18 **Abstract**

19 Atmospheric particles can impact cloud formation and play a critical role in regulating
20 cloud properties. However, particle characteristics at the single particle level and their
21 ability to act as ice nucleating particles (INPs) over the marine atmosphere are poorly
22 understood. In this study, we present micro-spectroscopic characterizations and ice
23 nucleation properties of particles collected during a cruise from South Korea to
24 Antarctica in 2019. Most of the samples were dominated by fresh sea salt, aged sea salt,
25 and sea salt mixed with sulfate particles, with total number percentages ranging from
26 48% to 99% over the Western Pacific and the Southern Ocean. The mixing state index
27 of the particle population ranged from 50% to 95% over the northern and southern
28 hemispheres. Multiphase processes on sea salt particles resulted in chlorine deficiency.
29 This selective aging process made the marine particle population more externally mixed.
30 Ice nucleation onset conditions were measured and the investigated particles showed
31 diverse ice nucleation abilities. The fresh sea salt particles with organic coatings
32 exhibited the highest ice nucleation ability at a relative humidity with respect to ice as
33 low as 121%. The sea salt mixed sulfate particle was enriched in INPs by a factor of
34 1.9. Aging processes affected both particles' mixing state and their ice nucleation
35 abilities. Our analysis shows that assuming an internally mixed particle population in
36 the marine atmosphere can lead to errors of several orders of magnitude in predicting
37 ice nucleation rates.

40 **Keywords:** Ice nucleation, ice nucleating particles, single particle analysis, marine
41 aerosols, elemental composition, mixing state

42 **1. Introduction**

43 As 70.8% of the Earth's surface is covered by oceans, marine aerosol particles are one
44 of the most important types of natural aerosols in the global inventory (Myriokefalitakis
45 et al., 2010; De Leeuw et al., 2011). Aerosols in marine environments can affect the
46 ocean biogeochemical cycles and indirectly or directly affect Earth system's radiation
47 budget (Song et al., 2022). The sixth Intergovernmental Panel on Climate Change
48 (IPCC) assessment report highlights a significant uncertainty in predicting the net
49 effective radiative forcing of aerosols, with aerosol-cloud interactions contribute the
50 most (IPCC, 2021). The impacts of atmospheric particles on cloud microphysical
51 processes are still poorly understood (IPCC, 2013). The physicochemical properties of
52 particles determine their abilities to serve as cloud condensation nuclei (CCN) and INPs,
53 thereby affecting cloud microphysical processes. Particles serving as INPs can
54 potentially trigger ice nucleation via four pathways: (1) deposition ice nucleation (DIN),
55 which forms ice by the direct deposition of water vapor onto particle surface; (2)
56 immersion freezing (IMF), which droplet freezing is triggered by immersed particles;
57 (3) contact freezing, when droplets freeze by the contact with particles; (4)
58 condensation freezing, when droplets freeze as water vapor condenses on droplets or
59 particles. The majority of recent studies have focused on the IMF and DIN under mixed-
60 phase and ice cloud conditions (Hoose and Möhler, 2012; Murray et al., 2012; Kanji et
61 al., 2017; Knopf et al., 2018).

62
63 Diverse sources and atmospheric processes bring great challenges to the study of the
64 physicochemical properties of marine particles. One of the major particle types in the
65 marine atmosphere is sea spray aerosol (SSA) generated from wave breaking and
66 bubble bursting over the ocean surface. Their compositions are mainly affected by
67 seawater, sea ice, and biological activities and have minimum influence from
68 anthropogenic activities (Kunwar et al., 2023). Other sources may also contribute to
69 marine aerosols, such as ship emission (Ault et al., 2009, 2010) and long-range transport
70 of aerosols from industrial emission, biomass burning, dust storms, and fossil fuel

71 combustion (Han et al., 2006; Fu et al., 2013; Geng et al., 2019). In addition,
72 atmospheric oxidation of volatile organic compounds from the ocean or anthropogenic
73 activities results in gas-particle conversion, multiphase reactions, and the formation of
74 secondary materials on particles (Cochran et al., 2017). For example, dimethyl sulfide
75 (DMS) from marine sources can be oxidized to form methanesulfonic acid (MSA) and
76 sulfuric acid (H_2SO_4) in the atmosphere (Barnes et al., 2006; Chen et al., 2018; Berndt
77 et al., 2023). Moreover, multiphase reactions can occur on the surface or within particles
78 causing changes in the physicochemical properties of particles (Cochran et al., 2017).
79 The oxidation products of DMS (H_2SO_4 and MSA) can react with sea salt particles
80 resulting in chloride depletion from acid displacements (Liu et al., 2011).

81

82 Due to the diverse sources and dynamic evolution in the atmosphere, individual
83 particles become mixtures of various compositions and have complex morphologies.
84 Chemical mixing state is a term used to describe how various chemical species are
85 mixed within individual particles in an aerosol population (Riemer et al., 2019). Riemer
86 and West (2013) proposed a framework to quantify the chemical mixing state, which is
87 described later in Section 2.3. Quantifying the chemical mixing state helps us to discuss
88 how the population with different internal or external mixing affects its optical
89 properties, cloud formation properties, and climatic impacts (Riemer et al., 2019). It is
90 necessary to study the physical and chemical characteristics of individual particles as
91 well as how they are mixed in the population to quantify the fundamental details of
92 cloud microphysical processes (Cziczo et al., 2017; Kanji et al., 2017; Knopf et al.,
93 2018; Riemer et al., 2019; Burrows et al., 2022). Using single-particle techniques,
94 previous studies have focused on mixing states including but not limited to marine
95 particles (Ault et al., 2010; Park et al., 2014; Tomlin et al., 2021), biomass burning
96 aerosol (BBA) (Tomlin et al., 2022; Healy et al., 2013), and dust particles (Fraund et
97 al., 2017; Adachi et al., 2020). Previous studies have quantified the chemical mixing
98 state of an aerosol population using the mixing state index (χ), which is based on the
99 mass percentages of various chemical species in single particles within a population
100 (Riemer et al., 2019). However, there have been limited studies focusing on quantifying

101 χ from single particle component information of marine particles.
102
103 Laboratory and field studies have shown that various particle types have potential
104 impacts on atmospheric ice crystal formation. Natural INPs include mineral dust, soil
105 particles, volcanic ash, SSA, BBA, and bioaerosols. Anthropogenic INPs include
106 agricultural particles, metals and metal oxides from industrial processes, and fossil fuel
107 combustion particles (Hoose and Möhler, 2012; Murray et al., 2012; Kanji et al., 2017).
108 For marine related particles, Schill and Tolbert (2014) found that SSA are efficient INPs
109 below 225 K. Wagner et al. (2018) showed that SSA and desert dust particles share the
110 same order of magnitude of ice nucleation active surface site density (n_s) for deposition
111 nucleation. Previous studies have also shown that n_s for SSA is 2-3 orders of magnitude
112 lower than that for dust particles in immersion freezing (DeMott et al., 2016;
113 McCluskey et al., 2018a; Cornwell et al., 2019). Knopf et al. (2011) confirmed that
114 intact cells or fragments of marine diatoms can act as INPs. Wilson et al. (2015)
115 demonstrated that the sea surface microlayer is enriched with ice nucleating materials.
116 McCluskey et al. (2018b) identified two types of INPs from mesocosm experiments,
117 which were dissolved organic carbon coated particles and particulate organic carbon
118 particles like intact cells or cell fragments from microorganisms. Alpert et al. (2022)
119 confirmed that INPs in the SSA were the sea salt with organic matter, which were
120 exudates released from planktonic microorganisms. Inoue et al. (2021) found high INP
121 concentrations under high wave conditions which were related to the release of organic
122 carbon from the ocean. Welti et al. (2020) collected the INP concentration data over the
123 Arctic, Atlantic, Pacific, and Southern oceans. They found that ship-based INP
124 measurements over the oceans were 1 to 2 orders of magnitude lower than continental
125 observations. INP concentrations were lowest in the polar regions and highest in the
126 temperate climate ocean (Welti et al., 2020). Most of the field investigations over
127 oceans focus on the INP concentration measurements for IMF and at mixed-phase cloud
128 conditions with relatively warmer temperatures (Hoose and Möhler, 2012; Murray et
129 al., 2012; Kanji et al., 2017; Knopf et al., 2018). Recent field studies have used
130 advanced micro-spectroscopes and mass spectrometry to image and characterize the

131 INPs and ice crystal residuals to understand their nature (e.g., Cziczo et al., 2017; Knopf
132 et al., 2018). INPs and ice residuals are often mixtures of chemical species. Ice
133 nucleation is inherently related to the mixing state of particles because it depends on
134 the particle surface properties. Quantifying the ice nucleation rate also depends on the
135 details of composition, surface area, and the mixing state of the particle population. The
136 importance of mixing state for INPs is well recognized, but there are limited studies
137 focusing on its quantification which is poorly understood (Kanji et al., 2017; Knopf et
138 al., 2018; Riemer et al., 2019).

139

140 In this study, we quantified ice formation potential and elemental composition of
141 particles over coastal and open oceans using microscope-based ice nucleation
142 instrumentation and computer-controlled scanning electron microscopy with energy
143 dispersive X-ray spectroscopy (CCSEM/EDX), respectively. The mixing state of
144 particle population based on the elemental composition was derived for 29 marine
145 ambient particle populations extending from the northern to the southern hemisphere.
146 Ice nucleation onset conditions were measured and the INPs were identified for
147 representative samples. Individual INPs were characterized and compared with the
148 particle population to relate ice nucleation ability to the mixing state. Potential errors
149 in predicting ice nucleation rate were briefly discussed if models assume an internally
150 mixed population. We performed ice nucleation kinetic analysis based on the
151 experimental data and provided parameterizations for cloud modeling.

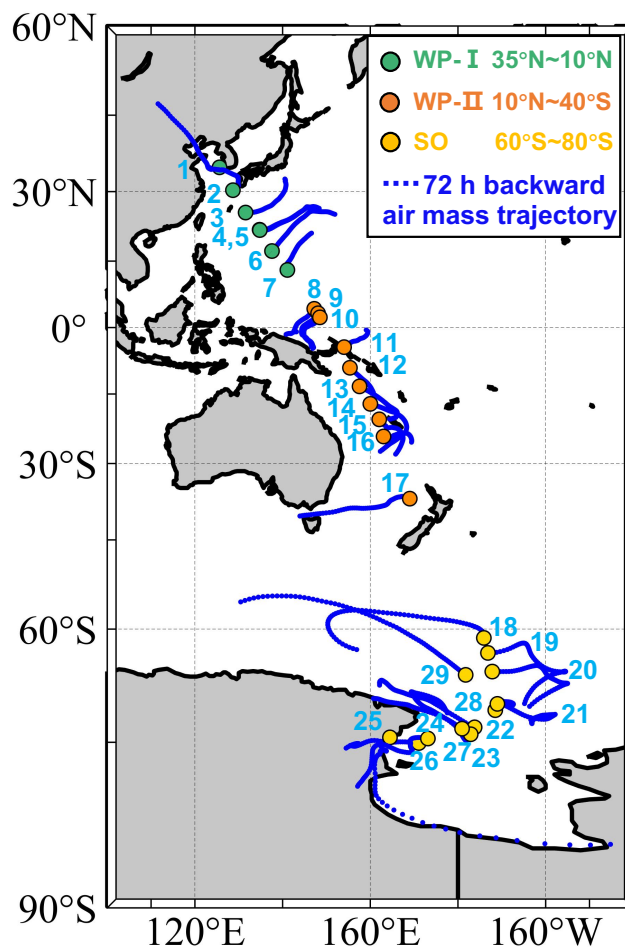

152

153 **2. Experimental methods**

154 **2.1 Particle sampling**

155 Aerosol particles were collected by a four-stage cascade impactor (SKC, Inc.) at a
156 sample flow of 9 L min^{-1} on board the Korean ice breaker R/V *Araon* from October 31st
157 to December 12nd in 2019. Particles were collected on the third and fourth stages of the
158 impactor with 50% collection efficiency at aerodynamic sizes of $0.5 \mu\text{m}$ and $0.25 \mu\text{m}$,
159 respectively. The inlet was located on the third deck of the ship at about 13 m above sea

160 surface level (Park et al., 2020). As shown in Fig. 1, the cruise crossed about 110
161 degrees of latitude from the Western Pacific near South Korea (34.93°N) to the Ross
162 Sea in the Southern Ocean (75.12°S). Samples were collected on transmission electron
163 microscopy (TEM) copper grids (Carbon Type-B, Ted Pella, Inc.) for single particle
164 analysis by CCSEM/EDX and silicon wafer chips (Silson, Ltd.) with the hydrophobic
165 coating (Si₃N₄) for ice nucleation experiments following our previous studies (Wang et
166 al., 2012a, 2016a; Knopf et al., 2014). Particles were collected simultaneously on these
167 two substrates which were placed side by side in the same impactor. Particle samples
168 were stored at room temperature in an airtight container with desiccant until analysis.
169 This study focuses on deposition ice nucleation at low temperatures and INP
170 identification. Particles with a smaller size range may have a longer lifetime and can
171 potentially be transported to higher altitudes in the atmosphere. Therefore, we limited
172 our analysis to the samples collected on the fourth stage. Meteorological conditions and
173 black carbon concentrations were measured by the onboard weather station and an
174 aethalometer (AE22, Magee Scientific Co., USA), respectively. When the relative wind
175 direction against the ship heading is between 110° and 260° and the relative wind speed
176 is below 2 m s⁻¹, samples may have been influenced by the ship exhaust (Park et al.,
177 2020). Potentially contaminated samples were excluded from the analysis, resulting in
178 a total of 29 selected samples. The sampling location and 72 h backward air mass
179 trajectories are shown in Fig. 1. Backward air mass trajectories were computed using
180 the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Stein
181 et al., 2015; Rolph et al., 2017). Detailed sampling information is listed in Table S1 and
182 includes the collecting time, location, and the corresponding meteorological data. Black
183 carbon concentration, air temperature, relative humidity, pressure, relative wind speed,
184 and wind direction are also shown in Fig. S1.

