**Abstract.** Photocatalytic reactions during the daytime, alongside aqueous-phase reactions occurring during both daytime and nighttime, are identified as the two primary processes facilitating the conversion of aerosol iron (Fe) from the insoluble state to the soluble state within the atmospheric environment. This study investigated the levels of total Fe ( $Fe_T$ ) and soluble Fe ( $Fe_S$ ) in  $PM_{2.5}$  samples collected during daytime and nighttime in Qingdao, a coastal city in eastern China, evaluating the distinctive roles of these two pathways in enhancing aerosol Fe solubility ( $\%Fe_S$ , defined as the ratio of  $Fe_S$  to  $Fe_T$ ). Under clean and humid conditions, characterized by prevailing sea breezes and a relative humidity (RH) typically above 80%, an average daytime  $\%Fe_S$  of 8.7% was observed, which systematically exceeded the nighttime  $\%Fe_S$  (6.3%). Photochemical conversions involving oxalate contributed to the higher  $\%Fe_S$  observed during daytime. Conversely, in scenarios where air masses originated from inland areas and exhibited slightly polluted, daytime  $\%Fe_S$  (3.7%) was noted to be lower than the nighttime  $\%Fe_S$  (5.8%). This discrepancy was attributable to the variations in RH, with nighttime RH averaging around 77%, conducive to the more efficient generation of acidic compounds, thereby accelerating  $Fe_S$  production compared to the daytime, when RH was only about 62%. Furthermore, the oxidation rates of sulfur (SOR) displayed a strong correlation with RH, particularly when RH fell below 75%. A 10% increase in RH corresponded to a 7.6% rise in SOR, which served as the primary driver of the higher aerosol acidity and  $\%Fe_S$  at night. These findings highlight the RH-dependent activation of aqueous-phase reactions and the augmentation of daytime photocatalysis in the formation of  $Fe_S$  in the coastal moisture atmosphere.

## 30 **1 Introduction**

31 Iron (Fe) plays a pivotal role as a micronutrient in marine ecosystems, being a critical component of atmospheric  
32 aerosol particles (Martin et al., 1994). Its deposition in high-nitrate, low-chlorophyll (HNLC) regions can trigger  
33 phytoplankton bloom, thus enhancing atmospheric carbon absorption and fixation in seawater (Watson et al., 1994;  
34 Watson and Lefèvre, 1999; Toner, 2023). Notably, only the soluble fraction of Fe ( $F_{es}$ ) in aerosols, referred to as  
35 bioavailable Fe, is accessible to phytoplankton (Zhuang et al., 1992; Sugie et al., 2013; Li et al., 2017). The  
36 proportion of  $F_{es}$  to the total aerosol Fe ( $F_{T}$ ), i.e., the aerosol Fe solubility ( $\%F_{es}$ ), is influenced by the aerosols'  
37 sources and the chemical conversion of Fe from insoluble forms to soluble forms in the atmosphere.  $\%F_{es}$  in fresh  
38 dust particles is typically below 1%, yet can exceed 10% in aerosols derived from combustion processes, such as  
39 fly ash from coal and oil combustion (Oakes et al., 2012; Shi et al., 2012; Wang et al., 2015; Li et al., 2022).  
40 The  $\%F_{es}$  in primary particles can significantly increase due to atmospheric processes, primarily through aerosol  
41 acidification via aqueous-phase reactions or photochemical conversions of precursors of acidic species (Solmon  
42 et al., 2009; Shi et al., 2015; Li et al., 2017; Hettiarachchi et al., 2019), affecting the deposition flux of aerosol  $F_{es}$   
43 over the open ocean (Chen and Siefert, 2004; Shi et al., 2013; Yang et al., 2020).

