NO_3^-$  (a, e, i, indigo diamonds),  $N_2O$  production from  $NO_2^-$  (b, f, j, blue diamonds), hybrid  $N_2O$  production (c, g, k, green diamonds), and  $N_2O$  production from solely  $NH_4^+$  (d, h, l, yellow diamonds) at stations PS1 (a–d), PS2 (e–h), and PS3 (i–l). Panels a, e, and i also show rates of  $NO_3^-$  reduction to  $NO_2^-$  (open circles). Panels b, f, and j show depth profiles of dissolved  $[O_2]$  (dashed lines) and  $[N_2O]$  (solid lines, from Kelly et al., 2021). Panels c, g, and k show rates of  $NH_3$  oxidation (gray circles).  $N_2O$  production rate error bars are calculated from 100 model optimizations, varying key parameters by up to 25%. Note the different x-axis scales for  $NO_3^-$  reduction to  $NO_2^-$  (a, e, i, bottom),  $N_2O$  production (top),  $[O_2]$  and  $[N_2O]$  (b, f, j, bottom), and  $NH_3$  oxidation (c, g, k, bottom).

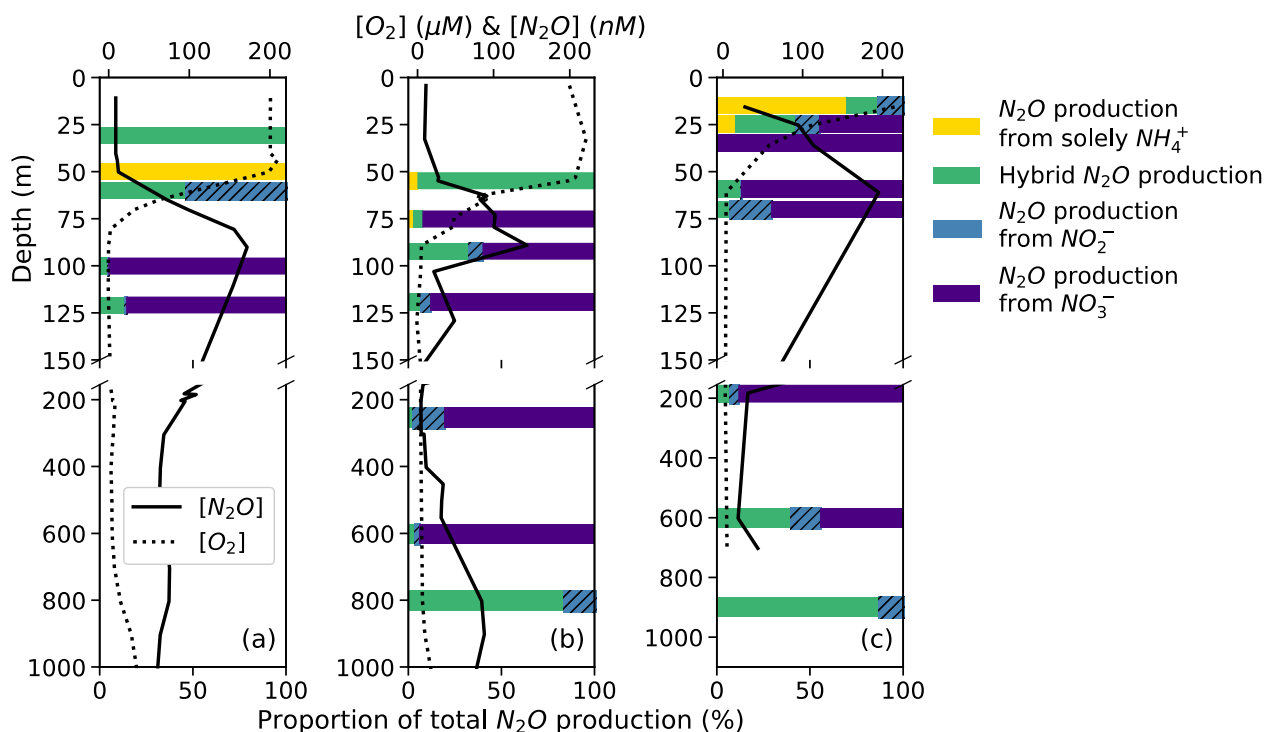

495 The percentage of N<sub>2</sub>O production from NH<sub>4</sub><sup>+</sup> comprised by hybrid N<sub>2</sub>O was calculated as:

$$\% \text{ hybrid} = \frac{\text{hybrid } N_2O \left( nM \text{ } N_2O / \text{day} \right)}{N_2O \text{ from hydroxylamine} \left( nM \text{ } N_2O / \text{day} \right) + \text{hybrid } N_2O \left( nM \text{ } N_2O / \text{day} \right)} \quad (20)$$

On average, hybrid N<sub>2</sub>O production was 86±28% of N<sub>2</sub>O production from NH<sub>4</sub><sup>+</sup>. Hybrid N<sub>2</sub>O production was > 75% of the total N<sub>2</sub>O production from NH<sub>4</sub><sup>+</sup> at all stations and depths except for the top of the oxycline at station PS1 (Fig. 7a), the middle of the oxycline at station PS2 (Fig. 7b), and the top of the oxycline at station PS3 (Fig. 7c), where it comprised 0%, 68%, and 19% of N<sub>2</sub>O production from NH<sub>4</sub><sup>+</sup>, respectively. Hybrid production as a percentage of total N<sub>2</sub>O production from NH<sub>4</sub><sup>+</sup> declined with increasing dissolved oxygen (Fig. S8), although more measurements are needed to fully evaluate this trend.

The percentage of hybrid N<sub>2</sub>O production as a proportion of total N<sub>2</sub>O production was more variable and tended to decline with decreasing dissolved oxygen as production from NO<sub>3</sub><sup>-</sup> increased (Fig. 7). Hybrid N<sub>2</sub>O production was greater than 75% of total N<sub>2</sub>O production only at the surface at station PS1 (Fig. 7a), the top of the oxycline and deep [N<sub>2</sub>O] maximum at station PS2 (Fig. 7b), and the deep [N<sub>2</sub>O] maximum at station PS3 (Fig. 7c).

N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> comprised a much greater proportion of total N<sub>2</sub>O production overall (Fig. 7). In the near-surface [N<sub>2</sub>O] maximum at station PS1, N<sub>2</sub>O production was predominantly (95.4%) from NO<sub>3</sub><sup>-</sup>, with smaller contributions from hybrid production (4.0%) and denitrification from NO<sub>2</sub><sup>-</sup> (0.6%; Fig. 7a). In the near-surface [N<sub>2</sub>O] maximum at station PS2, N<sub>2</sub>O was produced 60.2% from NO<sub>3</sub><sup>-</sup>, 32.1% from hybrid production, 7.3% from NO<sub>2</sub><sup>-</sup>, and 0.4% from solely NH<sub>4</sub><sup>+</sup> (Fig. 7b). In the near-surface [N<sub>2</sub>O] maximum at station PS3, N<sub>2</sub>O production was 87.0% from NO<sub>3</sub><sup>-</sup>, 12.4% from hybrid production, 0.5% from NO<sub>2</sub><sup>-</sup>, and 0.1% from solely NH<sub>4</sub><sup>+</sup> (Fig. 7c).

515 **Figure 7.**  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  (yellow bars), hybrid  $\text{N}_2\text{O}$  production (green bars),  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  (blue hatched bars), and  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  (indigo bars) as proportions of total  $\text{N}_2\text{O}$  production at stations PS1 (a), PS2 (b), and PS3 (c). Data are plotted over depth profiles of dissolved  $[\text{O}_2]$  (dashed lines) and  $[\text{N}_2\text{O}]$  (solid lines, from Kelly et al., 2021). Note broken y-axes and different x-axis scales for  $[\text{O}_2]$  and  $[\text{N}_2\text{O}]$  (top) and proportions (bottom).