185

186 **Figure 1.** Sampling locations with HYSPLIT 72 h backward air mass trajectories. Solid circles
 187 indicate the sample locations. Samples were labeled by numbers. Green, orange, and yellow circles
 188 represent the samples in 35°N – 10°N of Western Pacific (WP-I), 10°N – 40°S of Western Pacific
 189 (WP-II), and 60°S – 80°S of Southern Ocean (SO) regions, respectively. Blue lines show the
 190 backward trajectories starting from 100 m above sea level.

191

192 **2.2 Chemical imaging and characterization of particles and INPs**

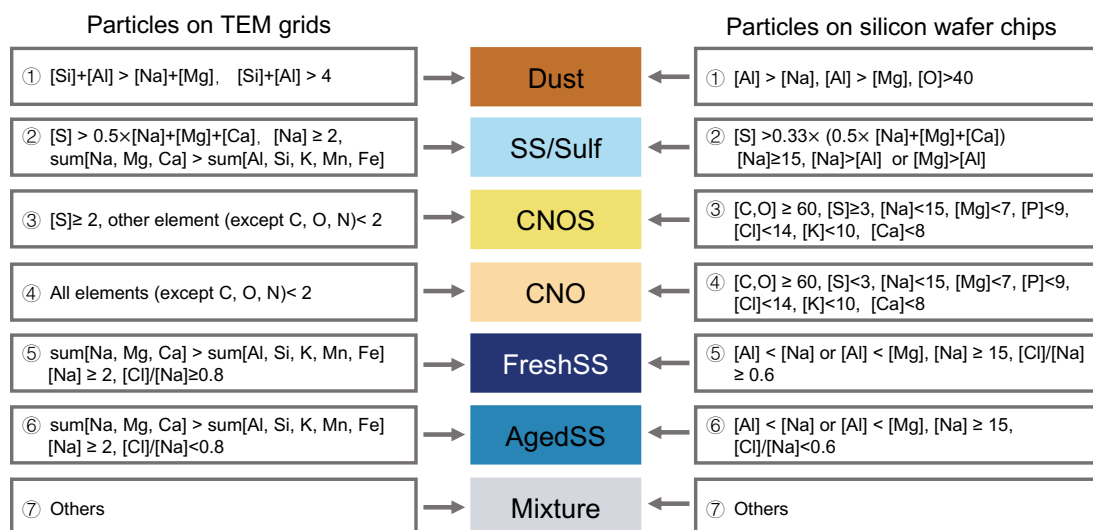

193 Chemical imaging and single particle analysis were used to obtain information on the
 194 morphology, size, and elemental composition of the particle population and INPs. The
 195 methods have been described in detail in previous work (Laskin et al., 2002, 2006, 2012;
 196 Wang et al., 2012a; Knopf et al., 2014; O’Brien et al., 2015) and are briefly introduced
 197 here. Samples collected on the TEM grids were analyzed using a scanning electron
 198 microscopy (Quanta 650, FEI Inc.) equipped with an energy dispersive X-ray

199 spectroscopy (Genesis, EDAX Inc.) in the computer-controlled mode (CCSEM/EDX).
200 CCSEM/EDX operating at 20 kV first detected the particles and determined their size.
201 The particle size reported here is the equivalent circle diameter (ECD) based on the
202 two-dimensional projected area of the particle as determined by CCSEM/EDX analysis.
203 Particles with a size (ECD) between 0.2 μm and 3 μm were included for analysis in this
204 study. The elemental composition of each particle was then quantified by determining
205 the relative atomic percentages of the selected elements, including C, N, O, Na, Mg, Al,
206 Si, P, S, Cl, K, Ca, Mn, and Fe. We obtained the elemental composition for a significant
207 number of particles, about 630 – 1480 particles for each sample depending on the
208 particle loading on the substrates (Table S1). We manually performed SEM/EDX
209 analysis to characterize the individual identified INPs on the silicon wafer chips after
210 ice nucleation experiments, as described later. In addition, about 10 particles that did
211 not nucleate ice (non-INPs) were randomly selected around each INP for SEM/EDX
212 analysis. X-ray spectra for the INPs and non-INPs were collected at 10 kV. The relative
213 atomic percentages of elements including C, O, Na, Mg, Al, P, S, Cl, K, and Ca were
214 quantified. N and Si were not included in the quantification due to their presence in the
215 background substrate.

216

217 The relative atomic percentage data were analyzed using a rule-based classification
218 method to assess the contributions of different particle types for each sample (Laskin et
219 al., 2012; Wang et al., 2012a; China et al., 2018; Lata et al., 2021). As shown in Fig. 2,
220 the classification scheme grouped particles into seven classes: *i*) “CNO” particles,
221 which mainly contain C, N, and O elements with traces of other elements. These are
222 carbonaceous particles such as black carbon, secondary or primary organic particles. *ii*)
223 “CNOS” particles, which mainly contain C, N, O, and S elements with traces of other
224 elements and are sulfates and other sulfur containing particles including their internal
225 mixtures with organics. *iii*) “FreshSS” particles, these are fresh sea salt particles
226 containing Na above a threshold level of 2% (atomic percentage) and the Cl/Na ratio
227 is > 0.8 . At the same time, the total atomic percentage of Na, Mg, and Ca, which are the
228 dominant cations in sea salt particles, is higher than that of other metals. CCSEM/EDX

229 analysis of fresh sea salt particles generated by nebulizing sea water shows that the
 230 Cl/Na ratio is slightly higher than 0.8 for particles at about 0.2 μm (Fig. S2). The
 231 samples we investigated contain a large number of small sea salt particles. Thus, we
 232 use a Cl/Na ratio of 0.8 as the threshold value to distinguish between the fresh and aged
 233 sea salt particles. *iv*) “AgedSS” particles, these are aged sea salt particles with Cl
 234 depletion and the Cl/Na ratio < 0.8. *v*) “SS/Sulf” particles, these are aged sea salt
 235 particles mixed with sulfur-containing compounds (e.g., sulfate) containing mainly Na
 236 and S without Cl. *vi*) “Dust” particles, these particles have the total atomic percentage
 237 of Al and Si above 4% and higher than the total atomic percentage of Na and Mg. They
 238 are likely from dust storms and road or soil emissions. *vii*) “Mixture” particles are all
 239 remaining particles that did not fit into the previous categories. The classification
 240 scheme for INPs and non-INPs on silicon wafer chips was modified to account for the
 241 Si and N background in the substrate. It is important to note that particles on either
 242 TEM grids or Si chips were collected at the same time using the same impactor, and
 243 therefore the contributions of the respective particle classes for the two are the same.
 244 Thus, we modified the classification scheme with this assumption.
 245

246
 247 **Figure 2.** Rule-based particle classification schemes for particles on TEM grids (left) and silicon
 248 wafer chips (right). Numbers in the schemes are the relative atomic percentages of corresponding
 249 elements or their ratios.

250

251 **2.3 Chemical mixing state**

252 Chemical mixing state was derived using a previous methodology based on mass and
253 entropy metrics (O'Brien et al., 2015; Riemer and West, 2013) and is described briefly
254 here. Particle mass was estimated from the density and volume of each particle.
255 Particles were assumed to be hemispherical and the volume of each particle was
256 calculated from the ECD obtained by CCSEM. Particle density was assigned according
257 to its classification, with FreshSS, AgedSS, SS/Sulf, CNO, CNOS, Dust, and Mixture
258 particles having a density of 2.0 g/cm³, 2.0 g/cm³, 1.7 g/cm³, 1.3 g/cm³, 1.3 g/cm³, 2.7
259 g/cm³, and 2.0 g/cm³, respectively (O'Brien et al., 2015; Tang et al., 2014). To calculate
260 the mass of each element in a particle, the atomic percentage of each element obtained
261 by EDX was converted to a weight percentage, and then multiplied by the mass of the
262 particle. For the particle i , the mass of element a is equal to:

$$263 \quad \mu_i^a = \mu_i \left(\frac{\text{elemental}\%^a \times \text{molar mass}^a}{\sum_{a=1}^A \text{elemental}\%^a \times \text{molar mass}^a} \right) \quad (1)$$

264 Where $a = 1, \dots, A$ (number of elements), $i = 1, \dots, N$ (number of particles), and μ_i is
265 the total mass of the i^{th} particle. a represents elements of Na, Mg, Al, Si, P, S, Cl, K, Ca,
266 Mn, and Fe, and for this list, $A = 11$. Note that C, N, and O are not included as these
267 three elements are semi-quantitative when EDX analysis is used (Laskin et al., 2006).

268

269 First, the total mass of element a in the particle population (μ^a), and the total mass of
270 the bulk particle population (μ) were calculated using the following equations,

$$271 \quad \mu^a = \sum_{i=1}^N \mu_i^a, \quad (2)$$

272 and

$$273 \quad \mu = \sum_{i=1}^N \mu_i. \quad (3)$$

274 Then, the mass fraction of element a in the i^{th} particle (p_i^a), the mass fraction of
275 individual particles (p^i) in the particle population, and the mass fraction of element a in
276 the bulk particle population (p^a) are

277
$$p_i^a = \frac{\mu_i^a}{\mu_i}, \quad (4)$$

278
$$p_i = \frac{\mu_i}{\mu}, \quad (5)$$

279 and

280
$$p^a = \frac{\mu^a}{\mu}. \quad (6)$$

281 Next, the following Shannon entropies (MacKay, 2003) were calculated, where the
282 mixing entropy of the i^{th} particle (H_i) is

283
$$H_i = \sum_{a=1}^A -p_i^a \ln p_i^a, \quad (7)$$

284 the average particle mixing entropy (H_a) is

285
$$H_a = \sum_{i=1}^N p_i H_i, \quad (8)$$

286 and the mass entropy of bulk particle population (H_γ) is

287
$$H_\gamma = \sum_{a=1}^A -p^a \ln p^a. \quad (9)$$

288 H_i and H_γ are used to describe the mass distribution of species (elements) with the i^{th}
289 particle or particle population, respectively. A higher entropy indicates a more uniform
290 distribution of elements in the individual particle or particle population whereas a lower
291 entropy towards a non-uniform mass distribution.

292

293 Individual particle diversity (D_i) is calculated by taking the exponent of H_i . D_i means
294 the effective number of elements in individual particles, or in other words, indicates the
295 distribution of elements in single particles. D_i ranges from the minimum value of 1
296 when the particle contains a single element to the maximum value of A when the particle
297 is composed of all A elements with equal mass. Particle elemental diversity (D_a) and
298 bulk population elemental diversity (D_γ) are calculated by taking the exponent of H_a
299 and H_γ , respectively. D_a indicates the average effective number of elements in particles.
300 D_γ indicates the effective number of elements in the whole particle sample.

301
$$D_i = e^{H_i} = \prod_{a=1}^A (p_i^a)^{-p_i^a} \quad (10)$$

302
$$D_\alpha = e^{H_\alpha} = \prod_{i=1}^N (D_i)^{p_i} \quad (11)$$

303
$$D_\gamma = e^{H_\gamma} = \prod_{a=1}^A (p^a)^{-p^a} \quad (12)$$

304 Mixing state index (χ) indicates the homogeneity or heterogeneity of the population and
 305 is defined as

306
$$\chi = \frac{D_\alpha - 1}{D_\gamma - 1} . \quad (13)$$

307 χ ranges from 0% for an externally mixed particle sample with a heterogeneous
 308 population composing single-component particles ($D_\alpha = 1$) to 100% for an internally
 309 well mixed particle sample with a homogeneous population where all particles have
 310 identical compositions.

311

312 **2.4 Ice nucleation experiment and INP identification**

313 Ice nucleation and water uptake by particles were examined following our previous
 314 studies (Knopf et al., 2011, 2014, 2022; Wang and Knopf, 2011; Wang et al., 2012b;
 315 Charnawskas et al., 2017; China et al., 2017; Alpert et al., 2022) and the methods are
 316 briefly introduced here. Onset conditions of the particle temperature (T_p) and relative
 317 humidity with respect to ice (RH_{ice}), when ice nucleation and water uptake occurred,
 318 were determined using a custom-built cryo-cooling system. The system consists of a
 319 water vapor control component, an ice nucleation cell (INC), and an optical microscope
 320 (OM). Prior to ice nucleation experiments, a particle sample collected on a silicon wafer
 321 was placed in the INC. Then, a humidified N₂ gas with targeted water vapor partial
 322 pressure was continuously introduced into INC at a flow rate of one standard liter per
 323 minute. The water partial pressure in the INC was determined by the dew point
 324 temperature (T_d) of the gas which was measured using a chilled mirror hygrometer (GE
 325 Sensing, Optica). After T_d was stable, T_p was set to about $T_d + 3$ K and $RH_{ice} < 100\%$.
 326 An ice nucleation experiment was started and T_p was cooled at a rate of 0.2 K min⁻¹.

