6 **Abstract**

7 Soils are the largest terrestrial carbon (C) pool on the planet, and targeted grassland management has
8 the potential to increase grassland C sequestration. Appropriate land management strategies, such as
9 organic matter additions, can increase soil C stocks and increase grassland resilience to drought by
10 improving soil water retention and infiltration. However, soil carbon dynamics are closely tied to
11 vegetation responses to management and climate changes, affecting roots and shoots differently. This
12 study presents findings from a three-year field experiment on two Swedish grasslands that assessed
13 the impact of compost amendment and reduced precipitation on plant biomass and on soil C at various
14 soil depths. Aboveground biomass and soil C content (% C) increased compared to controls in
15 compost-amended plots, but because bulk density decreased, there was no significant effect on soil
16 C stocks. Experimental drought did not significantly reduce plant biomass compared to control plots,
17 but stunted the increase in aboveground biomass in compost-treated plots and led to changes in root
18 traits. These results highlight the complexity of ecosystem C dynamics and the importance of
19 considering multiple biotic and abiotic factors across spatial scales when developing land
20 management strategies to enhance C sequestration.

21 **Introduction**

22 Soil management has been receiving increasing attention in the past years, with growing awareness
23 that soils provide vital ecosystem services and can act as C sinks (Minasny et al. 2017, European
24 Commission, Directorate-General for Health and Food Safety, 2020). The soil-plant system is integral
25 to this process, as plants capture atmospheric carbon dioxide through photosynthesis and transfer it
26 to the soil via roots and organic matter. Concerns about soil erosion and historic soil C depletion in
27 agricultural and grassland soils (Sanderman et al. 2017, Bai and Cotrufo, 2022) have motivated the

28 development of sustainable land management strategies, generally named “carbon farming” (Paul et
29 al. 2023) and promoted by the “4 per 1000” initiative (Minasny et al. 2017). These approaches include
30 mitigating soil organic carbon (SOC) loss in specific sites resulting from agricultural activities such
31 as tilling, which can be achieved with the use of soil C amendments like compost, biochar, and manure
32 on croplands or grasslands (Ryals and Silver 2013; Ryals et al. 2015; Keesstra et al. 2016; Fischer et
33 al. 2019; Garbowski et al. 2023). Soil C management via compost amendments aims to facilitate
34 accumulation of plant-derived C in the soil C pool, where it can be retained over long time scales –
35 i.e. decades to centuries (Shi et al. 2020). If the total C inputs and accumulation in the soil exceed the
36 total losses, C amendments can lead to C sequestration (Don et al. 2024, Moinet et al. 2023).

37 Since SOC accrual and C sequestration potential are uncertain and context dependent (Moinet et al.
38 2023), it is important to investigate the effects of C amendments across a range of climatic and
39 management conditions. Grasslands and croplands converted to grasslands can store considerable
40 amounts of soil C and are therefore ideal systems to apply C amendments. They can act as C sinks if
41 managed appropriately (Conant et al. 2001), and can have higher root biomass C compared to
42 agricultural lands, usually cultivated with annual crops (Beniston et al. 2014). Several studies have
43 investigated the effects of organic amendments on aboveground biomass (Ryals et al. 2016), crop
44 yields (Luo et al. 2018; Ahmad et al. 2009), and on roots in farming systems (Hirte et al. 2021), but
45 fewer focus on non-cultivated grasslands.

46 C amendments add C to the soil in two ways: directly, by moving plant biomass from one location to
47 another, and indirectly, by promoting plant growth (Ryals et al. 2016). Compost is rich in organic
48 matter, which serves as a substrate for soil microorganisms. As microbes decompose this organic
49 matter, they release nutrients in forms that plants can readily absorb (Malik et al. 2013). In turn, the
50 increased vegetation growth can increase the natural rate of C input and thus potentially SOC stocks
51 (Ryals et al. 2013). Indeed, model predictions suggest that compost additions on grasslands can lead
52 to soil C sequestration (DeLonge et al. 2013). By improving soil structure and reducing compaction,
53 compost additions may also reduce soil bulk density. As SOC stocks are calculated by multiplying C
54 concentration by the bulk density, improved management may also lead to net zero effects on C stock
55 despite increased soil C contents. Considering these indirect effects requires an ecosystem-level
56 perspective on the C sequestration potential of soils that accounts for both below- and above-ground

57 vegetation contributions to soil C stocks, as well as the soil depth at which management effects are
58 detectable. To this end, the use of isotope-labelled compost can improve our understanding of soil C
59 dynamics.

60 Land management practices—including compost amendments—can significantly impact both above-
61 and belowground plant biomass, which contribute differently to SOC storage. Root biomass and root
62 exudates are an integral part of soil C formation and retention (Jackson et al., 2017). In fact, roots are
63 more recalcitrant to decomposition compared to shoots (Rasse et al. 2005, Gaudinski et al. 2000), and
64 play a central role in C sequestration efforts. However, aboveground plant biomass should also be
65 included in these assessments to identify potential trade-offs in above- vs. belowground C allocation
66 within the vegetation pool, and to determine whether changes in plant biomass affect the soil C pool
67 (Hayes et al. 2017). Above- and belowground biomass may also respond differently to soil
68 amendments (Garbowski et al. 2020). This variation is expected, as roots and shoots respond
69 differently to changes in nutrient (Hayes et al. 2017) and water availability (Wilcox et al. 2017;
70 Guasconi et al. 2023). Therefore, an approach that accounts for above- and belowground interactions
71 is essential to understand the proportion of plant litter contributing to SOM formation and
72 stabilization (Cotrufo et al., 2015), and to achieve a comprehensive understanding of ecosystem C
73 dynamics (Heimann and Reichstein, 2008).