### 3.5 Oxygen dependence of $\text{N}_2\text{O}$ production

520 The oxygen dependencies of  $\text{N}_2\text{O}$  production pathways were determined by fitting model derived  $\text{N}_2\text{O}$  production pathways vs.  $[\text{O}_2]$  using the following rate law:

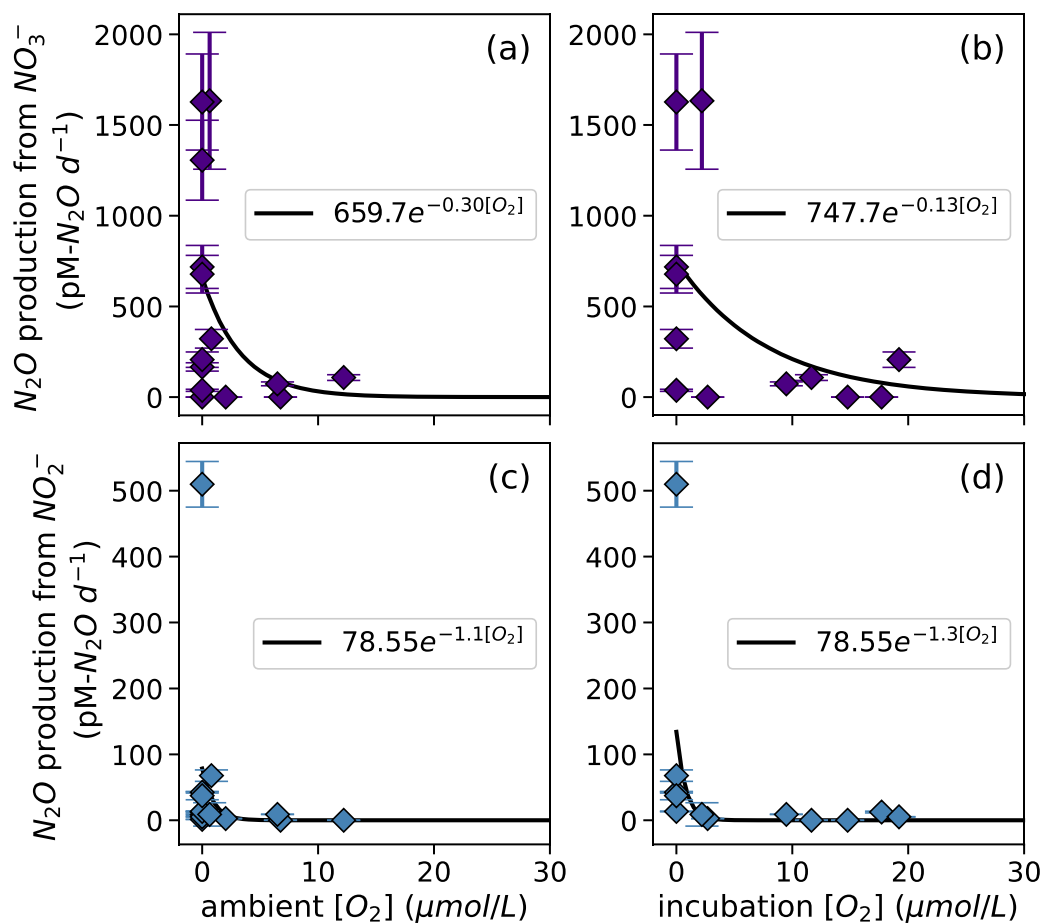

$$\text{rate} = ae^{-b[\text{O}_2]} \quad (21)$$

525 In this analysis, both ambient  $[\text{O}_2]$  measured by the Sea-Bird sensor mounted on the rosette (“ambient  $[\text{O}_2]$ ”) and  $[\text{O}_2]$  measured by chemiluminescent optodes mounted inside incubation bottles (“incubation  $[\text{O}_2]$ ”) were examined. The rate dependencies on ambient and incubation  $[\text{O}_2]$  reflect both preconditioning (i.e., the ambient  $[\text{O}_2]$  in which the microbial community was living before the incubation experiment), and response to perturbation (i.e., the experimental conditions inside the incubation bottles, if different from the environment). Those incubations that had higher incubation  $[\text{O}_2]$  than the ambient  $[\text{O}_2]$ , had received small oxygen perturbations.

N<sub>2</sub>O production via denitrification exhibited an exponentially declining relationship with dissolved O<sub>2</sub>, where N<sub>2</sub>O production from NO<sub>2</sub><sup>-</sup> was more inhibited by dissolved O<sub>2</sub> than N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> (Fig. 8). When looking at the oxygen dependence of denitrification, we found several instances of N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> via denitrification with dissolved [O<sub>2</sub>] greater than 3 μM (Fig. 8a–b). For example, at the oxic–anoxic interface at station PS2, where ambient [O<sub>2</sub>] was 6.49 μM and incubation [O<sub>2</sub>] was 6.29±0.07 μM (Table S1), N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> was 70±10 pM N<sub>2</sub>O/day (Fig. 6e, Table S4). N<sub>2</sub>O production from NO<sub>2</sub><sup>-</sup> at the same station and depth was 8.9±0.2 pM N<sub>2</sub>O/day (Fig. 6f, Table S4). Similarly, at the oxic–anoxic interface of station PS3, where ambient [O<sub>2</sub>] was 12.48 μM and incubation [O<sub>2</sub>] was 6.64±0.03 μM (Table S1), N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> was 120±20 pM N<sub>2</sub>O/day (Fig. 6i, Table S4). There were also two anoxic depths at station PS2 that were not sparged with He before tracer addition (“base of ODZ” and “deep ODZ core”), where ambient [O<sub>2</sub>] was below detection but incubation [O<sub>2</sub>] was significantly elevated (17.7±0.1 μM and 19.2±0.8 μM, respectively; Table S1). At these depths, N<sub>2</sub>O production from NO<sub>2</sub><sup>-</sup> was 12±1 pM N<sub>2</sub>O/day and 5.2±0.4 pM N<sub>2</sub>O/day, respectively (Fig. 6f, Table S4). N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> at the “deep ODZ core” depth was 210±40 pM N<sub>2</sub>O/day (Table S4).