327 Images of particle sample were recorded by OM every 0.02 K. T_d and T_p were recorded
328 every second throughout the experiment. Once ice formation was observed, the sample
329 was gradually warmed to 298 K to sublime and remove any ice that may be retained in
330 the pores or cavities of particles. Images of ice crystals were acquired during
331 sublimation at high magnification and the visible particle that served as the INP was
332 identified after complete crystal sublimation. The experiment was repeated 3 – 7 times
333 at similar T_d for reproducibility. Water uptake and ice formation by particles were
334 determined through visual observation and the changes in particle phase or size from
335 analyzing the recorded images using ImageJ software. through visual observation. DIN
336 and IMF were discriminated based on whether particles took up water before ice
337 formation. The freezing mechanism within the small droplets after the water uptake
338 could not be visualized due to the limited spatial resolution and imaging speed of the
339 OM used in this study. Thus, we assume that immersion freezing has occurred if the
340 RH_{ice} onset of freezing is lower than the homogeneous freezing limits. Only the
341 temperature and RH_{ice} conditions when the first ice crystal formed were reported. RH_{ice}
342 was derived from the measured T_d and T_p (Wang and Knopf, 2011). Particle surface
343 area available for ice nucleation for each sample was estimated from the particle
344 number and size derived from OM images, assuming that the particles were
345 hemispheres. The conservative uncertainty of a factor of 2 for particle surface area was
346 estimated using the standard deviation of the means with assumption of particles being
347 flat or spherical. This assumption likely underestimates the actual surface area since
348 most of the particles deposited on the substrate exhibited non-spherical geometry and
349 may have had rough surfaces including cracks or cavities. The particle surface areas
350 were later used for ice nucleation kinetic analysis. INPs were identified using the
351 recorded optical images during ice nucleation, ice growth, and ice sublimation. Using
352 these optical images, INPs were relocated in the SEM using digital pattern recognition
353 and triangulation and then were imaged and analyzed by SEM/EDX (Knopf et al., 2014).
354
355 The temperature and water vapor distribution within the INC were calibrated and
356 validated following our previous work (Wang and Knopf, 2011; Wang et al., 2016b).

357 Homogeneous water vapor distribution in the INC was confirmed by uniform
358 condensation and evaporation of micro-meter size water droplets across the 0.5 mm²
359 sample area. T_p was calibrated by the melting points of ice, dodecane, decane, octane,
360 and heptane. The calibration confirmed that the response of T_p is linear in the range of
361 180 – 273 K with an uncertainty less than 0.3 K. Conservative uncertainty in RH_{ice} for
362 this experimental system comes from the uncertainty in T_d and T_p ($\Delta T_d < \pm 0.15$ K and
363 $\Delta T_p < \pm 0.3$ K), resulting in $\Delta RH_{ice} < \pm 11\%$ at 200 K and $\Delta RH_{ice} < \pm 3\%$ at 260 K.

364

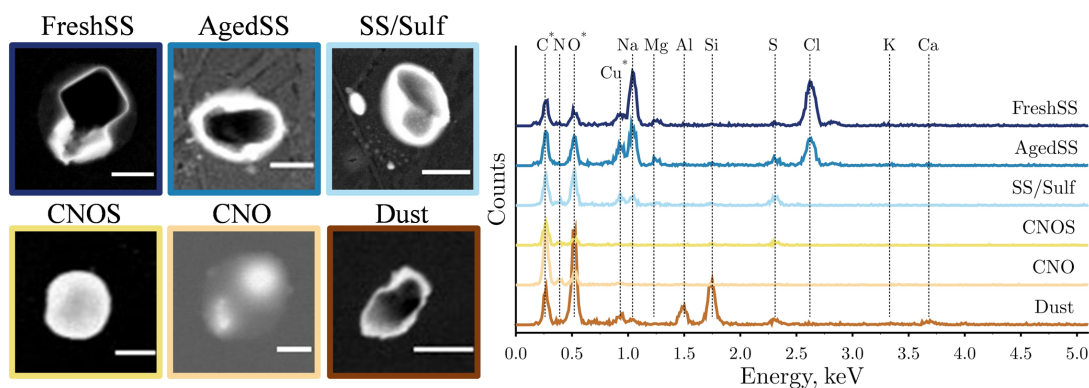

365 **3. Results and discussion**

366 **3.1 Particle characterization**

367 Figure 3 shows the typical SEM images and the corresponding EDX spectra of the
368 identified particle classes. FreshSS and AgedSS particles were dominated by Na with
369 different contents of Cl. The FreshSS particle exhibited a cubic NaCl crystal
370 morphology (black solid square) with irregular materials (bright coating) under the
371 transmission detector of SEM at darkfield mode. The coating likely comprised other
372 materials in seawater including MgSO₄ and CaSO₄ (Xiao et al., 2008). The AgedSS
373 particle showed a non-cubic shape NaCl crystal shape as its core surrounded by
374 substances containing Na with depletion of Cl. The depletion of Cl indicates that the
375 particle had been aged, possibly due to the formation of gaseous HCl by chemical
376 reactions with nitric acid, sulfuric acid, and organic acids in the atmosphere (Laskin et
377 al., 2012; Wang et al., 2015; Angle et al., 2021; Su et al., 2022). The SS/Sulf particle
378 showed in Fig. 3 had a core-shell structure and was mainly composed of Na and S
379 without Cl. This suggests that it was a completely aged sea salt particle coated with
380 sulfur-containing components, such as sulfate. The CNOS and CNO particles showed
381 a round-shaped morphology. The Dust-like particle exhibited clear Al and Si peaks with
382 minor Ca. Figure 4 shows the particle classification results of over 30,000 particles in
383 29 samples investigated by CCSEM/EDX. The size-resolved chemical distributions for
384 all samples are shown in Fig. S3, with FreshSS and AgedSS particles dominating all
385 size bins. The majority of SS/Sulf particles were larger than 0.5 μ m, while the CNOS

386 and CNO particles were mainly in the sub-micrometer size range. As shown in Fig. 1
 387 and Fig. 4, the samples (S1 – S29) were separated into the following three regions
 388 according to the latitudes of the sampling locations, 35°N – 10°N of the Western Pacific
 389 (WP-I), 10°N – 40°S of the Western Pacific (WP-II), and 60°S – 80°S of the Southern
 390 Ocean (SO).

391

392

393 **Figure 3.** Representative SEM images and the corresponding EDX spectra for particles from each
 394 class. The peaks in spectra for the C, O, and Cu elements (asterisked) may include some signal from
 395 substrate background of TEM grids. SEM images were captured at 20 kV using scanning
 396 transmission electron microscopy detector. The scale bar for all images is 1 μ m.

397

398 Figure 4 shows that in the WP-I region (35°N – 10°N, S1 – S7), the proportion of
 399 FreshSS and AgedSS particles increased from 10% to 91% as the ship moved away
 400 from the land, indicating an increased contribution of SSA. The contribution of the Dust
 401 particle class decreased from 59% to 8% for S1 to S3. The Navy Aerosol Analysis and
 402 Prediction System reanalysis (NAAPS-RA) product indicated a dust storm during the
 403 S1 and S2 sampling periods (Fig. S4). The 72 h backward air mass trajectories also
 404 showed that the air mass passed through areas affected by the dust storm.

405

406 **Figure 4.** Relative percentages of the seven particle classes (FreshSS, AgedSS, SS/Sulf, CNOS,
 407 CNO, Dust, and Mixture) for each sample sorted by the latitudes of sampling locations and separated
 408 into three regions (see Fig. 1).

409

410 In the WP-II region (10°N – 40°S, S8 – S17), the backward trajectories (Fig. 1) display
 411 that the air mass of most samples resided over the ocean. However, the samples
 412 demonstrated large variations in the particle composition. S8 – S10 were dominated by
 413 AgedSS, SS/Sulf, and CNOS particles. The percentage of SS/Sulf and CNOS particles
 414 increased from 18% to 36% and from 17% to 39%, respectively, from S8 to S10. The
 415 contributions of these two sulfur-containing particle classes increased simultaneously,
 416 implying the same sulfur source. This is consistent with the results showing high sulfate
 417 aerosol optical depth (AOD) from the NAAPS-RA products at the same period (Fig.
 418 S4D – F). The average BC concentration was $107.4 \pm 70.6 \text{ ng/m}^3$ for S8 (Table S1). It

419 likely originated from combustion emissions transported from land. As shown in Fig.
420 S4C, this is further supported by the air mass for S8 passed through the region where
421 fire spots were detected in NASA Fire Information for Resource Management System
422 (FIRMS). S14 and S15 were dominated only by the AgedSS and CNO particles, with
423 the latter accounting for 43% and 36%, respectively. These higher fractions of CNO
424 particles compared to other samples (Fig. 4) are likely related to BBA. As shown in Fig.
425 S1, the average BC concentrations of S14 and S15 were as high as 674 and 356 ng m⁻³,
426 respectively. Backward trajectories showed that the air mass passed through the high
427 smoke AOD regions (Fig. S4G – H). These two samples were collected on November
428 13th and 14th of 2019, when large wildfires occurred in Australia during the austral
429 summer of 2019 – 2020 (Hirsch and Koren, 2021). Dense fire spots along the east coast
430 of Australia at the time of sampling are shown in Fig. S4I. Chemical imaging of
431 elements (Fig. S5) showed that typical CNO particles from these two samples had thick
432 organic coatings with high carbon signal inclusions and likely are aged BC. This type
433 of aged BBA or smoke particles with organic coatings has been observed in the
434 stratosphere (Ditas et al., 2018). Similar complex organic compounds have also been
435 observed in the tropospheric smoke aerosol (Palm et al., 2020). Other samples in the
436 WP-II region (S11, S12, S13, S16, and S17) were dominated by the FreshSS and
437 AgedSS particles.

438

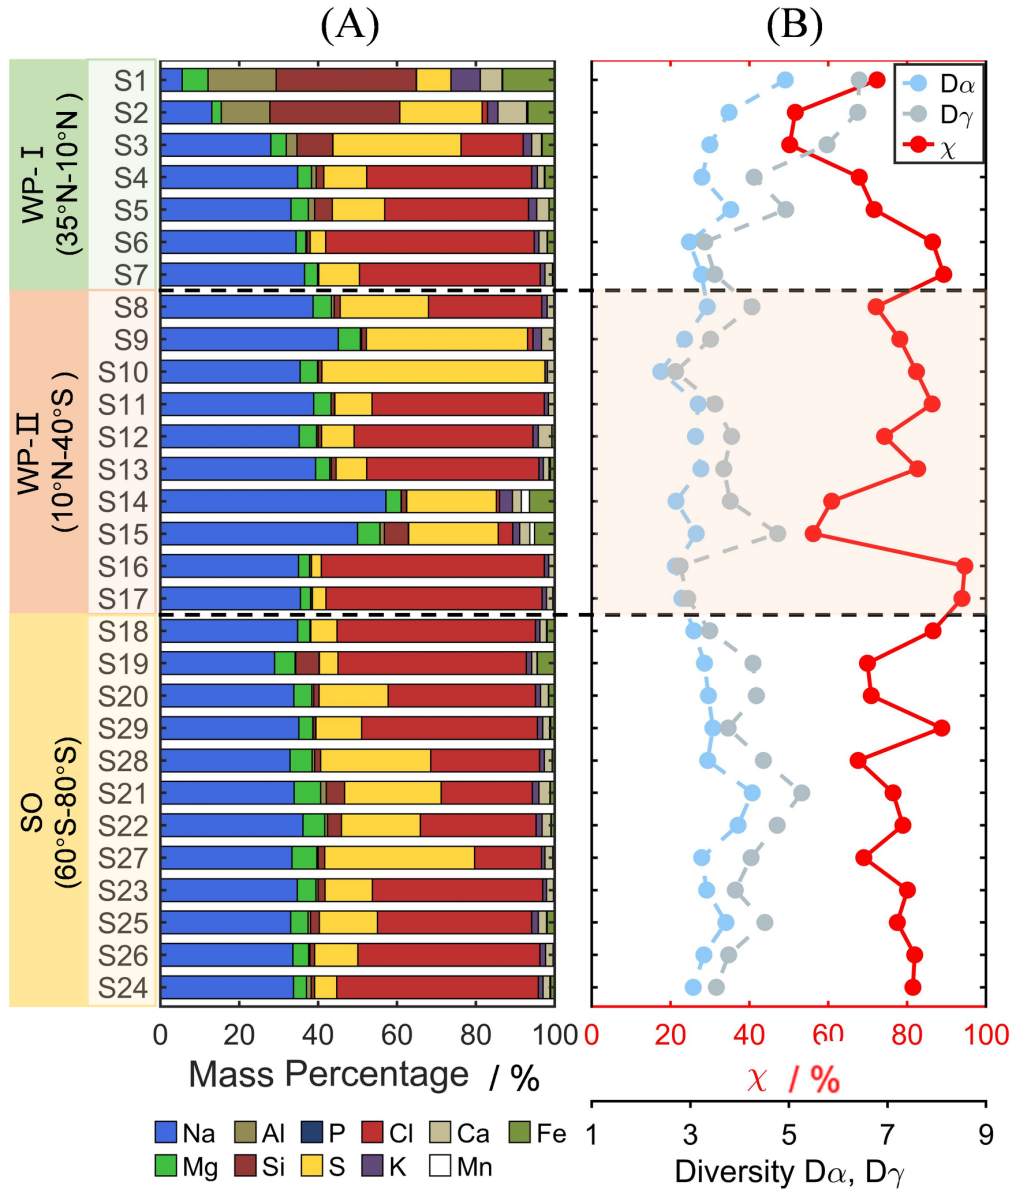

439 In the SO region (60°S – 80°S, sample S18 – S24), the number percentages of FreshSS
440 particles decreased first and then increased as moving toward higher latitude, whereas
441 the AgedSS, SS/Sulf, and CNOS particles had opposite trends. These three particle
442 types contributed to 11% to 93% of the total particles in the sample. As shown in Fig.
443 S6, the contributions of AgedSS, SS/Sulf, and CNOS particles from the middle of the
444 Ross Sea (S28, S21, S22, S27, S23) were significantly higher than those from the north
445 (S18, S19, S20, S29) and southwest (S25, S26, S24) of the Ross Sea. The increased
446 contribution of these three sulfur-containing particle classes may be related to the
447 biogenic sulfur emission from polynyas (areas of open water surrounded by sea ice) in
448 the central Ross Sea (Fig. S7) (Brean et al., 2021; Baccarini et al., 2021; McCoy et al.,