74 Another promising application of soil organic amendments is their use to mitigate the negative effects
75 of drought on vegetation and soil microbial communities, as has been observed with biochar (Fischer
76 et al. 2019). Future climate projections indicate an increase in extreme weather events, including
77 longer and more frequent droughts (IPCC, 2021). These conditions may decrease vegetation growth
78 both above- and belowground (Guasconi et al., 2023) and modify plant carbon (C) allocation
79 (Hasibeder et al., 2015), leading to lower C inputs to the soil and potentially decreased soil C stocks
80 (Deng et al., 2021). Organic soil amendments can enhance resilience to drought by increasing soil's
81 water-holding capacity (Fischer et al. 2019; Haque et al. 2021). These effects are modulated by soil
82 texture, by the quantity and quality of soil organic matter (Rawls et al. 2003; Yang et al. 2014; Franco-
83 Andreu et al. 2017; Sarker et al. 2022) and by its chemical composition (Franco-Andreu et al. 2017).
84 The increased moisture retention can also indirectly benefit the ecosystem C balance by partly
85 compensating the drought-induced loss of plant biomass (Kallenbach et al. 2019; Ali et al. 2017).

86 Soil and plant communities can show great variability in response to both drought (Guasconi et al.
87 2023; Canarini et al. 2017) and soil amendments (Gebhardt et al. 2017). This variability derives partly
88 from the variable physical properties of soil, but can also depend on land use history or on small- and
89 large-scale topography (Wang et al. 2020), and highlights the need for more field-based data
90 collections—in particular under experimental conditions that combine soil amendments and drought.

91 Here, we present the results of a field experiment designed to assess the effects of compost and of
92 reduced precipitation on both soil and plant biomass after three growing seasons. The changes were
93 observed at various soil depths, in two grasslands, and at two catenary positions, i.e. at the top and at
94 the bottom of a slope. We tested the hypotheses that:

95 1) compost amendment increases soil C content and plant growth (both having positive effects on C
96 stocks), while decreasing soil bulk density (having a negative effect on C stocks); we expect that these
97 mechanisms have counteracting effects on net soil C storage;

98 2) drought will have a weak negative or non-detectable effect on SOC by decreasing both productivity
99 (organic C input) and respiration (microbial decomposition of SOM);

100 3) compost amendment mitigates the loss of soil moisture under drought which may alleviate loss of
101 plant growth under drought.

102

103 Methods

104 **Site description and experimental setup**

105 The experimental site was established in summer 2019 in the proximity of Tovetorp Research Station
106 south of Stockholm, Sweden, and consists of two former arable fields (hereafter called “Tovetorp”
107 and “Ämtvik”), each with an upper and a lower catenary position (hereafter called “high” and “low”).
108 Today, the land management consists of cow grazing and hay production (see Roth et al. 2023). Soil
109 in all locations is rich in clay and ranges from silty clay to silty loam (table S1).

110 In each of these four locations, four treatments were applied in three replicates, resulting in 12 plots
111 per location and 48 plots in total: compost, drought, drought-compost, control (ambient precipitation,
112 no compost treatment). Each plot measured 2x2 m. Because the effects of already partly decomposed
113 organic amendments can be expected to be longer-lasting than those of easily decomposable ones
114 (Sarker et al. 2022), we applied a one-time compost treatment combined with a growing season

115 drought and investigated the effects on the soil C stocks after three full growing seasons. The compost
116 was made of *Zea mays* with a C:N ratio of 9.8 and $\delta^{13}\text{C}$ value of about -15.39‰. After the seasonal
117 corn harvest (summer 2019) the green parts of the plants were collected in an open field. The piled
118 material was regularly stirred to promote the composting process, and the resulting compost was
119 collected and applied in mid-February 2020 as a thin surface layer of ca. 11 kg per m² (wet weight),
120 similar to the procedure described in Ryals and Silver (2013). The total amount of C added is on
121 average ~0.54 kg C m⁻². The $\delta^{13}\text{C}$ isotope ratio of the compost is higher than that of bulk soil (-15.39
122 and -27.25, respectively), which means that the $\delta^{13}\text{C}$ isotope ratios of different treatments can be used
123 to assess if and where in the soil the compost material is retained after the three years of treatment.
124 The drought treatment followed the guidelines of the Drought-Net Research Coordination Network
125 (Knapp et al. 2017; Yahdjian and Sala, 2002), and consisted of 12 rainout shelters (3 per location)
126 with roofs made out of evenly-placed v-shaped polycarbonate strips designed to exclude 60% of the
127 precipitation during the entire growing season (in place from beginning of July to end of October in
128 2019, and from beginning of April to end of October in 2020, 2021 and 2022). This precipitation
129 reduction corresponds to the 1st quantile of the local 100-year precipitation record (Swedish
130 Meteorological and Hydrological Institute, 2021). Each shelter covered two plots, one for the drought
131 treatment and one for the combined drought-compost treatment. A rubber sheet, approximately 40
132 cm in depth, was inserted in the soil around each shelter to isolate the study plots from the ambient
133 soil moisture. Pictures and sketches of the sites and of the experimental design are presented in Roth
134 et al. (2023). Total annual precipitation during the study years was retrieved from the records of
135 Tovetorp Research Station (table S2). We note that while the precipitation in the growing seasons
136 2019 and 2022 (April through August) was roughly the same (157 mm and 156 mm, respectively),
137 the 2019 sampling followed an extremely dry summer in 2018, when the study area received only 77
138 mm of precipitation, about half of the precipitation compared to the average 1961-1990 (historical
139 data from SMHI, 2021). Conversely, the 2022 sampling followed the very wet 2021, when the area
140 received almost 140% of the normal precipitation over the same time period (250 mm).