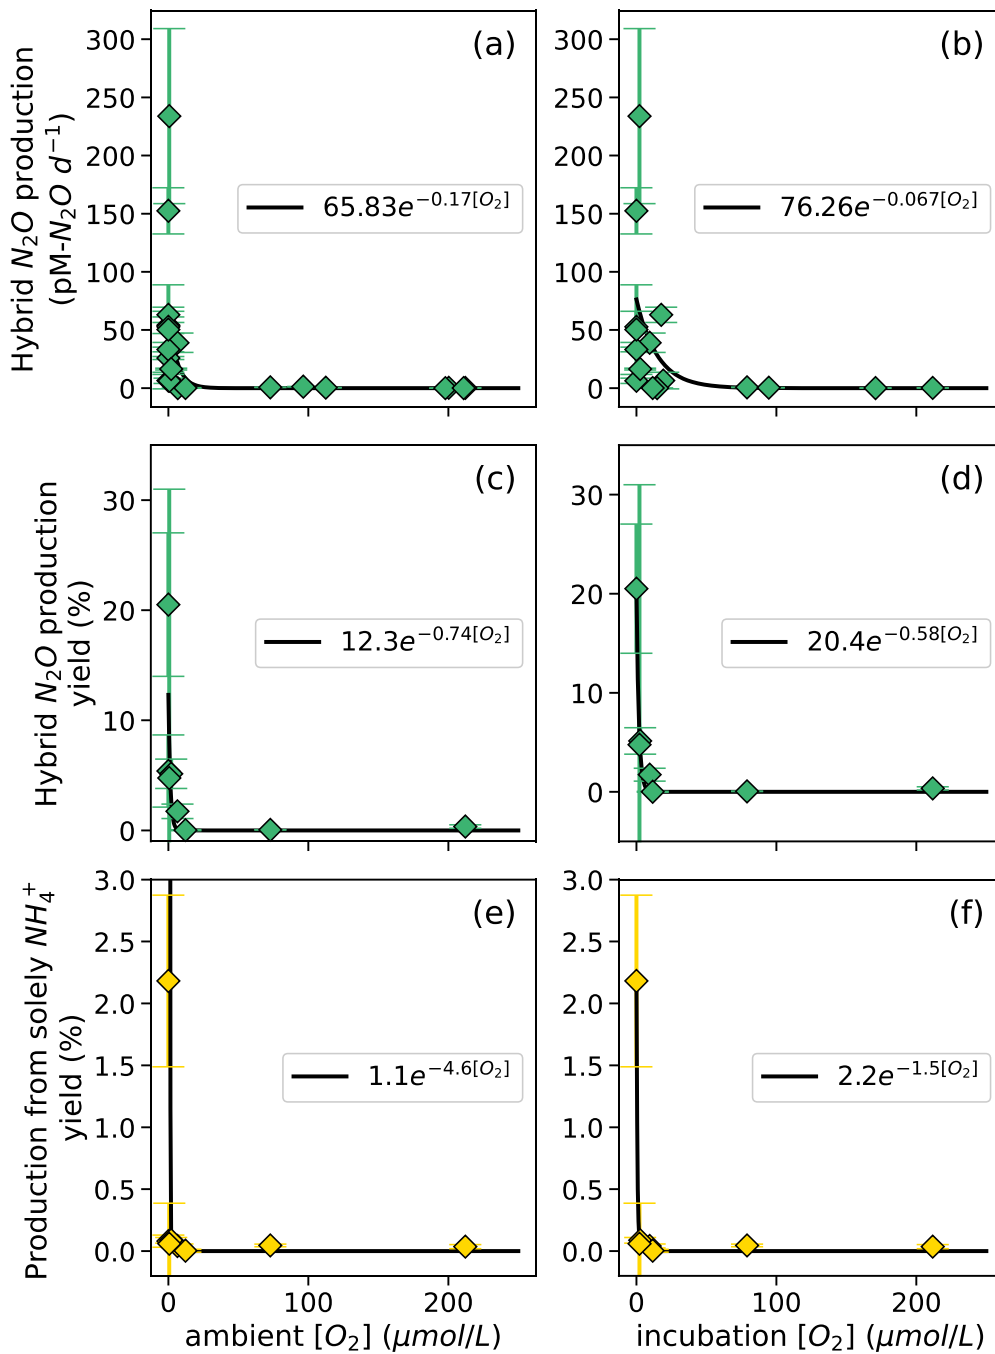

540

**Figure 8.** N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> via denitrification (a, b) and from NO<sub>2</sub><sup>-</sup> via denitrification (c, d), measured at a range of [O<sub>2</sub>] measured by a Seabird sensor (a, c) or by chemiluminescent optodes mounted inside incubation bottles (b, d). Curves of form yield =  $ae^{-O_2b}$  are fit through the data (black lines); values of  $a$  and  $b$  are shown in white boxes in each plot.

545

Hybrid N<sub>2</sub>O production rates also decreased exponentially with increasing dissolved [O<sub>2</sub>] (Fig. 9a–b). Fitting hybrid rates vs. ambient [O<sub>2</sub>] produced a rate Eq. (21) with  $a = 65.83$  and  $b = 0.17$  (Fig. 9a); hybrid rates vs. incubation [O<sub>2</sub>] produced fits with  $a = 76.26$  and  $b = 0.067$  (Fig. 9b).

550 **Figure 9.** Hybrid  $N_2O$  production rates (a,b),  $N_2O$  yield (%) during hybrid production (c, d), and  $N_2O$  yield (%) during production from solely  $NH_4^+$  (e, f) along a range of ambient  $[O_2]$  measured by a Seabird sensor for the Niskin bottles from which samples were taken (a, c, e) and  $[O_2]$  measured by chemiluminescent optodes mounted inside incubation bottles (b, d, f). Error bars are calculated from 100 model optimizations, varying key parameters by up to 25%. Yields are only calculated at stations and depths where rates

555 of NH<sub>3</sub> oxidation are greater than 0. Curves of form rate =  $ae^{-b[O_2]}$  are fit through the data (black lines); values of  $a$  and  $b$  are shown in white boxes in each plot.

The rate of N<sub>2</sub>O production from solely NH<sub>4</sub><sup>+</sup> also decreased exponentially with increasing dissolved [O<sub>2</sub>]. The highest rates of N<sub>2</sub>O production from solely NH<sub>4</sub><sup>+</sup> occurred in the secondary chlorophyll maximum at station PS3 (Table S4), where dissolved oxygen was below detection. N<sub>2</sub>O yield during production from solely NH<sub>4</sub><sup>+</sup> also exhibited exponentially decreasing relationships with dissolved [O<sub>2</sub>] (Fig. 9e–f). To ensure mass balance in terms of NH<sub>4</sub><sup>+</sup> consumption (Fig. S9), N<sub>2</sub>O yield (%) during production from solely NH<sub>4</sub><sup>+</sup> was calculated as:

$$\text{yield (\%)} = \frac{2 \left[ N_2O \text{ from solely } NH_4^+ \left( \frac{nM N_2O}{\text{day}} \right) \right]}{2 \left[ N_2O \text{ from solely } NH_4^+ \left( \frac{nM N_2O}{\text{day}} \right) \right] + \text{hybrid } N_2O \left( \frac{nM N_2O}{\text{day}} \right) + NH_3 \text{ oxidation} \left( \frac{nM N}{\text{day}} \right)} \quad (22)$$

where N<sub>2</sub>O production from solely NH<sub>4</sub><sup>+</sup> is in units of nM N<sub>2</sub>O/day, hybrid N<sub>2</sub>O production is in units of nM N<sub>2</sub>O/day, and NH<sub>3</sub> oxidation to NO<sub>2</sub><sup>-</sup> is in units of nM N/day. This assumes that the formation of N<sub>2</sub>O from solely NH<sub>4</sub><sup>+</sup> draws two nitrogen atoms from the NH<sub>4</sub><sup>+</sup> pool, while hybrid N<sub>2</sub>O production and the oxidation of NH<sub>4</sub><sup>+</sup> to NO<sub>2</sub><sup>-</sup> each draw one atom from the NH<sub>4</sub><sup>+</sup> pool (Fig. S9). Following the same convention, N<sub>2</sub>O yield (%) during hybrid production was calculated as:

$$\text{yield (\%)} = \frac{\text{hybrid } N_2O \left( \frac{nM N_2O}{\text{day}} \right)}{2 \left[ N_2O \text{ from solely } NH_4^+ \left( \frac{nM N_2O}{\text{day}} \right) \right] + \text{hybrid } N_2O \left( \frac{nM N_2O}{\text{day}} \right) + NH_3 \text{ oxidation} \left( \frac{nM N}{\text{day}} \right)} \quad (23)$$

The maximum N<sub>2</sub>O yield from hybrid production was 21±7% (Fig. 9c, d), while the maximum N<sub>2</sub>O yield during production from solely NH<sub>4</sub><sup>+</sup> was 2.2±0.7% (Fig. 9e, f). N<sub>2</sub>O yield during production from solely NH<sub>4</sub><sup>+</sup> declined more sharply with increased O<sub>2</sub> than N<sub>2</sub>O yield during hybrid production (Fig. 9c–f).