449 2021; Jang et al., 2019; Zhang et al., 2015). The formation of polynyas during the
450 austral summer allowed phytoplankton to grow and produce DMS. DMS is transferred
451 into the atmosphere and oxidized. The products increase the sulfur content in aerosol
452 particles. Previous works indicated that the MSA concentration over the Southern
453 Ocean was about two times higher than that of the Western Pacific (Kunwar et al., 2023).
454 High MSA levels were observed in the Ross Sea and were associated with the dynamic
455 sea ice edge at ~64°S in early December (Yan et al., 2020). This was caused by the
456 increase in phytoplankton from the release of algae from the melting sea ice. This also
457 suggests the potential impacts by the biogenic emission of DMS on these samples.

458

459 Except for the two samples impacted by the dust storm, most of the samples collected
460 during this cruise were predominantly sea salt containing particles including the
461 FreshSS, AgedSS, and SS/Sulf classes, with total number percentages ranging from 48%
462 to 99%. The varying proportions of these three particle classes indicated the
463 contribution of marine emission, but with different degrees of aging which will be
464 discussed in the next section. Figure S8A and Fig. S9A show the classification results
465 for super-micron particles (diameter > 1 μm) and submicron particles (diameter
466 between 0.2 and 1 μm), respectively. The sea salt containing particles including
467 FreshSS, AgedSS, and SS/Sulf classes had higher percentages in the super-micron size
468 range. The majority of CNOS particles were in the submicron size range. CNOS
469 represents sulfur containing particles (e.g., sulfate) including their mixtures with
470 organics. CNOS particles were predominantly in the submicron range, likely due to
471 new particle formation of MSA and H_2SO_4 and their condensation onto pre-existing
472 particles (Hopkins et al., 2008; Yan et al., 2020; Beck et al., 2021). Heterogeneous
473 aqueous chemical reactions may also contribute to CNOS particles, including cloud
474 processing (e.g., Ervens et al., 2018).

475

476

477 **Figure 5.** Relative mass percentages of elements (A), and mixing state (B) of all samples. Color
 478 codes for the elements are shown at bottom. Light blue, gray, and red circles represent the particle
 479 elemental diversity (D_α), population elemental diversity (D_γ), and mixing state index (χ),
 480 respectively.

481

482 3.2 Mixing state of particle population

483 Mixing state described here is based on the elemental composition and is referred to as
 484 the chemical mixing state. Figure 5A shows the elemental mass percentages of the
 485 particle population for each sample. Most of the samples were dominated by Na, Cl,
 486 and S, except the samples affected by dust storm (S1, S2). The proportion of Na in each

487 sample was relatively stable at about 38%. The rest was contributed mostly by Cl and
488 S. The aging of sea salt particles can be evaluated by the elemental ratio of Cl to Na
489 (Cl/Na). As shown in Fig. 5A and Fig. S10, the Cl/Na ratio ranges from 0 to close to 1
490 indicating complete Cl depletion and no aging on sea salt particles, respectively. The
491 samples with more S have less Cl. This is consistent with the increase in the proportion
492 of sea salt with different degrees of aging (AgedSS and SS/Sulf). The relationship
493 between S and Cl indicates that the chlorine loss in particles over ocean is attributed to
494 the acid displacement by H₂SO₄ and MSA. The samples affected by the dust storm were
495 dominated by the elements of Si, Al, and Fe, all of which were common in mineral dust
496 with traces of Ca and K. As the elements of C, N, and O were not considered in the
497 mass percentage calculation, the CNO particles prominent in S14 and S15 are not
498 reflected in the mass percentages (Fig. 5A). The elements of K, Si, and Fe presented in
499 the same samples are related to biomass burning (Chen et al., 2017). It is consistent
500 with the air mass from which they were sampled being impacted by biomass burning
501 plumes.

502

503 The mixing state parameters, namely D_α , D_γ , and χ for each sample, are presented in
504 Fig. 5B. The range of D_α and D_γ was from 2.4 to 4.9 and 2.7 to 6.4, respectively. χ
505 ranged from 50% to 95%. In the WP-I region, the Dust-dominated S1 had the highest
506 D_α of 4.9 and D_γ of 6.4. As the contribution of the Dust particles decreased from 59%
507 to 1% for S1 to S4, D_α and D_γ decreased from 4.9 to 3.2 and 6.4 to 4.3, respectively. χ
508 first decreased from 72% to 50% (S1 to S3) and then increased to 68% (S4) as the
509 dominant particle type switched from Dust to sea salt containing particles. χ further
510 increased to 86% (S6) when FreshSS particles dominated. In the WP-II region, D_α and
511 D_γ decreased as CNOS and SS/Sulf particles increased and the mass percentage of S
512 increased from S8 to S10, corresponding to a slight increase in χ from 72% to 82%.
513 When comparing the wildfire-influenced samples (S14, S15) and the FreshSS
514 dominated samples (S16, S17), the D_α values are very similar whereas D_γ values are
515 quite different (3.8 and 4.8 vs. 2.8 and 2.9) resulting in contrasting χ values. The highest
516 χ of about 95% for S16 and S17 indicated that these two samples dominated by Na and

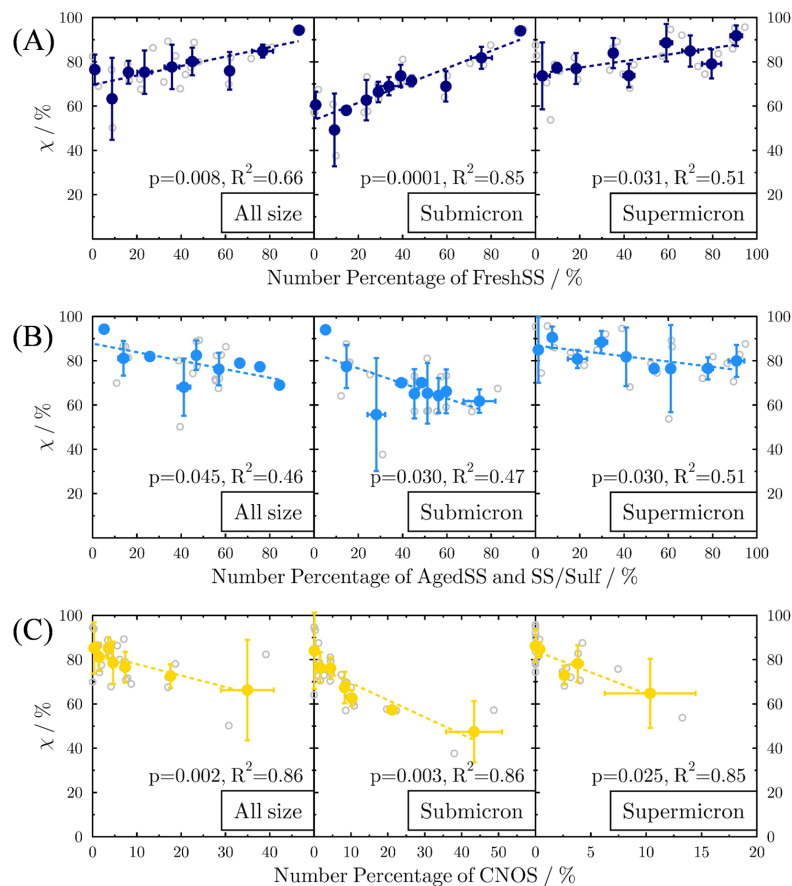

517 Cl were largely internally mixed. This can be expected since they were dominated by
518 FreshSS particles from the single marine source. AgedSS particles from marine
519 emission with additional atmospheric processing and CNO particles from biomass
520 burning had similar contributions to S14 and S15. This was reflected in χ of about 58%
521 for S14 and S15. The main elements of Na and S in these two samples are more
522 externally mixed. In the SO region, D_α and D_γ were similar to each other resulting in
523 relatively stable χ values. The changes in D_α and D_γ are mainly due to the changes in
524 the contribution of sulfur containing particles. Figure S8 and Fig. S9 show the elemental
525 mass percentages, D_α , D_γ , and χ for super-micron and submicron particles, respectively.
526 For submicron particles of each sample, D_α and D_γ are 1.9 – 3.9 and 2.4 – 7.1,
527 respectively. χ ranges from about 38% to 95%. For super-micron particles of each
528 sample, D_α and D_γ are 2.5 – 5.1 and 2.7 – 6.6, respectively. χ ranges from about 54% –
529 96%. In general, D_α and χ for the submicron particles are lower than super-micron
530 particles in most samples, whereas D_γ is similar. This suggests that the main elements
531 of Na, S, and Cl and the minor elements of Mg, K, Fe, Ca, and Si in super-micron
532 particles tend to be more internally mixed than in submicron particles (Fig. S8B and
533 Fig. S9B).

534

535 The changes in the particle composition may affect the mixing state of the particle
536 population. To focus on the effect of particle aging on the mixing state of marine
537 aerosols, we excluded four samples from two events from the analysis, i.e., the Dust-
538 dominated samples from a dust storm (S1 and S2) and the BBA-dominated samples
539 from wildfire emissions (S14 and S15). Figure 6 shows the relationship between χ and
540 the percentages of FreshSS, AgedSS and SS/Sulf, and CNOS particles in different size
541 ranges. To minimize the potential influence of extreme data points, the linear regression
542 was performed using the binned data based on the number percentage of particle type.
543 We found a strong correlation between the percentages of FreshSS particles in the
544 samples and their χ (Fig. 6A, $R^2 = 0.66$, $p = 0.008$), especially for submicron particles
545 ($R^2 = 0.85$). χ increased as the contribution of FreshSS particles increased. There is a
546 negative correlation between χ and the total percentage of AgedSS and SS/Sulf particles

547 (Fig. 6B, $R^2 = 0.46$, $p < 0.05$). We also found a strong negative correlation between χ
 548 and the contribution of CNOS particles (Fig.6C, $R^2 = 0.86$, $p = 0.002$). The results of
 549 the above-mentioned relationship also hold for both submicron and super-micron size
 550 range particles. The positive correlation between the contribution of FreshSS particles
 551 and χ indicates that the particle population became more internally mixed as more fresh
 552 SSA were added to the air parcel. When the FreshSS particles became the dominant
 553 type, the particle population was close to the complete internal mixing ($\chi = 100\%$), such
 554 as S16 and S17 as discussed above. Here, we show that adding more particles of the
 555 dominant particle class (FreshSS) makes the population more internally mixed. Adding
 556 CNOS particles (a new particle class) decreases the χ and makes the population more
 557 externally mixed. These results verify the schematic description of the evolution of the
 558 mixing state described by Riemer et al. (2019). It states that adding new particle types
 559 makes the population more externally mixed and adding particles of a dominant particle
 560 type makes the population more internally mixed.

561

562

563 **Figure 6.** Variation of mixing state index (χ) with the number percentages of different particle
564 classes: (A) FreshSS, (B) AgedSS and SS/Sulf, and (C) CNOS. Panels from left to right are for
565 particles with different size ranges: all particle size (All size), 0.2 – 1 μm (Submicron), and larger
566 than 1 μm in diameter (Super-micron). Original and binned data are shown in open circles and solid
567 color circles, respectively. Linear regression (dash line) is based on the binned data.

568

569 Atmospheric aging processes can change the composition and mixing state of aerosol
570 population. In marine environments, the degree of aging on sea salt particles can be
571 reflected by the contribution of AgedSS and SS/Sulf particles in the population. The
572 negative correlation between the number percentages of AgedSS and SS/Sulf particles
573 and χ indicates that aging has resulted in a more externally mixed particle population.
574 This seems to contradict the view that aging tends to drive a particle population towards
575 a more internally mixed state (Riemer et al., 2019). If an aging process (e.g.,
576 condensation of secondary organics) occurs uniformly on each particle and further
577 aging makes them more homogeneous, the population tends to be more internally mixed.
578 On the other hand, if the aging process occurs only on a specific type of particle, such
579 as acid displacement turning fresh sea salt into aged sea salt, this will increase particle
580 diversity and the population may move to a more externally mixed state. This may be
581 particularly true as fresh sea salt is continuously released even as aged sea salt particles
582 form. The availability of acids and the size distribution of fresh and aged sea salt
583 particles at different locations could result in particles with different chlorine
584 deficiencies and greater diversity. In this case, aging will increase the inhomogeneity
585 of particles and move the population toward a more externally mixed state.