141

142 **Soil and vegetation sampling and analyses**

143 Soil and root samples were collected in three replicates from each of the four sites and treatments
144 (one sampling per plot) at the end of the first growing season in 2019 (August - September), and again
145 at the end of the experiment in 2022 (August and October). Samples for soil bulk density were

146 collected with a large fixed volume root auger with a sharpened cutting edge (8 cm diameter and 15
147 cm in length; Eijkelkamp, The Netherlands). Three 15 cm segments were collected sequentially using
148 the same hole, reaching a total depth of 45 cm. Upon extraction, the cores were cut into 5 cm
149 segments, and the bulk density was determined after drying the samples at 105 °C. After drying, a
150 subsample from the same core was used to calculate the soil organic matter (SOM) content through
151 loss on ignition at 550 °C for 4 h. A subset was further burned at 960 °C in order to determine the
152 presence of inorganic C, which was low (0.5 %), indicating that the total C can be considered equal
153 to organic C (OC). Samples for total C and N and $\delta^{13}\text{C}$ were taken to a depth of 1 m with a Pürckhauer
154 soil corer (2.5 cm diameter; Eijkelkamp, The Netherlands) in 5 cm increments. The analyses for total
155 C and N contents, and for $\delta^{13}\text{C}$ were carried out on a subset of the samples by the Stable Isotope
156 Facility at UC Davis (California). A subset of these samples was sent to a commercial lab and used
157 for pH measurements (measured in a commercial lab using distilled water with a Mantech Automax
158 73, Guelph, ON., Canada) and nutrient content analyses (P, Ca, Mg and K; Avio 500 ICP Optical
159 Emission Spectrometer, Perkin Elmer, Waltham, MA; USA) (Table S3). Soil moisture was measured
160 every three weeks throughout the growing season (2019 through 2022) from one access tube (1 m
161 long) permanently installed in each plot, using a PR2 profile probe (Delta-T Devices Ltd, Cambridge,
162 UK). The values used in the analyses are growing season averages of volumetric soil water content
163 (%) in the first 30 cm in each plot.

164 Root biomass was collected in September 2019 and in August 2022 with one soil core sampled with
165 a root auger (8 cm diameter; Eijkelkamp, The Netherlands) by placing the auger on top of the plants,
166 but living aboveground plant biomass and fresh litter were removed and not included in the soil
167 samples. Samples were taken to a depth of 30 cm in all plots and to a depth of 45 cm in a subsample
168 of 16 plots (used as control for maximum rooting depth), with soil cores divided into 5 cm segments.
169 The roots were rinsed with water on a 0.5 mm mesh sieve to remove soil, then placed on a transparent
170 tray, covered with water and scanned with a flatbed scanner at 600 dpi (grey scale), followed by
171 drying at 60 °C for 48 h to obtain the dry weight. The scanned images were analyzed with WinRhizo
172 (Regent Instruments, Québec, CA) to obtain root volume, length and diameter, used to calculate root
173 mass density (g roots cm^{-3} soil), specific root length (cm g^{-1} roots) and root tissue density (g roots cm^{-3}
174 roots). Aboveground biomass was harvested from one quarter (1 m^2) of each plot every year in mid-

175 July, by cutting at ground level (including moss and dead biomass, table S4). More details of the
176 sampling design are presented in the Supplements (table S5).

177 **Statistical analyses**

178 Because of the sensitivity of vegetation to natural variability in precipitation (Liu et al. 2020) and
179 potential effects of landscape heterogeneity on both soil C dynamics and plant growth (Sharma et al.
180 2022; Guo et al. 2018), the analyses include testing for differences in the control plots between the
181 start and the end of the experiment, as well quantifying the variability given by grassland and catenary
182 position, which we expect might lead to variations in all C pools. The measured soil organic C
183 contents (mass of C per unit mass of soil) at different depths within the soil profile were used to
184 calculate soil C stocks (C content \times bulk density \times layer thickness). The soil C stocks were then
185 normalized by soil sample thickness (kg m^{-3}) to allow comparisons among soil layers with different
186 thickness. Because C contents were not measured in all samples, a regression was performed to
187 calculate SOC from SOM data (which was available for all samples) and thus obtain a complete
188 dataset,

$$189 \text{SOC} = 0.328 \times \text{SOM} + 0.217, \quad (1)$$

190 where SOC and SOM are expressed in kg/m^2 (Fig. S1).

191 The fraction F of compost-derived C detected in the soil in year 2022 was calculated with a two end-
192 member mixing model, as in Poeplau et al. (2023),

$$193 F = \frac{\delta^{13}\text{C}_{\text{compost treatment}} - \delta^{13}\text{C}_{\text{control}}}{\delta^{13}\text{C}_{\text{compost}} - \delta^{13}\text{C}_{\text{control}}}, \quad (2)$$

194 where $\delta^{13}\text{C}$ was measured in both compost-amended (compost or compost-drought) and control (no
195 compost or drought-no compost, respectively) plots.

196 All the results and statistical analyses are limited to the depth range of 0-45 cm. This is because this
197 soil depth contains the majority of the root biomass (95% within the first 30 cm, mean ~ 17 cm), and
198 no effect of treatments could be detected below this range (data not shown).

199 All analyses were made in R (version 3.3.3; R core Team 2017), and statistical models were designed
200 with the lmer function (package: lme4). Pairwise comparisons between categorical variables were
201 made with lsmeans (package: emmeans) and p-values ($\alpha = 0.05$) were obtained with the ANOVA
202 function and the lmerTest package. Residuals from the models were checked graphically. Effect sizes
203 were obtained by calculating Cohen's d , with the formula

204
$$d = \frac{\bar{x}_1 - \bar{x}_2}{s}, \tag{3}$$

205 where \bar{x}_1 and \bar{x}_2 are mean values for the two groups for which the effect size is calculated, and S is
206 the standard deviation.