## 570 4 Discussion

In this study, we found that N<sub>2</sub>O production from denitrification was the dominant source of N<sub>2</sub>O both within the ODZ and in the upper oxycline. Hybrid N<sub>2</sub>O production was a smaller but significant contributor to N<sub>2</sub>O in the upper oxycline, and the primary source of N<sub>2</sub>O in the deep oxycline. N<sub>2</sub>O production from solely NH<sub>4</sub><sup>+</sup> – which includes N<sub>2</sub>O from hydroxylamine oxidation, hybrid production with cellular NO<sub>2</sub><sup>-</sup>, and nitrifier–denitrification with cellular NO<sub>2</sub><sup>-</sup> – was negligible everywhere except surface waters. Our findings of equal formation of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> in most experiments indicate that N<sup>α</sup> retains an equal proportion of NO<sub>2</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup>-derived N during hybrid production, which may imply that hybrid N<sub>2</sub>O production exhibits a constant δ(<sup>15</sup>N<sup>sp</sup>). All of the processes measured in this study exhibited a strong dependence on dissolved oxygen, although denitrification was less inhibited by dissolved oxygen than previous work would suggest.

#### 4.1 Rates of N<sub>2</sub>O production via denitrification

580 Based on our rate data, N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> is the dominant source of N<sub>2</sub>O in both the near-surface [N<sub>2</sub>O] maximum and the anoxic ODZ core. This agrees well with natural abundance isotopocule measurements in the ETNP, which indicate that the near surface [N<sub>2</sub>O] maximum is likely to be comprised of ~80% N<sub>2</sub>O produced via denitrification and ~20% N<sub>2</sub>O produced via nitrification or archaeal N<sub>2</sub>O production, producing a local minimum in  $\delta(^{15}\text{N}^{\text{sp}})$  (Kelly et al., 2021). Natural abundance isotopomer work has shown that N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> could be an important source of N<sub>2</sub>O in the anoxic  
585 core of ODZs, as long as it has a positive  $\delta(^{15}\text{N}^{\text{sp}})$  (Casciotti et al., 2018; Kelly et al., 2021; Monreal et al., 2022). While denitrification is generally accepted to produce N<sub>2</sub>O with  $\delta(^{15}\text{N}^{\text{sp}}) \approx 0\%$  (Sutka et al., 2006; other refs), some strains of denitrifying bacteria can produce N<sub>2</sub>O with  $\delta(^{15}\text{N}^{\text{sp}}) = 10\text{--}22\%$  (Toyoda et al., 2005; Wang et al., 2023) and denitrifying fungi produce N<sub>2</sub>O with  $\delta(^{15}\text{N}^{\text{sp}}) = 35\text{--}37\%$  (Lazo-Murphy et al., 2022; Rohe et al., 2014; Sutka et al., 2008; Yang et al., 2014). Here, the dominance of N<sub>2</sub>O production from <sup>15</sup>N-NO<sub>3</sub><sup>-</sup>, combined with parallel natural abundance isotopomer studies,  
590 suggest that strains of denitrifying bacteria and fungi that produce N<sub>2</sub>O with a high site preference may be important contributors to N<sub>2</sub>O in the core of ODZs. The importance of N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> also presents an important exception to the modular view of the microbial nitrogen cycle network, which holds that intermediates are passed externally from one cell to the next, rather than being held internally (Kuypers et al., 2018). N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup> that utilizes an internal NO<sub>2</sub><sup>-</sup> pool is currently left out of most biogeochemical models of nitrogen cycling in and around oxygen-deficient zones  
595 (Bianchi et al., 2023), and modeling work is needed that includes this as a source of N<sub>2</sub>O.

#### 4.2 Pathways of hybrid N<sub>2</sub>O production and implications for hybrid $\delta(^{15}\text{N}^{\text{sp}})$

Hybrid N<sub>2</sub>O production peaked in the same depths as NH<sub>3</sub> oxidation (Fig. 6c, g, k), which were also the depths at which ammonia-oxidizing archaea were most abundant (Frey et al., 2023), consistent with N<sub>2</sub>O production associated with ammonia-oxidizing archaea. At most stations and depths, the production of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> in both the <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> and <sup>15</sup>N-NH<sub>4</sub><sup>+</sup>  
600 experiments were roughly equal. From this we conclude that during hybrid formation, N<sup>α</sup> and N<sup>β</sup> each retained nitrogen atoms derived from both NH<sub>4</sub><sup>+</sup> and NO<sub>2</sub><sup>-</sup>. The equal formation of <sup>45</sup>N<sub>2</sub>O<sup>α</sup> and <sup>45</sup>N<sub>2</sub>O<sup>β</sup> led to values of *f* within error of 0.5 in most of our experiments (Table S4), and the mean value of *f* across all stations and depths was 0.5±0.2. This means that during hybrid N<sub>2</sub>O production, half of the N<sup>α</sup> atoms were derived from NO<sub>2</sub><sup>-</sup>, and half were derived from NH<sub>4</sub><sup>+</sup> (likewise for N<sup>β</sup>).

605 Although our data do not allow us to comment directly on the enzymatic machinery of hybrid N<sub>2</sub>O formation, our data can be used to theorize hypothetical pathways for hybrid N<sub>2</sub>O production. Firstly, we see much higher rates of hybrid production using ambient NO<sub>2</sub><sup>-</sup> (Pathway 3 in Wan et al., 2023) than hybrid production using cellular NO<sub>2</sub><sup>-</sup> (Pathway 2 in Wan et al., 2023). Again, this agrees with the results of Wan et al. (2023), who see higher rates of hybrid formation from extracellular NO<sub>2</sub><sup>-</sup> within the range of [<sup>15</sup>N-NH<sub>4</sub><sup>+</sup>]/[NO<sub>2</sub><sup>-</sup>] covered by our experiments. In our model, hybrid N<sub>2</sub>O production is operationally  
610 defined as a 1:1 combination of N derived from NH<sub>4</sub><sup>+</sup> and NO<sub>2</sub><sup>-</sup>, which is generally consistent with previous work (Stieglmeier

et al., 2014). Any combination of N derived from  $\text{NO}_2^-$  with a second N derived from  $\text{NO}_2^-$  would be included in the modeled quantity of  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$ ; likewise, any combination of N derived from  $\text{NH}_4^+$  with a second N derived from  $\text{NH}_4^+$  would be included in the  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$ . The question, then, is what reaction would be specific enough to have one N derived from each substrate, but not specific enough to govern  $^{15}\text{N}$  placement in the resulting  $\text{N}_2\text{O}$ ? One such  
615 reaction could be the combination of  $\text{NH}_4^+$  and  $\text{NO}_2^-$  to form a symmetrical intermediate such as hyponitrous acid ( $\text{HONNOH}$ , or hyponitrite  $^-\text{ONNO}^-$  in its deprotonated form), which has been discussed as a possible intermediate in hybrid nitrous oxide formation (Wei et al., 2019). Hyponitrous acid may react to form  $\text{N}_2\text{O}$  via breakage of one of the N–O bonds, resulting in  $\text{N}_2\text{O}$  that contains a 1:1 ratio of  $\text{NH}_4^+:\text{NO}_2^-$ . With a precursor such as hyponitrite or hyponitrous acid, equal formation of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  could be achieved with non-selective N–O bond breakage.