586

587 **3.3 Ice nucleation properties at cirrus conditions**

588 We conducted ice nucleation experiments on six samples dominated by different
589 particle classes. These samples are separated into four groups: *i*) Dust dominated
590 sample (S1), where 59% of the particles are dust-like. *ii*) BBA influenced sample (S14).
591 This sample was affected by biomass burning. CNO and AgedSS particles contributed
592 43% and 51%, respectively. *iii*) CNOS and SS/Sulf dominated sample (S10) with

593 percentages of 39% and 36%, respectively. *iv*) FreshSS and AgedSS dominated samples
 594 (S4, S11, and S12). The number percentages of the FreshSS and AgedSS particles are
 595 70%, 82%, and 85% for S4, S11, and S12, respectively. Table 1 shows the dominant
 596 particle class, total particle surface area, number of particles available for ice nucleation
 597 during the experiments, IN-activated fraction at ice nucleation onsets, average ECD of
 598 INPs and non-INPs, and average ECD of INPs.

599

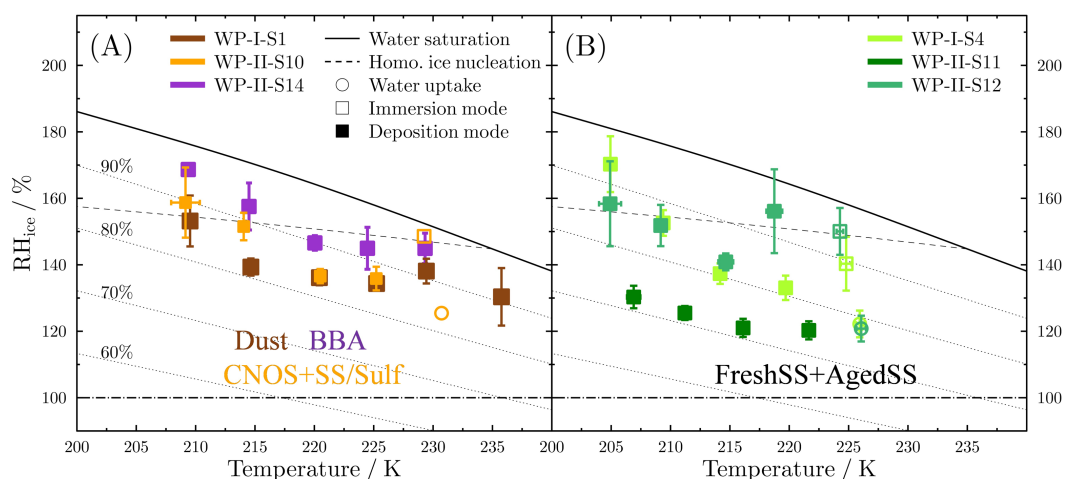

600 **Table 1.** Information of particle samples including the total particle surface area and number of
 601 particles, IN-activated fraction at ice nucleation onset conditions, the average ECD of INPs and
 602 non-INPs, and the average ECD of INPs.

Sample	Dominant particle type	Particle surface area ($\times 10^4 \mu\text{m}^2$)	Particle number ($\times 10^5$)	IN-activated fraction (%)	ECD for INPs (μm)	ECD for all (μm)
WP-I-S1	Dust	4.35	0.85	0.12 – 0.24	2.53 ± 1.76	1.45 ± 0.98
WP-I-S4	FreshSS+AgedSS	0.54	1.29	0.08 – 0.15	0.99 ± 0.25	0.89 ± 0.25
WP-II-S10	CNOS+SS/Sulf	6.81	9.13	0.01 – 0.03	1.54 ± 0.56	1.21 ± 0.57
WP-II-S11	FreshSS+AgedSS	7.76	6.37	0.02 – 0.03	1.19 ± 0.63	1.03 ± 0.50
WP-II-S12	FreshSS+AgedSS	12.91	8.26	0.01 – 0.02	1.91 ± 1.20	1.22 ± 0.78
WP-II-S14	BBA	13.84	0.56	0.18	5.17 ± 3.12	2.50 ± 2.01

603

604 Figure 7 shows the onset conditions of T_p and RH_{ice} for water uptake and ice nucleation
 605 on the representative samples. Below 235 K, only DIN was observed for the Dust and
 606 BBA samples (Fig. 7A). Particles on the Dust sample nucleated ice heterogeneously at
 607 RH_{ice} from $130\% \pm 9\%$ to $153\% \pm 8\%$ at T_p from 235 K to 209 K. These values are
 608 below the homogeneous nucleation limits of aqueous droplets (Koop et al., 2000; Koop
 609 and Zobrist, 2009). RH_{ice} onsets of the BBA sample ranged from $145\% \pm 5\%$ to 169%
 610 $\pm 1\%$ at T_p from 229 K to 209 K. The RH_{ice} onsets were only about 3% below the
 611 homogeneous nucleation limits between 220 K and 228 K, and thus the sample
 612 dominated by BBA may not have been efficient heterogeneous ice nuclei. As T_p
 613 decreased, the RH_{ice} onset of both the BBA and Dust samples gradually increased.
 614 Particles on the Dust sample initiated DIN at RH_{ice} lower than the BBA sample by 7%
 615 to 18% at each T_p . For the CNOS and SS/Sulf dominated sample (Fig. 7A), particles
 616 first took up water when RH_w reached about 83% and then froze via IMF or

617 homogeneous nucleation with RH_{ice} around the homogeneous line at the temperature
 618 close to 230 K. Particles formed ice via DIN below 225 K at RH_{ice} from $136\% \pm 4\%$ to
 619 $159\% \pm 11\%$. Figure 7B shows that the ice nucleated on particles from the FreshSS and
 620 AgedSS dominated samples via DIN and IMF pathways. The transition temperature
 621 between DIN and IMF pathways was about 225 K. At about 225 K, particles on S4 and
 622 S12 both took up water at $78\% \pm 2\%$ and then formed ice upon further cooling. The
 623 subsequent ice nucleation of S12 could be homogeneous nucleation or IMF since the
 624 onset RH_{ice} of $150\% \pm 7\%$ is close to the homogeneous nucleation limit. However,
 625 particles of S4 nucleated ice after water uptake through IMF at RH_{ice} of $140\% \pm 8\%$
 626 which is about 8% lower than the homogeneous nucleation limit. Below 225 K,
 627 particles of S4 and S12 nucleated ice via DIN at RH_{ice} from $133\% \pm 4\%$ to $170\% \pm 8\%$.
 628 DIN occurred on the S11 particles at about $121\% \pm 3\%$ to $130\% \pm 3\%$ RH_{ice} below 225
 629 K. S11 showed the lowest onset RH_{ice} among the investigated samples indicating that
 630 its ice nucleation efficiency was higher than other samples. The results of ice nucleation
 631 onset conditions for the investigated samples showed distinct variations in the ice
 632 nucleation ability for particles in the different marine atmospheres, even for the samples
 633 (S11, S12) with similar elemental composition and the dominant particle classes. The
 634 possible reasons for this are discussed in the later section.

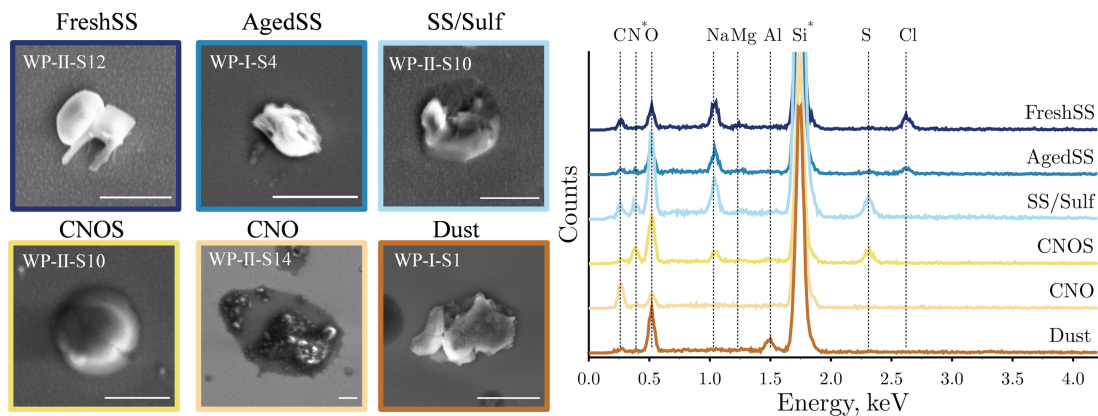

635
 636 **Figure 7.** Onset conditions of freezing temperature and RH_{ice} for water uptake (open circles),
 637 immersion freezing (open squares), and deposition ice nucleation (solid squares) on particle samples.
 638 (A) Dust dominated sample (S1), BBA influenced sample (S14), and CNOS and SS/Sulf dominated

639 sample (S10); (B) FreshSS and AgedSS dominated samples (S4, S11, S12). Dashed line indicates
640 the homogeneous freezing limits for aqueous droplets of 0.3 μm in diameter (Koop et al., 2000;
641 Koop and Zobrist, 2009). Dotted lines represent different relative humidity (RH_w) shown in panel
642 A. Solid and dashed-dotted lines represent water saturation (100% RH_w) and ice saturation (100%
643 RH_{ice}), respectively.

644

645 **3.4 INP characterization**

646 In total, 132 INPs together with 1317 non-INPs on the silicon wafer substrates were
647 identified and characterized individually for their morphology and elemental
648 composition. Figure 8 shows the representative SEM images and the corresponding
649 EDX spectra of different types of INPs. SEM images for each identified INP at different
650 temperatures are shown in Figs. S11, S12, and S13. The average ECD of INPs was
651 generally greater than the ECD of the population considering both INPs and non-INPs
652 together for each sample (Table 1). Of the 132 INPs, 71% of them were super-micron
653 particles and the rest were submicron particles. The INPs exhibited different
654 morphologies, such as crystalline irregular shapes (e.g., INPs classified as FreshSS,
655 Aged SS, and Dust) and spherical shapes (e.g., INPs classified as CNOS). We found
656 that the majority of INPs from S14 influenced by BBA had thick organic coatings (Fig.
657 8 and Fig. S11). The organic coating thickness of BBA INPs ($1.07 \pm 0.68 \mu\text{m}$, $n = 13$)
658 is significantly thicker than that of other BBA ($0.53 \pm 0.37 \mu\text{m}$, $n = 112$) at the
659 significant level of 0.001. Different number fractions of INPs identified in the FreshSS
660 and AgedSS dominated samples (S4, S11, and S12) have organic coatings. More than
661 80% of INPs in S11 were coated with organics compared to S4 (33%) and S12 (30%).
662 Figure S14 shows the elemental mapping of a representative INP with a thin organic
663 coating. The mapping shows that Na and Cl were distributed in the core, while C and
664 O were present throughout the whole 2-D projected area of this AgedSS INP. Previous
665 studies have shown that solid organics can form ice via DIN at low temperatures (Wang
666 et al., 2012b; Knopf et al., 2018; Lata et al., 2021; Alpert et al., 2022). We speculate
667 that the organic coatings on the particles of S11 triggered the ice nucleation which have
668 different ice nucleation abilities compared to S4 and S12.

669

670 **Figure 8.** Representative SEM images and the corresponding EDX spectra for 6 classes of INPs.

671 The spectra include the substrate background signal of N and Si (asterisked) from silicon wafer

672 coated with Si_3N_4 . Labels on SEM images are the name of samples. Scale bar is $2\ \mu\text{m}$ for all images.

673

674 All the identified INPs and non-INPs on the substrates used in the ice nucleation

675 experiments were categorized based on the SEM/EDX data. Figure 9 shows the

676 percentages of different classes for INPs and the particle population in stacked bars

677 marked with “INPs” and “All”, respectively. Taking S1 as an example, six particle

678 classes were identified in the particle population and the 19 identified INPs are from

679 five particle classes except for the CNO class. Similar to S1, the dominant particle

680 classes in the population of all respective samples are also the dominant classes of INPs.

681 This result suggests that all these major particle classes identified in our experiments

682 are potential INPs. We calculated the average elemental composition of INPs and non-

683 INPs for each particle type as shown in Fig. S15. A two-sample t-test was also

684 performed on the elemental compositions of INPs and non-INPs for each particle type.