207 The effect of the treatments was tested on all plots from the 2022 dataset. Values for root biomass
208 and root traits were log-transformed first. The model included compost (categorical variable), drought
209 (categorical variable) and sampling depth (continuous variable) as fixed factors and plot (nested
210 within site) as random factor. Cohen's d was calculated using the standard deviation of the control
211 group. The effect of the compost amendment on the $\delta^{13}\text{C}$ ratio was tested with a mixed linear model
212 that included compost and depth as fixed factors, and plot (nested within site) as random factor.
213 Changes in soil C, bulk density and C stocks were also tested with a model using depth as categorical
214 variable, to assess if changes occurred at specific depths. The variability in plant biomass and soil
215 properties across locations was tested on all data collected in 2019 and from the control plots in 2022.
216 The model included grassland site, catenary position and sampling depth (continuous variable) as
217 fixed factors and year and plot as random factors. Cohen's d was calculated using the standard
218 deviation pooled from all groups. Temporal changes during the experiment not caused by the
219 treatments were tested using data obtained in 2019 and 2022 from the control plots. The model
220 included year and sampling depth (continuous variable) as fixed factors and plot (nested within site)
221 as random factor. Cohen's d was calculated using the standard deviation of the 2019 dataset. The
222 variable depth was not included in the models for aboveground biomass.

223

224 Results

225 The drought treatment decreased soil moisture by 16% in the upper 0-30 cm during the growing
226 season (Fig. S2). The effect of drought was consistent over sites, years and seasons, and there were
227 no statistically significant differences in the drought-driven soil moisture loss between locations,
228 years, or between spring (April-May), summer (June-July-August) or growing season (April through
229 August). There was also no significant difference in soil moisture decrease between drought plots and
230 drought-compost plots (Fig. S3). Additionally, the compost addition did not have any significant
231 effect on soil pH or on soil P, Ca, Mg and K. The compost addition did, however, raise the value of
232 $\delta^{13}\text{C}$ in the treated plots (mean control plots = -27.44‰, mean compost plots = -27.10‰, $P < 0.01$),
233 and the difference was significant at 0-5 cm, 30-35 cm and 40-45 cm. The mixing model (Eq. 2)

234 indicated that after three growing seasons, the percentage of compost-derived C in the compost plots
 235 was 3.43 % in the 0-5 cm layer, 4.88 % in the 30-35 cm layer and 5.51 % in the 40-45 cm layer. In
 236 the compost x drought plots, the percentage of compost-derived C was 4.55 % in the 0-5 cm layer,
 237 6.52 % in the 30-35 cm layer and 2.96 % in the 40-45 cm layer.

239
 240 *Fig 1. Values of $\delta^{13}\text{C}$ in the soil in compost-treated (triangles) and untreated (control, green dots) plots under drought*
 241 *(dark red, dark blue) and at ambient precipitation (orange, light green) in 2022, at different depths. The percentage of*
 242 *compost-derived C in the soil was calculated with the isotope mixing model in Eq. 2.*

243 **Compost and drought effects**

244 Total soil C content ($P = 0.04$) and aboveground biomass ($P = 0.04$) increased in the compost-treated
 245 plots. The latter increased by 23% (mean control plots = 642 g m^{-2} , $\text{SD} = 129.23$, mean compost plots
 246 = 788 g m^{-2} , $\text{SD} = 221.7$). The effect on soil C was significant only in the top 5 cm layer (Fig. 2),
 247 where soil C content increased by 18% (mean control plots C content = 29.9 mg/g , $\text{SD} = 1.03$, mean

248 compost plots = 35.3 mg/g, SD = 0.75). Soil nitrogen (N) was higher in the top 5 cm layer in the
249 compost-treated plots (mean control plots = 2.44 mg/g, SD = 0.06, mean compost plots = 2.88 mg/g,
250 SD = 0.06; $p < 0.05$), but the treatment did not significantly affect the C:N ratio. The compost
251 treatment also decreased bulk density by 9% ($P = 0.03$) in the first 10 cm of soil (mean control plots
252 = 1.34 g cm³, SD = 0.18, mean compost plots = 1.22 g cm³, SD = 0.17), but did not affect any other
253 variable. The increase in the soil C content under compost addition was offset by the reduced bulk
254 density, so that there was no statistically significant change to soil C stocks. However, we note that,
255 albeit non-statistically significant, mean soil C stocks were 6% higher in the compost-treated (ambient
256 precipitation) plots in the first 15 cm, slightly higher than the percentage of compost-derived C found
257 in that layer (mean control plots = 4.02 kg m², SD = 0.92, mean compost plots = 4.26 kg m², SD =
258 0.59).

259 Experimental drought had only an effect on aboveground biomass, which decreased by almost 4%
260 under the rainout shelters (mean control plots = 642 g m², SD = 129.23, mean drought plots = 617 g
261 m², SD = 180.25). However, this effect was significant only relatively to the compost-treated plots (P
262 = 0.02), but not relatively to untreated control. Further, there was no significant difference in plant
263 biomass between the drought-treated plots with and without compost addition.

264
 265 *Fig. 2. Values of soil bulk density, soil carbon (C) contents, soil C stocks, root biomass, shoot biomass and root-shoot*
 266 *ratio, at different sampling depths in 2022 (n = 12). Values are averages of all sites. Green = control, red = compost,*
 267 *yellow = compost×drought, blue = drought. Boxes show mean (diamond inside the box), median (horizontal line) and*
 268 *interquartile range (IQR, colored box); whiskers extend to 1.5×IQR; dots in the graph are outliers. Different letters*
 269 *indicate statistically significant differences between means (P < 0.05). The yellow squares indicate the top layer (0-5 cm).*

270 **Root traits**

271 In all drought-treated plots we observed an increase in root tissue density (P = 0.048), in specific root
 272 length of fine roots (P = 0.049), and in average root diameter (P = 0.045). If only roots in the top layer

273 (0-5 cm) were considered, in addition to these patterns, specific root length of coarse roots decreased
274 under drought ($P = 0.04$), while root tissue density ($P = 0.02$) and specific root length of all roots
275 increased after compost addition ($P = 0.01$).