620

These findings of equal  $^{45}\text{N}_2\text{O}$  production have important implications for the natural abundance  $\delta(^{15}\text{N}^{\text{sp}})$  of  $\text{N}_2\text{O}$  produced by the hybrid  $\text{N}_2\text{O}$  process. Assuming that hybrid  $\text{N}_2\text{O}$  production proceeds through a symmetrical intermediate in which  $\text{NH}_4^+$  and  $\text{NO}_2^-$  are paired in a 1:1 ratio, we can model  $\delta(^{15}\text{N}^{\text{sp}})$  as:

$$\delta(^{15}\text{N}^{\text{sp}}) = \delta(^{15}\text{N}^\alpha) - \delta(^{15}\text{N}^\beta)$$

$$= [f\delta(^{15}\text{N} - \text{NO}_2^-) + (1 - f)\delta(^{15}\text{N} - \text{NH}_4^+)] - [(1 - f)\delta(^{15}\text{N} - \text{NO}_2^-) + f\delta(^{15}\text{N} - \text{NH}_4^+) - \varepsilon] \quad (24)$$

625 where  $f$  is the proportion of the  $\alpha$  nitrogen derived from  $\text{NO}_2^-$  and the proportion of the  $\beta$  nitrogen derived from  $\text{NH}_4^+$ , and  $\varepsilon$  is the fractionation factor associated with  $\text{N}^\beta\text{--O}$  bond breakage. If  $f \neq 1/2$ , hybrid  $\delta(^{15}\text{N}^{\text{sp}})$  retains a dependence on the  $\delta(^{15}\text{N})$  of the substrates – or more accurately, the difference in  $\delta(^{15}\text{N})$  of the two substrates; if the  $\delta(^{15}\text{N})$  of the substrates is equal, it will cancel out regardless of  $f$ . If  $\delta(^{15}\text{N}\text{--}\text{NH}_4^+) > \delta(^{15}\text{N}\text{--}\text{NO}_2^-)$ , as is generally the case in the secondary nitrite maximum (Buchwald et al., 2015; Casciotti, 2016), then low values of  $f$  should produce high hybrid  $\delta(^{15}\text{N}^{\text{sp}})$ , and high values of  $f$  should produce  
630 low hybrid  $\delta(^{15}\text{N}^{\text{sp}})$  (Fig. 10). If, however,  $f = 1/2$ , as was the case for most experimental depths in this study, hybrid  $\delta(^{15}\text{N}^{\text{sp}})$  should depend only on  $\varepsilon$  and not the isotopic composition of each substrate. This means that a  $\delta(^{15}\text{N}^{\text{sp}})$  endmember could potentially be established for hybrid  $\text{N}_2\text{O}$  production, even though hybrid  $\text{N}_2\text{O}$  production draws from different substrate pools. Wei et al. (2019) discuss possible pathways or end members of hybrid  $\text{N}_2\text{O}$  formation, i.e. via cis-hyponitrous acid, trans-hyponitrous acid and nitramide, all leading to  $\text{N}_2\text{O}$  with different  $\delta(^{15}\text{N}^{\text{sp}})$  values. More studies are needed to determine the  
635  $\delta(^{15}\text{N}^{\text{sp}})$  of  $\text{N}_2\text{O}$  produced by ammonia-oxidizing archaea under a range of conditions.

The unequal production of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  observed at certain depths led to values of  $f$  significantly different from 0.5 (Table S4). At these depths,  $\text{N}^\alpha$  retained a different proportion of nitrogen derived from  $\text{NO}_2^-$  and  $\text{NH}_4^+$  than  $\text{N}^\beta$ , causing  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  to diverge. The depths with  $f \neq 0.5$  anchored significant relationships between  $f$  and ambient  $[\text{O}_2]$  ( $R^2 =$   
640  $0.84$ ,  $p < 0.001$ ; Fig. S10a) and potential density anomaly ( $\sigma_\theta$ ) ( $R^2 = 0.72$ ,  $p < 0.001$ ; Fig. S10b). The oxygen and potential

density gradients may be proxies for changing archaeal community compositions at different depths in the water column, which may exhibit different patterns of incorporation of  $\text{NO}_2^-$ -derived N and  $\text{NH}_4^+$ -derived N into  $\text{N}^\alpha$  and  $\text{N}^\beta$ . It is also possible that we sampled a different “hybrid”  $\text{N}_2\text{O}$ -producing process at these depths, such as fungal co-denitrification (Shoun et al., 2012), which may proceed via a different pathway from archaeal hybrid  $\text{N}_2\text{O}$  production.

645

**Figure 10.** Simulated values of  $\delta(^{15}\text{N}^{\text{sp}})$  calculated with a range of  $f$  (the proportion of  $\text{N}^\alpha$  derived from  $\text{NO}_2^-$  during hybrid  $\text{N}_2\text{O}$  production) and  $\delta(^{15}\text{N}-\text{NH}_4^+) - \delta(^{15}\text{N}-\text{NO}_2^-)$ , assuming  $\epsilon = 30.3\%$  (Santoro et al., 2011). Results are shaded by  $\delta(^{15}\text{N}-\text{NH}_4^+) - \delta(^{15}\text{N}-\text{NO}_2^-)$ . When  $f$  is less than or greater than  $\frac{1}{2}$ , there is the potential for  $\delta(^{15}\text{N}^{\text{sp}})$  to depend on the isotopic compositions of each substrate.

650

### 4.3 Rates of nitrification and $\text{N}_2\text{O}$ production from solely $\text{NH}_4^+$

The rates of  $\text{N}_2\text{O}$  production from  $\text{NH}_4^+$  in this study – i.e. the sum of hybrid  $\text{N}_2\text{O}$  production and  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  – peaked at  $240 \pm 80$  pM  $\text{N}_2\text{O}/\text{day}$  (Table S4). These were similar to those measured on the same cruise by Frey et al. (2023), who measured rates of  $\text{N}_2\text{O}$  production from  $\text{NH}_4^+$  in the oxycline of 28 – 149 pM  $\text{N}_2\text{O}/\text{day}$  (Frey et al., 2023). The low rates of  $\text{NH}_3$  oxidation to  $\text{NO}_2^-$  in this study (0.05 – 4.68 nM N/day) were also similar to those measured by Frey et al. (2023), who measured  $\text{NH}_3$  oxidation rates of 1.0 – 11.7 nM/day in the oxycline.  $\text{NH}_3$  oxidation rates in this study were smaller

655

than those measured on the same cruise by Travis et al. (2023), who measured  $\text{NH}_3$  oxidation rates as high as  $90 \pm 2$  nM/day in fully oxygenated incubations at station PS3. The highest rates of  $\text{NO}_2^-$  oxidation we observed occurred in anoxic depths at stations PS2 and PS3 (Fig. 3e, h), which agrees with mounting evidence suggesting the importance of  $\text{NO}_2^-$  oxidation in apparently anoxic regions (Sun et al., 2017, 2021b).