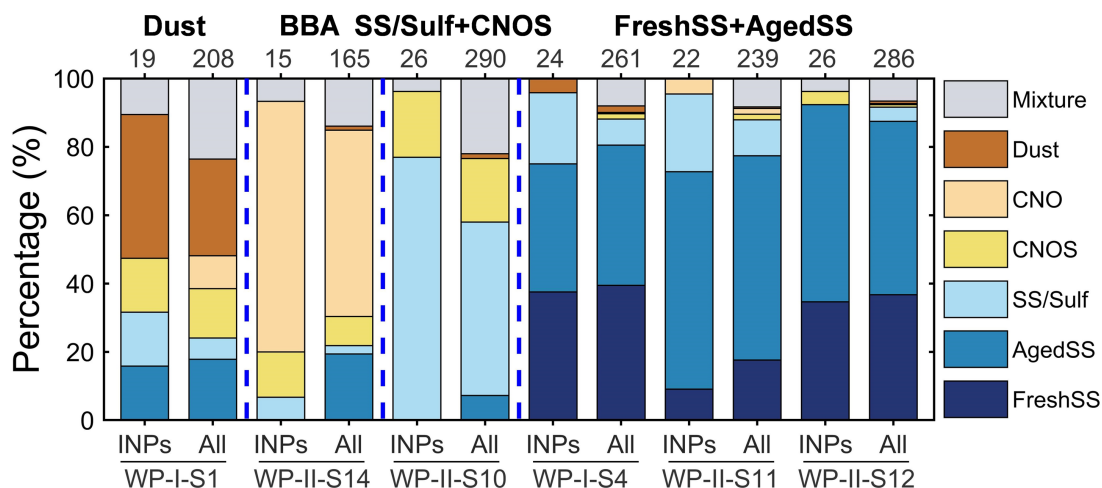

685 At the significant level of 0.05, there is no sufficient evidence showing that the

686 elemental compositions of INPs and non-INPs are different. We also found that the

687 contributions of the same particle class in INPs and the particle population are different

688 in some cases. The most notable example is S10 where SS/Sulf particles contributed

689 77% of INPs, but only 51% of the population.

690

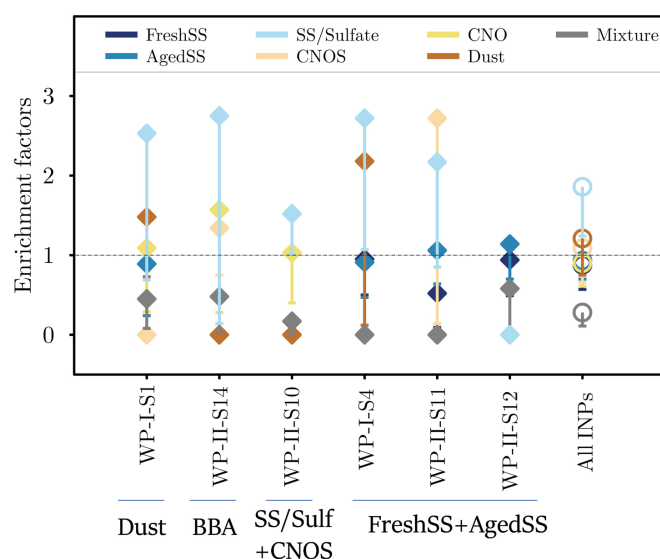

691 **Figure 9.** The number percentages of different particle classes for INPs and the particle population.
 692 Data marked with “All” including both INPs and non-INPs. The corresponding numbers on the top
 693 represent the investigated particle number. Blue dashed lines separate the samples with different
 694 particle classes.

695

696 To further explore whether a particle class is unique when acting as INPs, we calculated
 697 the enrichment factor (EF) for a given particle class (A) according to the following
 698 formula:

$$699 \quad EF(A) = \frac{\left(\frac{N_{INPs}^A}{N_{INPs}} \right)}{\left(\frac{N_{INPs+non-INPs}^A}{N_{INPs+non-INPs}} \right)} \quad (14)$$

700 where N is the number of particles. $EF(A)$ is the ratio of the contributions of the particle
 701 class A in the INPs to the whole particle population (INPs + non-INPs). EF values of
 702 each particle class for different samples are shown in Fig. 10. EF values with upper and
 703 lower limits determined from Poisson distributed errors at 95% confidence level are
 704 listed in Table S2. Although the enriched particle classes are diverse for different
 705 samples, EF of the SS/Sulf class is greater than 1 for most of the samples except S12.
 706 No INP was identified as SS/Sulf particle for S12 which only has 4% of SS/Sulf in the
 707 population. The overall EF of the SS/Sulf class is 1.9 with the upper and lower limits
 708 of 9.2 and 1.2, respectively. This indicates that the SS/Sulf particles were enriched in
 709 INPs in these marine environments.

710

711 **Figure 10.** The *EF* of all INP classes for each sample (solid diamonds) and all INPs (open circles).
 712 The dashed line indicates *EF* of 1. The lower limits of *EF* were calculated by Poisson distribution
 713 at the confidence level of 95%. For the readability, the upper limits were not plotted here but the
 714 values are listed in Table S2.

715

716 3.5 Comparison of ice nucleation properties with previous studies

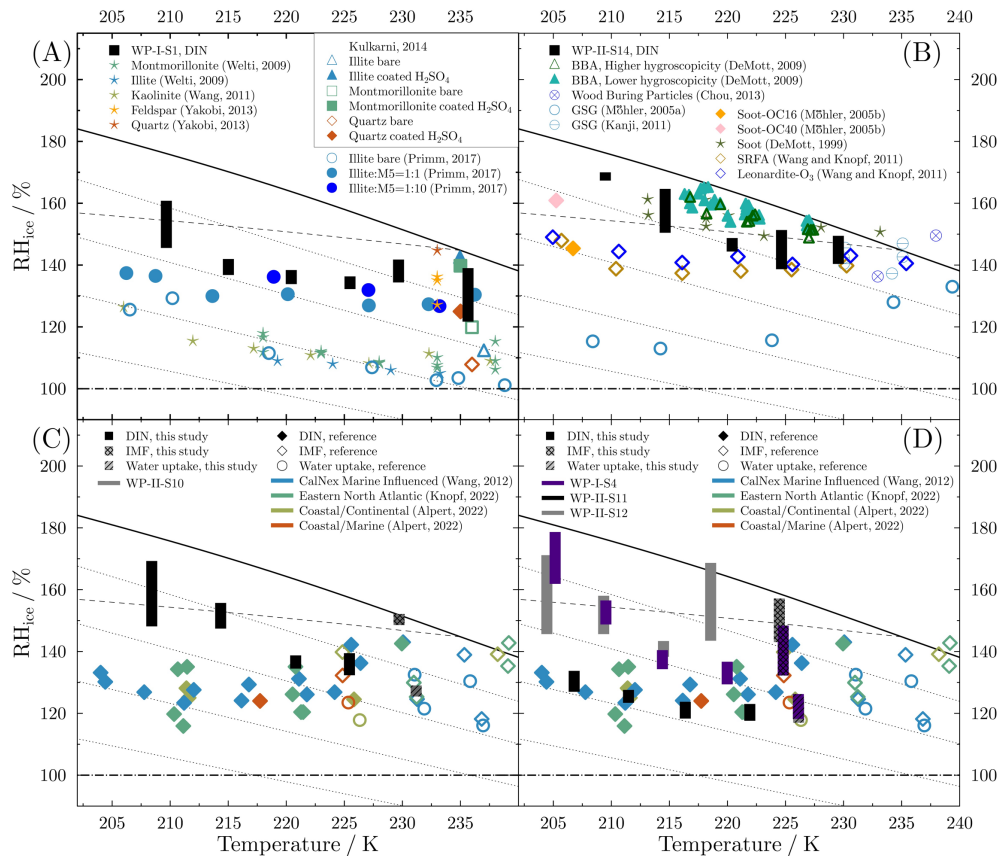

717 Figure 11 shows the comparison of ice nucleation data from our work and previous
 718 studies. The DIN onset conditions of the Dust dominated sample (S1) are similar to the
 719 feldspar between 230 K and 235 K (Yakobi-Hancock et al., 2013) and less efficient
 720 compared to bare dust particles, including montmorillonite (Welti et al., 2009; Kulkarni
 721 et al., 2014), illite (Welti et al., 2009; Kulkarni et al., 2014), quartz (Kulkarni et al.,
 722 2014), and kaolinite (Wang and Knopf, 2011). Previous laboratory studies showed that
 723 the aging processes can reduce the ice nucleation ability of mineral dust at temperatures
 724 relevant to cirrus clouds (Tang et al., 2016). For example, Primm et al. (2017) indicated
 725 that the ice nucleation ability of illite can be slightly suppressed by organic acids when
 726 mixed with a mixture of five dicarboxylic acids (referred to as M5) at an organic-illite
 727 mass ratio greater than 1:1. The DIN onset conditions of S1 are similar to the M5/illite
 728 (10:1) mixtures (Fig. 11A). We also found that coated particles (Fig. S16) in S1 serving
 729 as INPs have a similar coating thickness (Fig. S11) as organic coatings on M5/illite

730 greater than 1:1. Kulkarni et al. (2014) observed a decrease in ice nucleation ability of
731 montmorillonite, illite, and quartz at 235 K when coated with H₂SO₄. These H₂SO₄
732 coated dust particles had a similar onset RH_{ice} as compared to particles on S1 at 235 K.
733 During the cruise, S1 and S2 in the WP-I region were impacted by the dust storm
734 originating from western Asia. The dust particles were aged during the transport to the
735 coastal areas and some of them had clear coatings (Fig. S11 and Fig. S16). This is
736 consistent with the finding by Jang et al.(2023) from the same cruise that aerosol
737 particles in the S1 sample area have a high fraction of lignin-like organics. S1 had a
738 similar ice nucleation ability as dust particles with organic coatings. We suspect that the
739 ice nucleation efficiency of the dust particles at temperatures where DIN occurred on
740 the INP's surface was affected by coatings after aging.

741

742 Our results for S14 suggest that BBA from the Australian wildfires may have served as
743 INPs via DIN below 230 K. Combustion and burning processes produce a large number
744 of particles with mixed organic and inorganic components into the atmosphere (e.g.,
745 Fuzzi et al., 2007; Chen et al., 2017; Hodshire et al., 2019). Previous studies have shown
746 that soot, combustion ash, and BBA particles from different burning sources
747 demonstrated various ice nucleation properties (e.g., Jahl et al., 2021; Jahn et al., 2020;
748 Kanji et al., 2017 and references therein). Soot particles or their organic coatings on
749 S14 may have played a role in the observed ice nucleation events. Several studies have
750 reported that combustion related particles can serve as INPs via DIN below 233 K
751 (DeMott et al., 1999; Möhler et al., 2005a, b; Koehler et al., 2009; Kanji et al., 2011;
752 Chou et al., 2013). Kanji et al. (2011) showed the ice nucleation activated by soot
753 generated using a graphite spark generator (GSG) at about 145% RH_{ice} , a value similar
754 to S14 at 230 K. Chou et al. (2013) showed that wood burning particles nucleated ice
755 at about 136% RH_{ice} at about 233 K. DeMott et al. (1999) reported that the freezing
756 RH_{ice} of soot was close to the homogeneous freezing limits. S14 nucleated ice at higher
757 RH_{ice} than soot generated by GSG and particles containing organic carbon (Möhler et
758 al., 2005a, b), but lower than the soot studied by DeMott et al. (1999). Suwannee River
759 standard fulvic acid (SRFA) and leonardite were used as surrogates of atmospheric

760 organics from biomass burning (Wang and Knopf, 2011). Ice nucleation onset
 761 conditions of S14 are very similar to those of SRFA and ozone aged leonardite particles
 762 above 220 K but higher at lower temperatures.

763
 764 **Figure 11.** Ice nucleation and water uptake onset conditions (bars) for (A) Dust dominated sample
 765 (S1), (B) BBA influenced sample (S14), (C) CNOS and SS/Sulf dominated sample (S10), and (D)
 766 FreshSS and AgedSS dominated samples (S4, S11, S12) compared with previous studies (symbols)
 767 (DeMott et al., 1999, 2009; Möhler et al., 2005a, b; Welti et al., 2009; Kanji et al., 2011; Wang and
 768 Knopf, 2011; Wang et al., 2012a; Yakobi-Hancock et al., 2013; Kulkarni et al., 2014; Primm et al.,
 769 2017; Alpert et al., 2022; Knopf et al., 2022). Descriptions for the lines are the same as in Fig. 7.

770
 771 Figures 11C and 11D show the comparison of data on marine related particles from
 772 previous studies with our data on sea salt containing particles. Several studies have
 773 shown that the aerosol particles collected in marine environments or coastal areas can
 774 act as efficient INPs at RH_{ice} between 115% and 143% (e.g., Wang et al., 2012a; Alpert
 775 et al., 2022; Knopf et al., 2022). Using the micro-spectroscopic analysis, these studies

776 identified the INPs and demonstrated that the major particle types in the population
777 initiate ice formation. These particle types include the marine influenced particles with
778 thin organic coatings collected during the CalNex field campaign (Wang et al., 2012a),
779 the relatively fresh sea salt particles with marine-produced organics collected from the
780 coast of Long Island, New York (Alpert et al., 2022), and the processed sea salt
781 containing particles collected over the eastern North Atlantic (Knopf et al., 2022). There
782 is one FreshSS and AgedSS dominated sample (S11) that nucleated ice at the same
783 RH_{ice} onsets as compared to those marine-influenced particles from above mentioned
784 studies. The other sea salt containing samples in this work including the CNOS and
785 SS/Sulf dominated sample (S10) and the FreshSS and AgedSS dominated samples (S4,
786 S12) showed very similar RH_{ice} onsets only at temperatures above 220 K but higher
787 onsets below 220 K. The reason for this discrepancy at lower temperatures is not clear.
788 Future work on the coating composition may provide more insight. Together with
789 previous studies, we show that these marine influenced particles exhibit different ice
790 nucleation efficiencies. These variations are likely contributed not only to the complex
791 compositions but also to the physical and chemical mixing state of these particles.