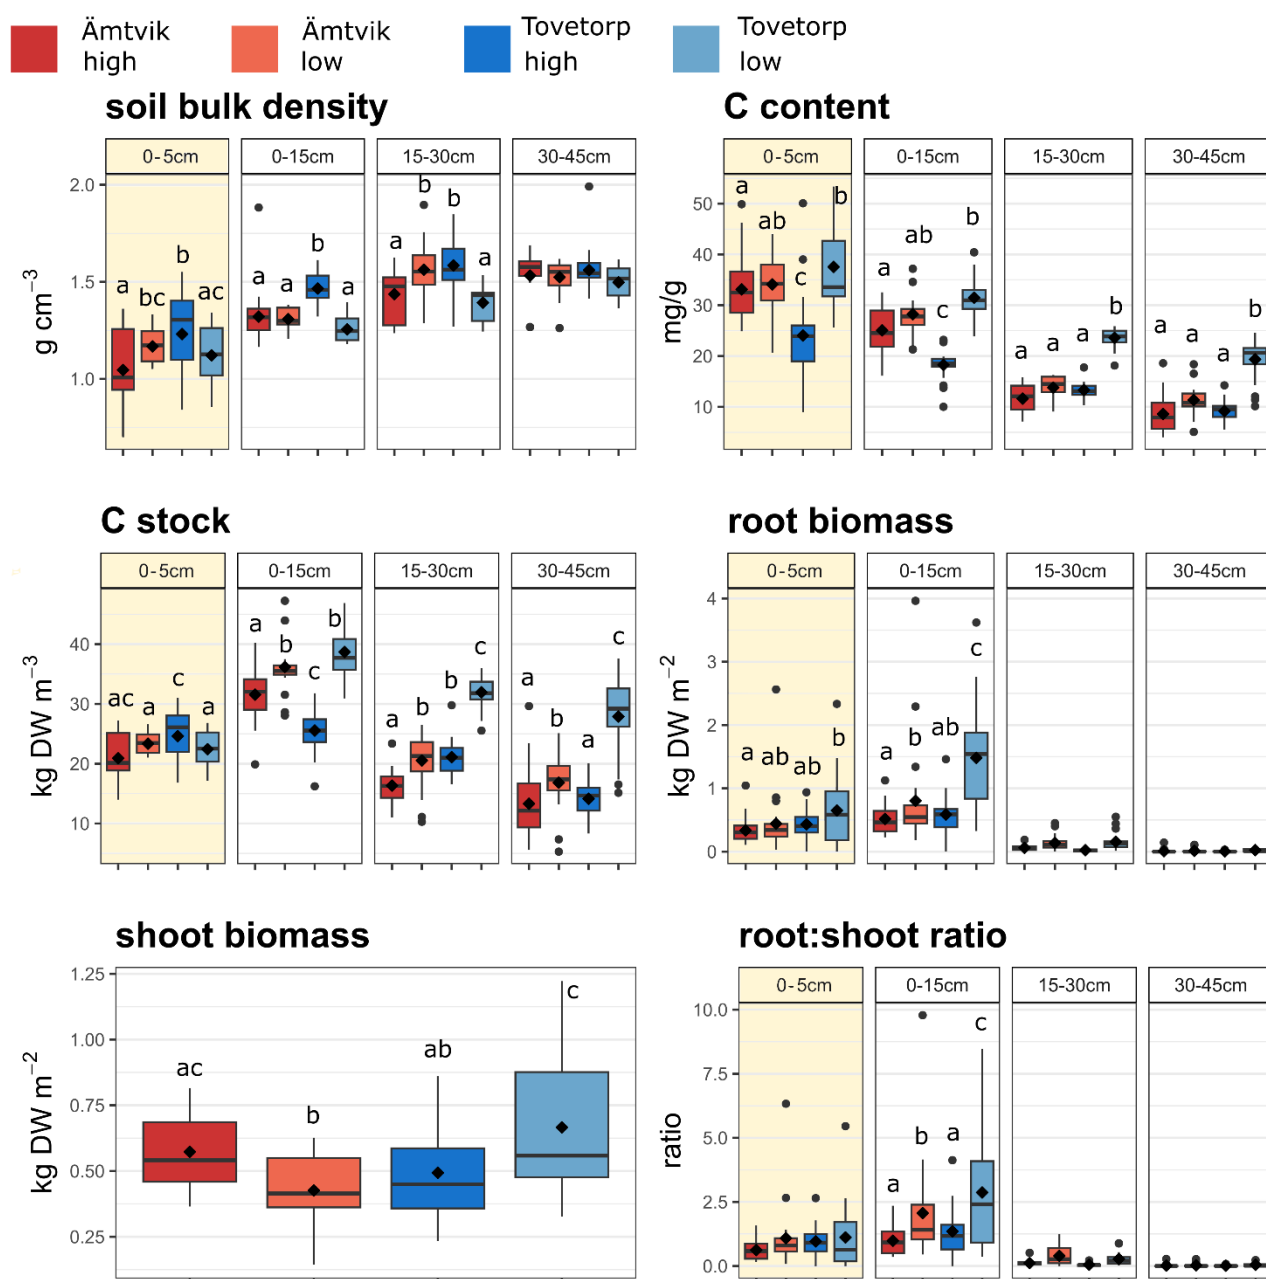

276
277 In all control plots, soil C and root biomass was positively correlated both in the top 5-15 cm (5-10
278 cm, $r = 0.42$, $P = 0.04$; 10-15 cm, $r = 0.5$, $P = 0.01$) and in the whole 0-30 cm layer (0-30 cm, $r = 0.63$,
279 $P < 0.01$). Soil C content was also positively correlated to the root:shoot ratio (5-10 cm, $r = 0.44$, $P =$
280 0.03 ; 10-15 cm, $r = 0.4$, $P = 0.052$; 0-30 cm, $r = 0.43$, $P = 0.04$). In the compost-treated plots, the only
281 significant correlation was between soil C and root biomass when considering the whole 0-30 cm
282 layer (0-30 cm, $r = 0.55$, $P < 0.01$). The strength of the correlation did not differ between control and
283 compost-treated plots ($r = 0.22$, $P < 0.01$ in control and compost-treated plots).