When  $[\text{O}_2]$  was less than  $10 \mu\text{M}$ , the rates of hybrid  $\text{N}_2\text{O}$  production ( $6 - 230 \text{ pM N}_2\text{O/day}$ ) were orders of magnitude greater than the rates of  $\text{N}_2\text{O}$  production from solely  $\text{NH}_4^+$  at the same depths ( $0 - 8 \text{ pM N}_2\text{O/day}$ ) (Fig. 6). Indeed, at the upper oxic-anoxic interface, the rates of hybrid  $\text{N}_2\text{O}$  production were on a similar order of magnitude to  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  via denitrification ( $8 - 510 \text{ pM N}_2\text{O/day}$ ). These results agree with previous work showing that hybrid  $\text{N}_2\text{O}$  formation represents a high percentage of total  $\text{N}_2\text{O}$  production from  $\text{NH}_4^+$  in the ETNP and eastern tropical South Pacific (ETSP) (Frey et al., 2020, 2023). The results in this study also agree with recent culture work: the  $^{15}\text{N-NH}_4^+$  experiments in this study fell along a range of  $[\text{N}_2\text{O}]/[\text{NO}_2^-]$  of 0.14–0.5, in which Wan et al. (2023) found that hybrid  $\text{N}_2\text{O}$  production occurred at a rate two to four times greater than  $\text{N}_2\text{O}$  production via hydroxylamine oxidation (N derived from solely  $\text{NH}_4^+$ ) in cultures of *Nitrosopumilus maritimus*.

We found three depths near the surface where hybrid production comprised a smaller percentage (0%–68%) of total  $\text{N}_2\text{O}$  production from  $\text{NH}_4^+$  (Fig. 7a–c). Previous work in the ETNP found that hybrid  $\text{N}_2\text{O}$  production always comprised  $> 90\%$  of  $\text{N}_2\text{O}$  production from  $\text{NH}_4^+$  (Frey et al., 2023), and where our samples overlapped with this previous work, we observed similarly high proportions of hybrid production (Fig. 5). The depths where we observed a smaller proportion of hybrid production had not been sampled previously; it is possible that we sampled different microbial communities there, acclimated to different levels of  $\text{NH}_4^+$ ,  $\text{NO}_2^-$ , and dissolved oxygen. We also found that hybrid  $\text{N}_2\text{O}$  formation generally comprised a small proportion of total  $\text{N}_2\text{O}$  production, which was dominated by  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$ , especially at suboxic depths (Fig. 7d–h). This is similar to previous findings from the ETSP, which showed that hybrid formation comprised 0 – 95% of total  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  along the natural  $[\text{O}_2]$  gradient (Frey et al., 2020). This large range is due to the large range of rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$ , which can occur at orders of magnitude higher or lower than hybrid  $\text{N}_2\text{O}$  production.

#### 4.4 Oxygen dependence of $\text{N}_2\text{O}$ production rates and yields

$\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  and  $\text{NO}_3^-$  exhibited exponential dependence on dissolved oxygen, albeit with smaller maximum rates than those found in the ETSP (Frey et al., 2020; Ji et al., 2015). Most surprising were the significant rates of  $\text{N}_2\text{O}$  production via denitrification at  $[\text{O}_2] > 3 \mu\text{M}$  (Fig. 8a–d), which has previously been suggested as the threshold above which denitrification ceases (Dalsgaard et al., 2014). These observations are particularly evident in the plots of  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  vs. incubation  $[\text{O}_2]$  (Fig. 8b), where positive, significant rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  were evident in incubations containing  $[\text{O}_2]$  as high as  $19.2 \pm 0.8 \mu\text{M}$  (PS2 Deep ODZ Core experiment). One explanation for  $\text{N}_2\text{O}$  production via denitrification at such high levels of ambient dissolved oxygen is particle-associated denitrification (Bianchi et al., 2018;

690 Smriga et al., 2021; Wan et al., 2023a). Fungal denitrification may also have contributed to these fluxes, since denitrifying fungi can tolerate a higher level of oxygen than their bacterial counterparts. Additionally, denitrifying microbial communities acclimatized to lower ambient  $[O_2]$  may be able to continue to produce  $N_2O$  when  $[O_2]$  is suddenly increased.

These results showed that  $N_2O$  production from  $NO_3^-$  can occur in  $[O_2]$  as high as  $19.2 \pm 0.8 \mu M$ , which is similar to results  
695 from the ETSP showing that  $N_2O$  production from  $NO_3^-$  in manipulated  $[O_2]$  as high as  $30 \mu M$  (Frey et al., 2020). The volume of suboxic water in the ocean has been increasing over the last 50 years and will likely continue to expand over the 21<sup>st</sup> century (Oschlies et al., 2018; Schmidtko et al., 2017; Stramma et al., 2008), although the extent of this deoxygenation remains uncertain (Bianchi et al., 2018; Busecke et al., 2022; Cabré et al., 2015). Constraining the window of oxygen concentrations under which denitrification leads to  $N_2O$  production will be key to understanding how marine deoxygenation and  $N_2O$  cycling  
700 will interact.

While this study and others have found that hybrid  $N_2O$  production represents a consistent *percentage* of  $N_2O$  production from  $NH_4^+$  along a range of ambient  $[O_2]$  (Frey et al., 2020, 2023), the *rate* of hybrid  $N_2O$  production followed a clear exponential dependence on dissolved oxygen (Fig. 9). The differences in ambient and incubation  $[O_2]$  resulted in slight differences in the  
705 coefficients for each yield curve; nevertheless, hybrid rates plotted along both ambient and incubation  $[O_2]$  gradients exhibited remarkably similar  $[O_2]$  inhibition curves, with the highest rates at  $[O_2] < 7 \mu M$ . These results are similar to those of Frey et al. (2023), who showed a decrease in  $N_2O$  production from  $NH_4^+$  with increasing  $[O_2]$ .

The maximum  $N_2O$  yield for hybrid production (21%; Fig. 8c,d) was an order of magnitude higher than previous estimates of  
710  $N_2O$  yields during  $NH_3$  oxidation from ETSP and ETNP, which did not include hybrid  $N_2O$  production (Ji et al., 2018). These high yields occurred at the oxic–anoxic interface at Station PS1 and just below the oxic–anoxic interface at Station PS3, where ambient  $[O_2]$  was below detection but  $NH_3$  oxidation still occurred (Fig. 3). This indicates the potential for extremely high yields of  $N_2O$  from hybrid production where  $NH_3$  oxidation is active in suboxic to anoxic environments.

$N_2O$  yields during production from solely  $NH_4^+$  also increased with decreasing  $[O_2]$  (Fig. 9,b), as previously reported (Frey et al., 2020; Goreau et al., 1980; Ji et al., 2018; Nevison et al., 2003).  $N_2O$  yields during production from solely  $NH_4^+$  increased sharply with decreasing  $[O_2]$  along both ambient and incubation  $[O_2]$  gradients but were much smaller than the yields from hybrid  $N_2O$  production (Fig. 8c–d). The maximum yields during production from solely  $NH_4^+$  were similar to the maximum yields found by another study in the ETNP, which were around 3% (Frey et al., 2023), and much higher than yields from  
720 ammonia–oxidizing archaea in soils and culture (up to 0.03%) (Hink et al., 2017b, a).

## 4.5 Experimental artifacts

Care was taken to minimize the effects of experimental set-up on the microbial communities in each sample. In addition to the steps taken to prevent oxygen contamination (described in Sect. 2 Methods), a relatively short 24-hour incubation period was selected to minimize bottle effects and shifts in the microbial community composition over the course of each incubation.