792

793 **3.6 Ice nucleation kinetics**

794 Ice nucleation kinetic analysis was conducted using the experimental data, including
795 the RH_{ice} and temperature onsets, particle surface area, number of nucleation events,
796 and nucleation time. Classical nucleation theory (CNT) has been widely used in cloud
797 models (e.g., Pruppacher and Klett, 2010; Khvorostyanov and Curry, 2004; Liu and
798 Penner, 2005). In this study, heterogeneous ice nucleation rate coefficient (J_{het}), contact
799 angle (θ), and their parameterizations are presented and discussed. Ice nucleation
800 activated fraction of each sample was listed in Table 1 and discussed in Text S2. n_s
801 based on the singular hypothesis (Vali, 1971; Connolly et al., 2009) and its
802 parameterizations are also presented in Text S2.

803

804 **3.6.1 Heterogeneous ice nucleation rate coefficient (J_{het})**

805 According to CNT, ice nucleation is a stochastic process and continues with time, in
806 contrast to the singular hypothesis (Pruppacher and Klett, 2010). J_{het} depends on
807 temperature and RH_{ice} . J_{het} was derived following the approach in previous works
808 (Wang and Knopf, 2011; Wang et al., 2012a; China et al., 2017; Knopf et al., 2022).
809 Using the observed ice nucleation data, $J_{\text{het}} = N_{\text{ice}}/(t \times A_{\text{tot}})$, where N_{ice} is the
810 number of the observed ice nucleation events that occurred in a temperature interval,
811 A_{tot} is the total particle surface area available for ice nucleation experiment in the
812 temperature interval, t of 6 seconds is the time interval between two consecutive OM
813 images used to monitor ice formation. In the four groups of particle samples we
814 investigated, J_{het} for DIN ranged from 130 to 1370 $\text{cm}^{-2} \text{s}^{-1}$, 40 to 2970 $\text{cm}^{-2} \text{s}^{-1}$, 40 to
815 1480 $\text{cm}^{-2} \text{s}^{-1}$, and 10 to 390 $\text{cm}^{-2} \text{s}^{-1}$ for the Dust dominated, BBA influenced, CNOS
816 and SS/Sulf dominated, and FreshSS and AgedSS dominated samples, respectively.
817 J_{het} for IMF ranged from 540 to 4780 $\text{cm}^{-2} \text{s}^{-1}$ for the FreshSS and AgedSS dominated
818 samples.

819

820 **3.6.2 Parameterizations of J_{het} and θ**

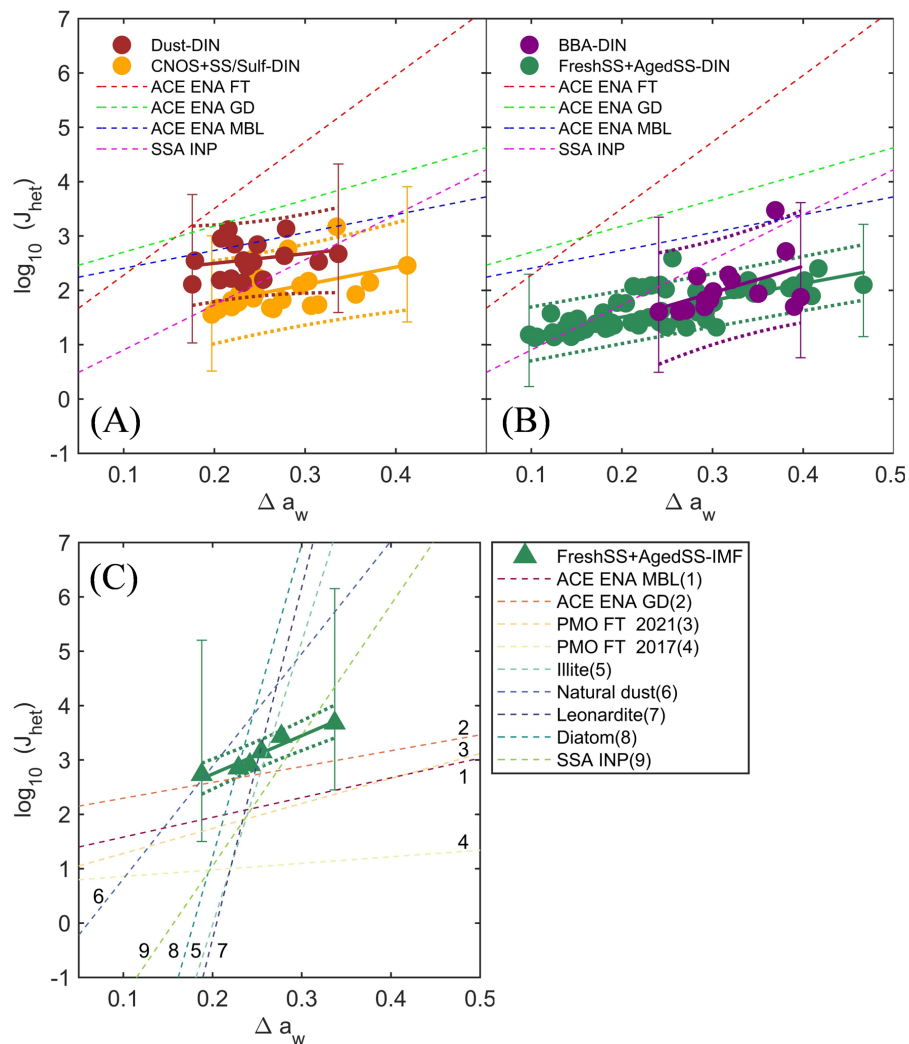

821 The experimentally derived J_{het} was parameterized based on the water-activity-based
822 approach. The water-activity-based approach has been widely used to describe the
823 homogeneous ice nucleation of droplets and depends only on a droplet's water activity
824 (a_w) and T_p (Koop et al., 2000). Homogeneous ice nucleation temperature follows a
825 single curve as a function of a_w and is parameterized by a constant shift of a_w (i.e.,
826 Δa_w) from the ice melting temperature curve (Koop and Zobrist, 2009). This approach
827 has also been applied to heterogeneous ice nucleation including DIN and IMF (Koop
828 and Zobrist, 2009; Knopf and Alpert, 2013; China et al., 2017). It is assumed that
829 particles were in equilibrium with the gas phase during the experiments, so $a_w =$
830 $RH_w/100$. For each nucleation event, $\Delta a_w(T_f)$ is the difference between the RH_w at
831 which ice nucleated and the RH_w on the ice melting curve at the observed ice nucleation
832 temperature (T_f), or $a_w(T_f)$ and $a_w^{\text{ice}}(T_f)$, respectively. Then, $\Delta a_w(T_f) = a_w^{\text{ice}}(T_f) -$
833 $a_w(T_f)$ (Knopf and Alpert, 2013; Koop and Zobrist, 2009), which can be calculated for
834 each ice nucleation event using the ice nucleation onset temperature and RH_w . J_{het} was

835 calculated for all ice nucleation events and parameterized as a function of Δa_w
836 following the previous works (China et al., 2017; Alpert et al., 2022; Knopf et al., 2022,
837 2023). Figure 12 presents the $J_{\text{het}}(\Delta a_w)$ for the DIN and IMF data along with the
838 parameterizations according to $\log(J_{\text{het}}) = c \times \Delta a_w + d$. The values of c and d
839 parameters are listed in Table 2. The Dust dominated sample has higher J_{het} at the same
840 Δa_w compared with the other samples. The BBA influenced sample only nucleated ice
841 at higher Δa_w . The DIN J_{het} for the FreshSS and AgedSS samples changes by 2 orders
842 of magnitude over a wide range of Δa_w . For the FreshSS and AgedSS samples, IMF J_{het}
843 with a larger c displays a steeper slope than DIN J_{het} .

844

845 In Fig. 12, we compared our J_{het} parameterizations with previous studies. DIN J_{het} of
846 the Dust-dominated sample is similar to the particles collected during the Aerosol and
847 Cloud Experiments in the Eastern North Atlantic (ACE ENA) field campaign within
848 the marine boundary layer (ACE ENA MBL) (Knopf et al., 2022, 2023). It is about 1-
849 2 orders of magnitude lower than particles collected from the free troposphere (ACE
850 ENA FT). DIN J_{het} of the other particle types investigated in this study are lower than
851 particles collected from ACE ENA FT, ground site (ACE ENA GD), and ACE ENA
852 MBL. This is consistent with the results showing that our particles nucleated ice at
853 higher RH_{ice} than particles collected during ACE ENA (Fig. 11). DIN J_{het} for the
854 FreshSS and AgedSS samples is similar to the SSA investigated by Alpert et al. (2022)
855 in the lower Δa_w range (less than 0.25). This is likely because S11 nucleated ice in this
856 Δa_w range (i.e., RH_{ice}) is similar to the SSA INP investigated by Alpert et al. (2022) as
857 they have similar morphology and composition. IMF J_{het} of the FreshSS and AgedSS
858 samples is slightly higher than particles from ACE ENA GD and 1-2 orders of
859 magnitude higher than the other field samples (Fig. 12C). The IMF J_{het} of the FreshSS
860 and AgedSS samples displays a smaller slope with Δa_w compared to the laboratory-
861 generated particles, such as illite (Knopf and Alpert, 2013), natural dust (Alpert and
862 Knopf, 2016; Niemand et al., 2012), leonardite particles (Knopf and Alpert, 2013), and
863 diatomaceous material (Knopf and Alpert, 2013; Knopf et al., 2011; Alpert et al., 2011a,
864 b). This is consistent with the study by Knopf et al. (2022) which suggested that the

865 diversity of ambient particles exhibit different ice nucleation efficiencies compared to
 866 single-component INP types studied in the laboratory at different temperature ranges.
 867 Our results emphasize the importance of studying the ice nucleation ability of particles
 868 and their parameterizations from different geological areas with different diversities in
 869 particle characteristics.

870
 871 **Figure 12.** J_{het} as a function of Δa_w . Circles represent DIN J_{het} for (A) Dust, CNOS and SS/Sulf
 872 dominated samples, (B) BBA, FreshSS and AgedSS dominated samples. Triangles represent IMF
 873 J_{het} (C) for FreshSS and AgedSS dominated samples. Solid lines indicate the fittings according to
 874 $\log(J_{\text{het}}) = c \times \Delta a_w + d$ with associated dotted lines representing the 95% prediction intervals.
 875 Representative ΔJ_{het} (error bars) are plotted (Text S2). (A-B) Dashed red, green, and blue lines
 876 represent DIN J_{het} parameterizations of particles collected from ACE ENA FT (Knopf et al., 2023),
 877 ACE ENA GD (Knopf et al., 2022), and ACE ENA MBL (Knopf et al., 2023), respectively. Dashed

878 magenta line indicates J_{het} for SSA INPs (Alpert et al., 2022). (C) Dashed lines with the number
 879 label of 1-4 represent IMF J_{het} for particles from ACE ENA MBL (Knopf et al., 2023), ACE-ENA
 880 GD (Knopf et al., 2022), and the Pico Mountain Observatory (PMO) under free-tropospheric (FT)
 881 conditions in the Azores (PMO FT 2017 and PMO FT 2021) (China et al., 2017; Lata et al., 2021),
 882 respectively. Dashed lines with the number label of 5-8 represent IMF J_{het} for illite particles (Knopf
 883 and Alpert, 2013), natural dust (Alpert and Knopf, 2016; Niemand et al., 2012), leonardite particles
 884 (Knopf and Alpert, 2013), diatomaceous material (Diatom) (Knopf and Alpert, 2013; Knopf et al.,
 885 2011; Alpert et al., 2011a, b), and SSA INP (Alpert et al., 2022), respectively.