284

285 **Spatial variability at the landscape scale**

286 Soil C contents, total C stocks, bulk density, root biomass and root:shoot ratio showed significant (P
287 < 0.05) differences between catenary positions and depths, and soil C content and bulk density also
288 differed significantly between grasslands (Fig. 3, table S8). Grassland identity and the interaction
289 between grasslands and catenary positions were the only significant predictors of aboveground
290 biomass (Fig. 3).

291

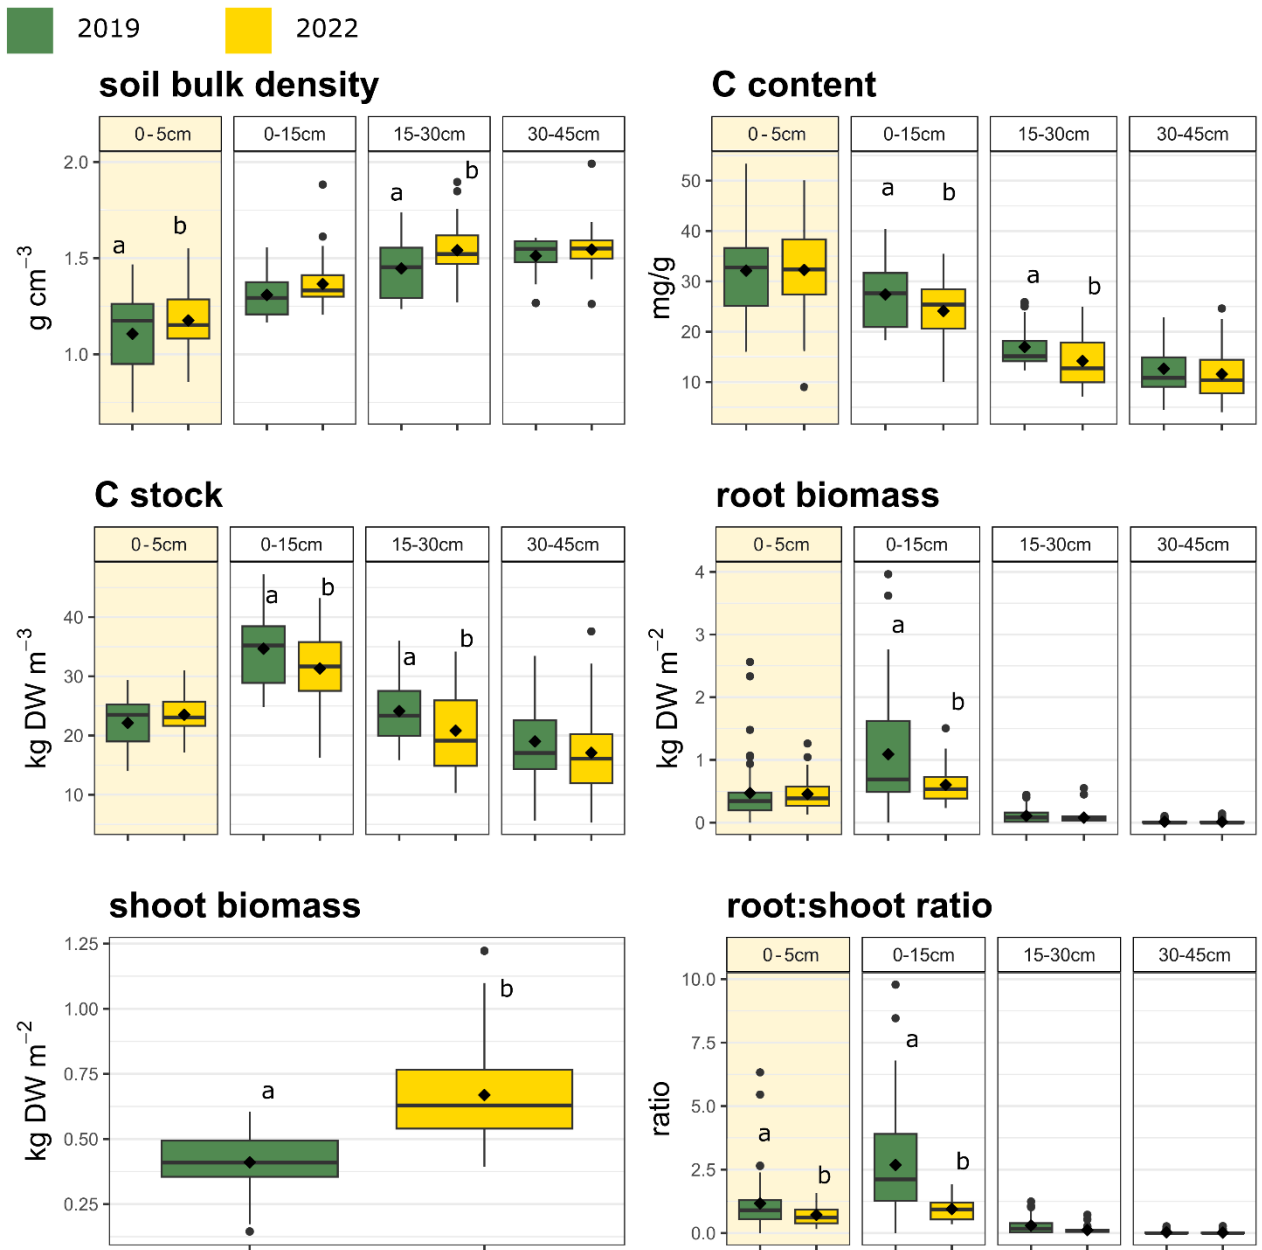

292

293 Fig. 3. Values of soil bulk density, soil carbon (C) content, soil C stocks, root biomass, shoot biomass and root-shoot
 294 ratio, at different sampling depths at the four sites, excluding treatments. The data consists of average values from 2019
 295 (all plots, n = 48) and 2022 (only control plots, n = 12). Red = Ämtvik High catenary position, orange = Ämtvik Low
 296 catenary position, blue = Tovetorp High catenary position, light blue = Tovetorp Low catenary position. Boxes show
 297 mean (diamond inside the box), median (horizontal line) and interquartile range (IQR, colored box); whiskers extend to
 298 1.5×IQR; dots in the graph are outliers. Different letters indicate statistically significant differences between means (P
 299 < 0.05). The yellow squares indicate the top layer (0-5 cm).