725 Nonetheless, sample collection, preparation and incubation conditions could have affected the microbial communities in several ways. First, samples were frequently collected from depths where the water temperature was cooler than that of the laboratory, and while samples were returned to a cool temperature during incubation (12° C), they were exposed to warmer temperatures (>20° C) during the two hours in which they underwent collection and manipulation prior to incubation. Likewise, during this interval, samples were exposed to higher light levels before being returned to the dark for incubation. While oxygen

730 contamination was minimized during sample collection, it was not eliminated entirely, and a temporary oxygen intrusion before sparging may have poisoned certain anaerobic processes. The 90-minute sparge also likely removed carbon dioxide in addition to oxygen and N<sub>2</sub>O, increasing the pH of each sample. Finally, the NH<sub>4</sub><sup>+</sup> and NO<sub>2</sub><sup>-</sup> tracer and carrier additions exceeded the ambient concentrations of these substrates, potentially stimulating the rates of processes that rely on these substrates. All of these perturbations, while common among incubation studies, may have affected the microbial community

735 differentially in each sample. Thus, the results presented here represent processes able to withstand these perturbations to ambient environmental conditions. Any abiotic reactions between the HgCl<sub>2</sub> preservative and NO<sub>2</sub><sup>-</sup> tracer and carrier would have shifted all three timepoints equally, and thus should not introduce a bias into the slopes of <sup>15</sup>N-labeled N<sub>2</sub>O with time and the rates calculated there from.

## 4.6 Alternate sources of N<sub>2</sub>O

740 Other processes may have contributed to N<sub>2</sub>O production in our samples. A complementary set of experiments found that fungal denitrification comprised 50% of total N<sub>2</sub>O production via denitrification in the secondary chlorophyll *a* maximum depths discussed here (Peng and Valentine, 2021). Additionally, since our samples were unfiltered, particle associated N<sub>2</sub>O production and consumption may have occurred in some of our experiments, especially in experiments at the highly productive coastal station. We cannot rule out any of these alternative sources of N<sub>2</sub>O in our samples, so we consider these processes as

745 potential contributors to the bulk denitrifying flux discussed here.

## 5. Conclusions

We applied N<sub>2</sub>O isotopocule measurements to <sup>15</sup>N tracer incubations to measure N<sub>2</sub>O production rates and mechanisms in the ETNP. We found that N<sub>2</sub>O production rates peaked at the oxic-anoxic interface above the ODZ, with the highest rates of N<sub>2</sub>O production from NO<sub>3</sub><sup>-</sup>. Hybrid N<sub>2</sub>O production peaked in both the shallow and deep oxyclines, where NH<sub>3</sub> oxidation was also

750 active, and exhibited yields as high as 21% of ammonia oxidation.

Based on the equal production of  $^{45}\text{N}_2\text{O}^\alpha$  and  $^{45}\text{N}_2\text{O}^\beta$  in the vast majority of our experiments, we posit a two-step process for hybrid  $\text{N}_2\text{O}$  production involving an initial bond-forming step that draws nitrogen atoms from each substrate to form a symmetric intermediate, and a second bond-breaking step that breaks an N–O bond in the symmetric intermediate to form  $\text{N}_2\text{O}$ . From this, we infer that hybrid  $\text{N}_2\text{O}$  production likely has a consistent  $\delta(^{15}\text{N}^{\text{sp}})$ , despite drawing from two distinct substrate pools. This has important implications for the interpretation of natural abundance isotopocule measurements, since it implies that it may be possible to define a  $\delta(^{15}\text{N}^{\text{sp}})$  endmember for hybrid  $\text{N}_2\text{O}$  formation. More culture experiments are needed to quantify the  $\delta(^{15}\text{N}^{\text{sp}})$  of  $\text{N}_2\text{O}$  produced by ammonia-oxidizing archaea under different temperatures, oxygen levels, and ratios of  $\text{NH}_4^+:\text{NO}_2^-$ .

760

$\text{N}_2\text{O}$  production rates and yields of every process examined here were inhibited by dissolved oxygen. The  $\text{N}_2\text{O}$  yield from hydroxylamine oxidation was most sensitive to  $\text{O}_2$ , followed by the rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_2^-$  via denitrification, hybrid  $\text{N}_2\text{O}$  production, and  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  via denitrification. Indeed, we measured positive, significant rates of  $\text{N}_2\text{O}$  production from  $\text{NO}_3^-$  at ambient  $[\text{O}_2]$  as high as 12.5  $\mu\text{M}$ , and at manipulated  $[\text{O}_2]$  as high as 19.2  $\mu\text{M}$ . These denitrifying fluxes may have derived partially from fungal  $\text{N}_2\text{O}$  production, since fungal denitrifiers can tolerate higher oxygen levels than bacteria (Peng and Valentine, 2021), or particle-associated denitrification (Bianchi et al., 2018; Smriga et al., 2021). These results suggest that a broad window of  $[\text{O}_2]$  could support net  $\text{N}_2\text{O}$  accumulation and additional studies are needed to further constrain this window and the resulting feedbacks between denitrification and marine deoxygenation.

765

## 6. Appendix A: Estimating uncertainties for nitrate isotope analyses from tracer samples

Since only 2 mL of sample was available for preparation and analysis of nitrate isotopes using the denitrifier method, it was not possible to always achieve consistent peak areas. Instead of discarding low peak area samples, however, we wanted to establish a method to estimate the uncertainties associated with individual samples, based on their peak area. This uncertainty arises from a correction scheme for  $\delta(^{15}\text{N})$  that assumes constant blank:sample quantity ratios. What follows is a method for estimating this uncertainty, using the slope and intercept of the calibration curve and blank peak area.

775

In brief, the first step of this method is to calculate the peak area and  $\delta(^{15}\text{N})$  of the blank for an individual run (batch of bacteria) using the slope and intercept of the nitrate isotope calibration curve (Casciotti et al., 2002). Then, a range of theoretical measured  $\delta(^{15}\text{N})$  is calculated for a set of dummy samples based on a range of “actual”  $\delta(^{15}\text{N})$ , a range of theoretical peak areas, and the peak area and  $\delta(^{15}\text{N})$  of the blank. Then, we correct each of these theoretical measured  $\delta(^{15}\text{N})$  values with the calibration curve, as one would do normally, to obtain  $\delta(^{15}\text{N}_{\text{corrected}})$  for each dummy sample. We estimate the error for each dummy sample by comparing the  $\delta(^{15}\text{N}_{\text{corrected}})$  we have calculated to the  $\delta(^{15}\text{N}_{\text{sample}})$  we have assigned to it. Then, for each run (and associated blank), we can fit a function through these errors, their corresponding peak areas, and corresponding

780

$\delta(^{15}\text{N}_{\text{sample}})$ . We can then feed this function the peak area and measured  $\delta(^{15}\text{N})$  of actual samples in that run to estimate their uncertainties.

785

In practice, we start with a simple mass balance that states that the measured  $\delta(^{15}\text{N})$  is a function of the sample  $\delta(^{15}\text{N})$ , sample peak area  $A_{\text{sample}}$ , blank  $\delta(^{15}\text{N})$ , and blank peak area  $A_{\text{blank}}$ :

$$\delta(^{15}\text{N}_{\text{measured}})(A_{\text{measured}}) = \delta(^{15}\text{N}_{\text{sample}})(A_{\text{sample}}) + \delta(^{15}\text{N}_{\text{blank}})(A_{\text{blank}}) \quad (\text{A1})$$

where  $\delta(^{15}\text{N}_{\text{measured}})$  is the measured  $\delta(^{15}\text{N})$ ,  $A_{\text{measured}}$  is the measured peak area,  $\delta(^{15}\text{N}_{\text{sample}})$  is the actual sample  $\delta(^{15}\text{N})$ ,  $A_{\text{sample}}$  is the peak area attributable to sample N,  $\delta(^{15}\text{N}_{\text{blank}})$  is the  $\delta(^{15}\text{N})$  of the blank, and  $A_{\text{blank}}$  is the peak area attributable to blank N. Dividing through by  $A_{\text{measured}}$ :