886

887 **Table 2** The c and d values for the parameterizations of J_{het} as a function of Δa_w ,

888

$$\log(J_{\text{het}}) = c \times \Delta a_w + d.$$

Sample type	c	LCL _{c}	UCL _{c}	d	LCL _{d}	UCL _{d}	RMSE
Dust-DIN	1.78	-0.15	3.72	2.14	1.67	2.61	0.31
BBA-DIN	4.88	2.38	7.39	0.49	-0.31	1.30	0.43
CNOS+SS/Sulf-DIN	3.24	1.91	4.57	1.13	0.77	1.50	0.35
FreshSS+AgedSS-DIN	3.09	2.76	3.42	0.89	0.81	0.97	0.24
FreshSS+AgedSS-IMF	7.06	6.03	8.09	1.33	1.06	1.60	0.09

889

890 θ for DIN is derived based on CNT following our previous studies (Wang and Knopf,
 891 2011; Wang et al., 2012a). θ is calculated from J_{het} and the ice nucleation onset
 892 temperature and RH_{ice} using the following formula: $J_{\text{het}} = A \times \exp\left(\frac{-\Delta F_{\text{g,het}}}{kT}\right)$, where
 893 A is a pre-exponential factor and k is the Boltzmann constant. $\Delta F_{\text{g,het}}$ is the free energy
 894 of ice embryo formation, which is defined as $\Delta F_{\text{g,het}} = \frac{16\pi M_w^2 \sigma_{i/v}^3}{3[RT\rho \ln S_{\text{ice}}]^2} \times f(m)$, where R
 895 is the universal gas constant, ρ is the density of ice, S_{ice} is the ice saturation ratio ($S_{\text{ice}} =$
 896 $RH_{\text{ice}}/100\%$), M_w is the water molecular weight, $\sigma_{i/v}$ is the surface tension at the ice-
 897 vapor interface. $f(m)$ is the geometric factor and is defined as $f(m) = (m^3 - 3m +$
 898 $2)/4$, where $m = \cos(\theta)$. A smaller value of θ implies higher ice nucleation efficiency
 899 and should translate to relatively lower RH_{ice} onsets in our experiments. Figure 13
 900 represents the mean θ as a function of temperature for INPs of all sample types. When
 901 comparing θ at the same temperature, the FreshSS and AgedSS dominated samples, in
 902 general, have the smallest θ , followed by the Dust dominated, CNOS and SS/Sulf

903 dominated, and BBA influenced samples. For all the investigated samples, θ was
 904 relatively constant above 220 K and increased as temperature decreased to 205 K. We
 905 propose new parameterizations of θ as a function of $T^3 \ln[RH_{ice}]^2$ (Text S2). θ for
 906 various particle types fall tightly into the parameterization as shown in Fig. S19.

907
 908 **Figure 13.** Mean values with one standard deviations of contact angle for DIN by the Dust, BBA,
 909 CNOS and SS/Sulf, FreshSS and AgedSS dominated samples.

911 3.7 Ice nucleation propensity and mixing state of particle population

912 Previous studies have used χ to estimate the error in predicting aerosol CCN activity
 913 and optical properties when assuming idealized mixing states (Ching et al., 2017; Yao
 914 et al., 2022). For example, Ching et al. (2017) quantified the error in predicting CCN
 915 concentration as a function of χ . When internal mixing was assumed, errors of up to
 916 100% overpredicting CCN concentration were found for populations with more
 917 external mixing ($\chi < 60\%$). However, CCN concentrations were well predicted for
 918 populations with $\chi > 75\%$. Inspired by these studies, we used θ as a measure of particle
 919 ice nucleation propensity to discuss the potential link between the mixed state of
 920 population and particle ice nucleation propensity. We investigated the relative
 921 difference (error) in θ for the field samples compared to pure NaCl particles. Ice
 922 nucleation experiments were conducted on the laboratory-generated NaCl particles
 923 (Text S3) and θ was calculated for NaCl particles (see Section 3.6.2 for the calculation

924 details). Pure NaCl particles were used as a surrogate of complete internally mixed
925 marine aerosols ($\chi = 100\%$). We analyzed the relationship between the relative error in
926 θ of INPs (*Err*) and the mixing state of the population in which the INPs were identified.
927 *Err* of each INP from a field sample with a given mixing state (χ) was defined as:

$$928 \quad Err = \frac{\theta(\chi) - \theta(100\%)}{\theta(100\%)} \times 100 \quad (15)$$

929 where $\theta(100\%)$ is the average θ for the NaCl standard. As shown in Fig. 14, χ for the
930 six investigated samples changed from 61% to 86%. Five samples (S1, S4, S10, S12,
931 and S14) exhibited positive mean *Err* ranging from $2.3\% \pm 7.5\%$ to $16.3\% \pm 6.6\%$,
932 while S11 had a negative mean *Err* of $-18.6\% \pm 6.2\%$. The FreshSS and AgedSS
933 dominated samples, S4 and S12, have a mean *Err* of $6.9\% \pm 12.4\%$ and $13.0\% \pm 9.2\%$,
934 respectively.

935

936 The θ for particles in the marine environment is different from that for NaCl particles.
937 This can lead to errors in J_{het} of several orders of magnitude if the model assumes an
938 internally mixed particle population. According to CNT, we calculated DIN J_{het} for
939 NaCl and particles with *Err* of 5% and 10% under different temperature and humidity
940 conditions (Fig. S20). Between 135% and 180% RH_{ice} , *Err* of 5% and 10% will result
941 in 1.5 – 4 and 2 – 10 orders of magnitude differences in J_{het} , respectively. Moreover,
942 the lower the temperature and RH_{ice} , the larger the error in J_{het} . This suggests that the
943 effects of aging processes and mixing state need to be considered in the ice nucleation
944 modeling. No specific correlation or trend was found between χ and the *Err* from this
945 data set with the limited number of samples. This may be expected since ice nucleation
946 is controlled by various physiochemical properties of individual particles, particularly
947 for DIN. For example, one crucial factor is the physical mixing state of particle, such
948 as coating. Organic coatings play a significant role in altering the θ of sea salt particles,
949 as exemplified by S11 compared to S4 and S12. In contrast to CCN, which in general
950 can be described by the κ -Köhler theory, there are still no appropriate physical models
951 to describe INPs. In addition, ice nucleation propensity for DIN is determined on the
952 individual particle basis, whereas the chemical mixing state (i.e., χ here) characterizes

953 the overall mixing of species within the particle population. There is a large gap in the
 954 understanding of the relationship between INP propensity and χ .

955
 956 **Figure 14.** *Err* in θ for the investigated samples relative to the internally mixed particles (pure
 957 NaCl particles, $\chi = 100\%$). Black thick lines indicate the average θ and the gray boxes represent
 958 one standard deviation. Green circles represent θ for individual INPs.

959

960 4 Atmospheric implications

961 We found that the distinct mixing states of particle populations were affected by several
 962 processes over different oceans. In the marine atmosphere that already has a
 963 contribution of sea salt particles, adding more fresh sea salt particles makes the
 964 population more internally mixed (Fig. 6). We suspect that over open oceans where sea
 965 salt particle flux is large, the population will be mostly internally mixed. The addition
 966 of new particle types from other sources, such as dust storms (WP-I, S1, S2), biomass
 967 burning (WP-II, S14, S15), and secondary sources (CNOS in the SO region), will
 968 decrease the mixing state index and the population will become more externally mixed.
 969 These results are consistent with the proposed schematic description by Riemer et al.
 970 (2019) on the evolution of particle mixing state. We showed that multiphase processes

971 lead to the aging of fresh sea salt particles resulting in chlorine deficiency and thus
972 changing the mixing state of the population (Fig. 5). This is a selective process that
973 occurred on the sea salt particles and is different from the aging by condensation of
974 secondary materials. As discussed in Section 3.2, these types of selective or
975 inhomogeneous aging on particles move the population toward a more externally mixed
976 state. To the best of our knowledge, this is not considered in the models predicting the
977 mixing state of aerosols, even for the particle-resolved model. Our study suggests that,
978 when discussing the influence of aging on the evolution of the mixing state, it is
979 necessary to consider whether the aging processes occur uniformly on all particles.

980

981 We characterized chemical compositions for particle population and INPs at the single
982 particle level. We found that all the identified particle types from different sources have
983 the potential to serve as INPs, but have different ice nucleation efficiencies (Fig. 7 and
984 Fig. 9). We found that S11 showed the highest ice nucleation efficiency among the
985 FreshSS and AgedSS dominated samples (Fig. 7), which we attributed to the organic
986 coatings on the particles. This indicates the importance of characterizing the physical
987 mixing state of particles (i.e., morphology). INPs were enriched in SS/Sulf class,
988 suggesting that the aging process alters ice nucleation ability by changing the chemical
989 mixing state of particles. Considering the characterizations of individual particles and
990 INPs, the ice nucleation onset conditions, and the derived freezing kinetics, it is
991 suggested that the ice nucleation abilities at cirrus conditions of these complex marine
992 aerosols are affected not only by the particle compositions but also by the mixing state
993 of particle population. Future investigations on how the chemical and physical mixing
994 state of particles affects ice nucleation in the atmosphere are needed for a better
995 understanding of aerosol-cloud interactions in the climate system.

996

997 According to the singular hypothesis and CNT, ice nucleation kinetic parameters, J_{het}
998 and n_s , were derived from the experimental data. We derived parameterizations of n_s as
999 a function of temperature for IMF and DIN of different dominated particle classes. We
1000 also proposed parameterizations of J_{het} as a function of Δa_w for IMF and DIN based on

1001 the water-activity based theory. In addition, θ was derived for DIN based on CNT. We
1002 propose new parameterizations of θ that take into account both temperature and RH_{ice} .
1003 These parameterizations can be used to estimate the INP concentrations or ice crystal
1004 production rates when particle surface area data are available. These parameterizations
1005 can be used in cloud models with different ice nucleation descriptions to evaluate the
1006 potential sources and impacts of different particles on cloud formation in the marine
1007 atmosphere.

1008

1009 **5 Conclusions**

1010 Composition, mixing state, and ice nucleation properties were investigated for the
1011 aerosol particles collected over the Western Pacific and Southern Ocean during a cruise
1012 from South Korea (34.93°N) to the Ross Sea (75.12°S) in 2019. Seven particle classes
1013 were identified including fresh sea salt, aged sea salt, sea salt mixed with sulfate,
1014 carbonaceous particle, sulfur-containing particle, dust, and mixture. Contributions of
1015 these particles varied across oceans at different latitudes. Except for the samples
1016 impacted by dust storm, fresh sea salt, aged sea salt, and sea salt mixed with sulfate
1017 particles were the most prevalent particle types with the total number percentage
1018 ranging from 48% to 99%. Particles showed different degrees of chloride depletion due
1019 to the aging processes of acid displacements on sea salt particles. Significant
1020 contributions of sulfur-containing particles up to 93% in number were found in the Ross
1021 Sea, which was affected by phytoplankton blooms in the austral summer. The chemical
1022 mixing state index of particle population ranges from 50% to 95%. The mixing state
1023 index was positively correlated with the number percentages of fresh sea salt and
1024 negatively correlated with the proportion of sulfur-containing particles. Particle
1025 populations tended to be more internally mixed as the fresh sea salt fraction increased.
1026 When sea salt particles were a background or dominant particle type, inhomogeneous
1027 aging processes and new particle sources made the population more externally mixed.

1028

1029 We showed that different types of particle samples demonstrated a variety of ice

1030 nucleation abilities at cirrus conditions. The sample dominated by the fresh sea salt
1031 particles with organic coatings exhibited the highest ice nucleation efficiency with RH_{ice}
1032 onset as low as 121%, while particles influenced by biomass burning were the least
1033 efficient among the investigated samples. According to the individual INP
1034 characterizations, the dominant particle types in the population all contribute to the
1035 identified INPs but with different enrichment factors. The sea salt mixed with sulfate
1036 particles were enriched in INPs with an overall factor of about 1.9. Ice nucleation
1037 abilities of marine aerosol particles were affected not only by composition but also by
1038 the chemical and physical mixing state of the particle population. Ice nucleation kinetic
1039 parameters, time-dependent J_{het} , time-independent n_s , and contact angle, were derived
1040 from the experimental data. The corresponding parameterizations for different particle
1041 types are provided for cloud modeling. In this study, we demonstrated the diversity in
1042 the particle characteristics at the single particle level, the mixing state of particle
1043 population, and particles' abilities to form ice crystals in different marine atmospheres
1044 in both the northern and southern hemispheres. The results motivate the need for further
1045 investigations of how the mixing state of particles affects ice nucleation in the
1046 atmosphere.

1047

1048 **Data availability.** All data are given in the main text or in the Supplement. HYSPLIT
1049 data were obtained through the NOAA website ([https://www.ready.noaa.gov/hypub-](https://www.ready.noaa.gov/hypub-bin/trajasrc.pl)
1050 [bin/trajasrc.pl](https://www.ready.noaa.gov/hypub-bin/trajasrc.pl)). NAAPS aerosol reanalysis data were obtained from
1051 <https://nrlgodae1.nrlmry.navy.mil/ftp/outgoing/nrl/NAAPS-REANALYSIS/>. FIRMS
1052 data were obtained from <https://firms.modaps.eosdis.nasa.gov/>.

1053

1054 **Supplement.** The supplement related to this article is available online.

1055

1056 **Author contributions.** XJ performed the experiments and wrote the first draft of the
1057 manuscript. XJ, TZ, JP, and BW performed the data analysis. JP and KP collected
1058 the samples. BW, JP and KP initiated and designed the study. BW supervised the

1059 project. BW, YJY, and XJ led the discussion and all authors contributed to the data
1060 interpretation and the manuscript writing.

1061

1062 **Competing interests.** The authors declare that they have no conflict of interest.

1063

1064 **Acknowledgements.** BW, XJ, and TZ thank the support by National Science
1065 Foundation of China (42075076, 41775133), Fundamental Research Funds for the
1066 Central Universities (20720160111, 20720190147). This study is also partially
1067 funded by the Korea Polar Research Institute research grant (PE23110, PE23030).
1068 BW and JY thank the support by the Fund of Key Laboratory of Global Change and
1069 Marine-Atmospheric Chemistry, MNR (GCMAC2004). TZ acknowledges the
1070 support by the PhD Fellowship of the State Key Laboratory of Marine Environmental
1071 Science at Xiamen University. We thank the staff onboard R/V *Araon* helping the
1072 sampling during the Antarctic cruise and Peter A. Alpert for helpful discussion and
1073 manuscript revision.