300 **Natural changes during the 2019-2022 period**

301 Aboveground biomass also differed significantly between sampling years. Between 2019 and 2022
302 (Fig. 4, table S9) total soil C contents and root biomass in the first 5 cm of the control plots decreased
303 by 10.7% (from 33.5 mg/g, SD = 1.05 to 2.99 mg/g, SD = 1.03) and 8.4% (from 522.96 g m⁻², SD =
304 626.48 to 479.25 g m⁻², SD = 320.75), respectively. In the first 15 cm, they decreased by 21.5% (from
305 29.7 mg/g, SD = 0.73 to 23.3 mg/g, SD = 0.71) and 38.7% (from 1017.95 g m⁻², SD = 955.16 to
306 623.65 g m⁻², SD = 65.19), respectively. Aboveground biomass instead increased by 53% (from
307 419.68 g m⁻², SD = 137.45 to 642.23 g m⁻², SD = 129.23).

315 Discussion

316 **Compost effects on soil C and plant growth**

317 Total soil C contents increased after compost application, but because bulk density was also reduced,
318 there was no significant increase in soil C stocks (partly confirming our first hypothesis), despite
319 higher mean soil C stocks in the compost treated plots in the first 15 cm of soil. This difference was
320 lower than the C addition ($\sim 0.54 \text{ kg C m}^{-2}$) and thus lower than expected, but is likely due to
321 respiration loss. Compost is partly decomposed organic matter, and thus more chemically recalcitrant
322 than fresh grass residues. As a result, its effects on SOC accrual can be persistent over several years
323 (Sarker et al. 2022) even after a single application (Ryals et al. 2013). Despite evidence that compost
324 amendments can lead to SOC accumulation already within two years after application (Gravuer et al.
325 2023), it is likely that the effect of our treatment on soil properties and soil C will persist beyond the
326 2022 sampling. This is also supported by the isotope tracing (Fig. 1), indicating that at least a fraction
327 of the compost-derived C is still present in the soil after three growing seasons. The significant
328 increase in aboveground biomass three years after the compost application could partly be explained
329 by the persistence of favorable plant growing conditions, such as increased N in the soil. This
330 mechanism was invoked by Oladeji et al (2020), and may interact with precipitation-related
331 interannual variability in plant growth (Sala et al. 2012). Our results suggest that compost treatments
332 might benefit the ecosystem C balance indirectly through increased biomass production, such as in
333 this case, or by extending the growing season, such as in Fenster et al. (2023). These interactions
334 between land management, vegetation growth and plant-derived C inputs also underline the
335 importance of including vegetation dynamics when assessing the effectiveness of C management.
336 Our compost addition treatment did not lead to an increase in soil C accumulation, but resulted in a
337 lower net C loss from the grassland. In fact, soil C in a given layer increased more than the amount
338 of compost-derived C remaining in that layer. This suggests that the increase in soil C is not only
339 derived from the amendment itself, but also from increased plant C inputs. However, longer-term
340 studies are necessary to understand whether SOC saturation limits the effectiveness of compost
341 amendments in sustaining these gains over time (Moinet et al. 2023).

342 Compost enhanced aboveground biomass growth, but not root growth, possibly in response to the
343 increased nutrient supply (Bloom et al. 1985; Poorter and Nagel 2000), thereby only partly confirming

344 our first hypothesis. In broader terms, this suggests that the compost treatment led plants to
345 preferentially allocate to aboveground organs the resources that would otherwise be allocated to
346 nutrient acquisition belowground (Cleland et al. 2017). Nevertheless, increased root tissue density
347 and specific root length in the top 5 cm layer suggest that root response to organic amendments is
348 manifested in more subtle changes in root traits related to nutrient acquisition (Bardgett et al. 2014),
349 rather than in net root biomass production.

350 Microbial activity and microbial biomass can be higher after compost addition (Sarker et al. 2022;
351 Gravuer et al. 2019). Here, the limited effects of the compost treatment on soil C stocks suggest that
352 the potential C accrual brought by the increased plant productivity might have been offset by
353 increased microbial respiration (promoted by either compost or enhanced rhizodeposition of more
354 productive plants) (Borken et al. 2002). Finally, the significant spatial and temporal variability in both
355 soil C and vegetation biomass observed in the control dataset suggests that treatment effects might be
356 site-specific (Garbowski et al. 2020), and management plans seeking to increase C accrual should
357 consider the potentially interactive effects of several biotic and abiotic factors, such as plant
358 community composition, soil type and climate. For instance, in our experiment, aboveground biomass
359 increase was highest at the site with the greatest abundance of grasses (table S4).