790

$$\delta(^{15}\text{N}_{\text{measured}}) = \delta(^{15}\text{N}_{\text{sample}}) \left( \frac{A_{\text{sample}}}{A_{\text{measured}}} \right) + \delta(^{15}\text{N}_{\text{blank}}) \left( \frac{A_{\text{blank}}}{A_{\text{measured}}} \right) \quad (\text{A2})$$

Eqn. (A2) can be expressed as a linear equation  $y = mx + b$ , where  $m$  is the slope of  $\delta(^{15}\text{N}_{\text{measured}})$  vs.  $\delta(^{15}\text{N}_{\text{sample}})$  and  $b$  is the y-intercept. Thus:

$$m = \left( \frac{A_{\text{sample}}}{A_{\text{measured}}} \right) \quad (\text{A3})$$

$$b = \delta(^{15}\text{N}_{\text{blank}}) \left( \frac{A_{\text{blank}}}{A_{\text{measured}}} \right) \quad (\text{A4})$$

We can obtain the mean blank peak area  $A_{\text{blank}}$  from the slope and the mean peak area of the measured reference materials ( $A_{\text{measured}}$ ):

$$\left( \frac{A_{\text{blank}}}{A_{\text{measured}}} \right) = 1 - \left( \frac{A_{\text{sample}}}{A_{\text{measured}}} \right) = 1 - (m) \quad (\text{A5})$$

$$A_{\text{blank}} = [1 - (m)](A_{\text{measured}}) \quad (\text{A6})$$

795 Finally, we obtain  $\delta(^{15}\text{N}_{\text{blank}})$  from:

$$\delta(^{15}\text{N}_{\text{blank}}) = b / \left( \frac{A_{\text{blank}}}{A_{\text{measured}}} \right) = \frac{b}{1 - (m)} \quad (\text{A7})$$

We assign the dummy samples a range of theoretical measured peak areas  $A_{\text{measured}}$ . The ratio of the blank peak area to the measured peak areas for a given sample is given by dividing  $A_{\text{blank}}$  (calculated from eqn. A6) by this theoretical peak area to

obtain  $\left(\frac{A_{blank}}{A_{measured,i}}\right)$ , where  $A_{measured,i}$  is the theoretical peak area for that sample. Then, the ratio of sample peak area to measured peak area for a given theoretical sample is given by:

$$\left(\frac{A_{sample}}{A_{measured,i}}\right) = 1 - \left(\frac{A_{blank}}{A_{measured,i}}\right) \quad (A8)$$

800 As a first example, we assign all of the theoretical samples the same  $\delta(^{15}N_{sample})$  of 180‰. Then, to obtain a range of theoretical measured  $\delta(^{15}N_{measured})$ , we plug the  $\delta(^{15}N_{blank})$  calculated from eqn. (A7), the range of theoretical peak areas  $A_{measured,i}$  and this  $\delta(^{15}N_{sample})$  into eqn. (A2):

$$\delta(^{15}N_{measured,i}) = 180\text{‰} \cdot \left(\frac{A_{sample}}{A_{measured,i}}\right) + \delta(^{15}N_{blank}) \left(\frac{A_{blank}}{A_{measured,i}}\right) \quad (A9)$$

We correct the range of  $\delta(^{15}N_{measured,i})$  calculated from eqn. (A9) with the slope and intercept of the calibration curve  $\delta(^{15}N_{sample})$  vs.  $\delta(^{15}N_{measured})$ :

$$\delta(^{15}N_{corrected,i}) = m \left(\frac{A_{sample}}{A_{measured,i}}\right) + b \quad (A10)$$

805 Then we calculate the error associated with each dummy sample using:

$$\delta(^{15}N_{error}) = |\delta(^{15}N_{corrected,i}) - 180\text{‰}| \quad (A11)$$

Following this exercise with a range of theoretical peak areas from 0.5 Vs to 10 Vs produces the following curve (Fig. A1). It shows that these theoretical errors increase as peak area decreases, reflecting the basis of the error.

810 **Figure A1.  $\delta(^{15}\text{N}_{\text{error}})$  vs. peak area for a range of dummy samples with measured peak areas from 0.5 Vs to 10 Vs, based on a blank peak area of 0.15 Vs and  $\delta(^{15}\text{N}_{\text{blank}})$  of  $-69.3\%$ .**

Repeating this exercise with a range of  $\delta(^{15}\text{N}_{\text{sample}})$  values from  $-20\%$  to  $180\%$ , produces a 3D version of this curve (Fig. A2). This shows that the estimated uncertainty is highest for samples with  $\delta(^{15}\text{N}_{\text{sample}})$  most divergent from  $\delta(^{15}\text{N}_{\text{blank}})$  and for the peak areas most divergent from the reference materials.

815 **Figure A2.  $\delta(^{15}\text{N}_{\text{error}})$  vs. peak area and  $\delta(^{15}\text{N}_{\text{sample}})$  for a range of dummy samples with peak areas from 0.5 Vs to 10 Vs and  $\delta(^{15}\text{N}_{\text{sample}})$  from  $-20\%$  to  $180\%$ , based on a blank peak area of 0.15 Vs and  $\delta(^{15}\text{N}_{\text{blank}})$  of  $-69.3\%$ .**

Finally, we fit a function of the following form through these theoretical data:

$$\delta(^{15}\text{N}_{\text{error}}) = a \cdot e^{c \cdot A_{\text{sample}}} + d \cdot \delta(^{15}\text{N}_{\text{sample}}) \quad (\text{A12})$$

820 where  $a$ ,  $c$ , and  $d$  are constants,  $A_{\text{sample}}$  is the measured peak areas of the theoretical samples, and  $\delta(^{15}\text{N}_{\text{sample}})$  is the assigned value for the dummy samples.

This procedure was repeated for each denitrifier run to produce coefficients  $a$ ,  $c$ , and  $d$  specific to that set of analyses. Then, to estimate the uncertainty associated with each measurement, we used the corrected  $\delta(^{15}\text{N})$  for each sample's  $\delta(^{15}\text{N}_{\text{sample}})$ , and  
825 its measured peak area for  $A_{\text{sample}}$  in eqn. (A12).

### **Code and Data availability**

The data reported in this study can be found in the Stanford Digital Repository (<https://doi.org/10.25740/sS774md4840>). Forward-running model code is available via Zenodo (<https://doi.org/10.5281/zenodo.11475416>). pyisotopomer, which was used for N<sub>2</sub>O isotopocule data corrections, is available for installation via the Python Package index (<https://pypi.org/project/pyisotopomer/>) and Zenodo (<http://doi.org/10.5281/zenodo.7552724>).

### **Author contributions**

CLK and KLC conceptualized the study, with input from CF and BBW. CLK and NMT carried out the experiments at sea, with assistance and supervision from CF and BBW. CLK and PAB analyzed the incubation samples in the laboratory. CLK performed the formal analysis of the data, developed the model code, and performed the model optimizations. XS provided N<sub>2</sub>O consumption data for inclusion in the model. KLC acquired funding for the study. CLK prepared the manuscript with contributions from all co-authors.

### **Competing interests**

The authors declare that they have no conflict of interest.

### **Acknowledgements**

We would like to thank Stanford University and the Stanford Research Computing Center for providing computational resources and support that contributed to this research. We would also like to thank Julie Granger and three anonymous reviewers for their constructive feedback during the review process. This research was supported by U.S. NSF grant OCE-1657868 to K. L. Casciotti. C. L. Kelly was supported by an NSF Graduate Research Fellowship. The authors declare no competing financial interests.