360 **Drought effects on soil moisture, soil C and plant growth**

361 Drought treatments reduced soil moisture and aboveground plant biomass, but did not significantly
362 decrease root biomass (table S7), indicating preferential biomass allocation and resource investment
363 to belowground organs under precipitation reduction. Plant growth is very sensitive to yearly
364 fluctuations and even intra-annual distribution of precipitation (Knapp and Smith 2001, Porporato et
365 al. 2006). Because our analyses are based on only two temporal datapoints (2019 and 2022), it is
366 difficult to assess whether drought reduced plant turnover, defined as the ratio of standing biomass to
367 net primary productivity (NPP). As there was some natural variability in the annual precipitation (see
368 methods section), it is possible that a legacy effect of this variability may have affected plant growth
369 (Sala et al. 2012) particularly aboveground (Fig. 4), where growth is more sensitive than root biomass
370 to yearly fluctuations in water availability (Zhang et al. 2021). In particular, legacy effects of the 2018
371 drought could have hampered growth in 2019, as aboveground vegetation in the control plots
372 increased by more than 50% between 2019 and 2022. Conversely, the high summer precipitation in

373 2021 could have buffered the effects of the experimental drought in 2022, leading to overall weak
374 drought effects (Sala et al. 2012).

375 The drought treatment had a relatively small impact on plant biomass and on roots in particular (Fig.
376 2). Because we do not know which plant species the sampled roots belong to, we cannot make any
377 conclusions related to belowground drought responses of different plant functional groups (Zhang et
378 al. 2017; Mackie et al. 2019; Zhong et al. 2019). However, we note that the magnitude of the drought
379 did not differ between locations and soil physical properties were similar across sites, but drought
380 effects differed across locations (Fig. S4). Therefore, we can hypothesize that differences in the plant
381 communities account for at least some of the spatial heterogeneity observed in our study, as was
382 observed by Garbowski et al. (2020). Also, while drought effects on root biomass were marginal, the
383 drought treatment did increase both root tissue density and average root diameter. Climate is a strong
384 predictor of root trait variation (Freschet et al. 2017), and higher root tissue density is correlated with
385 resource-conservative acquisition strategies (Bardgett et al. 2014) and longer root life span (Ryser,
386 1996), suggesting some degree of drought adaptation in our plant communities.

387 Adopting a standardized drought experimental design improves comparability, but partial rainout
388 shelters will still allow for a substantial amount of precipitation to pass through, potentially raising
389 soil moisture above the wilting point. Experimental droughts also fail to account for reduced air
390 humidity, which may underestimate negative responses of plant biomass to drought in field
391 experiments (Kröel-Dulay et al. 2022), and for increased temperatures, which often occur in
392 combination with natural droughts. These methodological limitations might explain why we observed
393 minor drought effects on vegetation. To understand the ecosystem-level implications of drought, soil
394 C changes need to be considered as well. Dry conditions decrease heterotrophic respiration because
395 microbial activity is inhibited due to both physiological mechanisms, such as osmoregulation
396 diverting efforts from resource acquisition to survival, and physical mechanisms, like the slower
397 transport of substrates in dry soils (as the water films around soil particles shrink and pore
398 connectivity is lost) (Moyano et al. 2013; Schimel 2018). However, heterotrophic respiration
399 increases again after soil rewetting, leading to disproportionately large C emissions during the short
400 post-rewetting period (Canarini et al. 2017; Barnard et al. 2020). Because the drought plots with
401 added compost had a higher fraction of compost-labelled isotopes compared to the non-drought plots

402 in the topsoil (Fig. 1), this would imply that any soil C emission pulses at rewetting were not sufficient
403 to compensate for the possibly lowered microbial activity during the soil moisture dry-downs. As a
404 result, in our experiment drought had no effects on soil C contents and stocks, as per our second
405 hypothesis, although it slightly reduced soil bulk density (in a pre-treatment vs post-treatment
406 comparison, data not shown), possibly in relation to shrinkage in dry soil.

407 **Interactive effects of compost and drought**

408 While previous studies indicated increased soil water retention after soil amendments (Franco-Andreu
409 et al. 2017; Ali et al. 2017), in our study compost-treated drought plots did not have higher soil
410 moisture than the untreated drought plots three years after compost application (Fig. S3), which leads
411 us to reject our third hypothesis. As the negative effects of drought on aboveground biomass were
412 weak, they were not visibly compensated for by the compost addition. On the contrary, the
413 experimental precipitation reduction obliterated the biomass increase detected in the compost-treated
414 plots in ambient rainfall, overriding the positive effects of the increased C and N provided through
415 the compost. This suggests that the vegetation response in our experiment does not only depend on
416 nutrient addition and interannual variability in precipitation, but likely also on plant physiological
417 processes related to water availability (Bista et al. 2018) and on the ability of soil microbes to render
418 the nutrients available for plant uptake. Interestingly however, while both compost and drought
419 tended to reduce root biomass, there was a tendency for higher root:shoot ratio in the plots with
420 combined compost and drought treatment (Fig. 2). While our results from the compost-treated plots
421 show that plants may reduce their belowground biomass investment relative to aboveground growth
422 when adding organic matter, this mechanism appeared to work differently under drought conditions,
423 when plants may shift C allocation belowground to aid in water acquisition (Eziz et al. 2017; Guswa
424 et al. 2010). This improved capacity for soil water absorption could potentially offset any compost-
425 induced increase in soil water retention capacity. However, since our experiment did not include
426 drought recovery, it is not known if this change would persist after the end of the experimental
427 drought.

428 **Conclusions**

429 We explored how drought and compost amendment affect soil properties and above- and
430 belowground plant biomass within a grassland ecosystem. Compost amendment and drought had

431 distinct effects on plant shoot and root growth, revealing the presence of trade-offs in their responses
432 to environmental change. The compost treatment led to an increase in biomass in shoots but not in
433 roots, and ultimately did not result in an increase in soil C stocks. Drought did not significantly affect
434 plant biomass, but led to changes in root traits and stunted the compost-induced increase in plant
435 growth measured in plots under ambient precipitation. These findings improve our understanding of
436 C dynamics in grasslands by illustrating the different components of plants and soil properties
437 affected by land management. We also observed significant spatial and temporal variability in
438 vegetation and soil C dynamics over the study period, which may be driven by differences in
439 topography, land use and plant community composition, as well as temporal variability in
440 precipitation.