44 Solar radiation and ambient humidity are two key meteorological factors that greatly influence the processes of  
45 aerosol acidification. Solar irradiation induces photochemical reactions during daytime, leading to the formation  
46 of free radicals and accelerating the production of acidic species within aerosols, thereby facilitating Fe dissolution  
47 (Chen and Grassian, 2013; Liu et al., 2021b). Studies such as Fu et al. (2010) have demonstrated increased  $F_{es}$  in  
48 dust samples exposed to light in the HCl solution. Furthermore, daytime photolysis of Fe-organic complexes is  
49 another pathway for  $F_{es}$  formation, contributing to increased  $\%F_{es}$  (Weller et al., 2014; Zhang et al., 2019; Zhou  
50 et al., 2020). For example, Zhou et al. (2020) and Zhang et al. (2019) reported that photolysis of oxalate-Fe(III)  
51 complex can result in the degradation of oxalate, enhancing Fe dissolution in aerosol particles during daytime.  
52 These mechanisms have been supported by laboratory experiments and model simulations (Zhu et al., 1993; Chen  
53 and Grassian, 2013; Sorooshian et al., 2013; Pang et al., 2019; Li et al., 2021). In contrast, high ambient relative  
54 humidity (RH) can facilitate the heterogeneous/liquid phase formation of sulfate and nitrate during nighttime,  
55 increasing aerosol acidity and promoting acids-associated Fe dissolution (Liu et al., 2020; Pye et al., 2020; Wong  
56 et al., 2020). Studies like Zhang et al. (2022) observed enhanced  $\%F_{es}$  ( $>1\%$ ) at high RH levels ( $>60\%$ ) in winter,  
57 while Zhu et al. (2020) highlighted the greater impact of  $SO_4^{2-}$  and  $NO_3^-$  on  $\%F_{es}$  at RH above 50%. Shi et al.

58 (2020) noted efficient  $\text{Fe}_s$  formation under foggy conditions, where  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  concentrations were high due  
59 to the absorption of precursor gases on wet particle surfaces, facilitating further water vapor absorption, and  $\text{Fe}_s$   
60 increase.

61 Aqueous-phase processes can occur during both daytime and nighttime, given adequate moisture. The formation  
62 of  $\text{Fe}_s$  results from the interplay between photochemistry and aqueous chemistry during daytime, whereas it relies  
63 solely on aqueous chemistry at night. The synergistic mechanisms and their individual contributions to  $\text{Fe}_s$   
64 formation remain partially understood.

65 To elucidate the roles of aqueous-phase and photochemical reactions on  $\text{Fe}_s$  formation, we collected  $\text{PM}_{2.5}$  samples  
66 during daytime and nighttime, separately, in a Chinese coastal city (Qingdao). Positioned under the westerlies of  
67 the Northern Hemisphere, Qingdao acts as a primary conduit for East Asian terrestrial aerosols to the Northwestern  
68 Pacific. Our research focuses on ascertaining the % $\text{Fe}_s$  enhancement under clean and slightly-polluted air  
69 conditions, reflecting typical coastal air quality. The primary goal is to delineate the contributions of aqueous-  
70 phase reactions and photochemical processes to % $\text{Fe}_s$  enhancement, thereby elucidating the dynamics of Fe  
71 dissolution within the atmospheric chemistry of coastal areas.

## 72 **2 Methodology and materials**

### 73 **2.1 Sample collection and classification**

74 The observation was carried out on the following dates: April 24<sup>th</sup> to May 27<sup>th</sup>, 2017; March 28<sup>th</sup> to April 30<sup>th</sup>,  
75 2018; and May 22<sup>nd</sup> to 28<sup>th</sup>, 2018. Two high-volume  $\text{PM}_{2.5}$  samplers (TISCH, TE-6070BLX-2.5, USA) were  
76 applied to collect  $\text{PM}_{2.5}$  onto quartz microfiber filters (QM-A, PALL) and Whatman<sup>®</sup> 41 filters, respectively, on  
77 the roof of Baguanshan Atmospheric Research Observatory (BARO, 36°03' N, 120°20' E, 76 m asl.). BARO is  
78 located on the top of a small hill in the urban area of Qingdao, and around 0.7 km away from the coastline of the  
79 Yellow Sea (Figure S1).  $\text{PM}_{2.5}$  samples were collected separately during daytime and nighttime. Field blank  
80 samples were also collected during the campaign by placing filters in the samplers with the samplers switched off.  
81 After the sampling process,  $\text{PM}_{2.5}$  samples were sealed and stored at  $-20^\circ\text{C}$  before analysis.

82 For the measurement of water-soluble ions (WSIs) and carbonaceous matters, aerosol samples collected on QM-  
83 A filters were utilized. The samples collected on Whatman<sup>®</sup> 41 filters were used for the detection of elements.  
84 Firstly, samples were cut into pieces and immersed in Milli-Q pure water. Then, water-soluble matters were  
85 extracted by ultrasonic vibration at approximately  $0^\circ\text{C}$  for 40 min. The water extracts were then filtered through

86 syringes with 0.45  $\mu\text{m}$  strainer heads (PALL). The filtered extracts were analyzed for WSIs, including  $\text{Na}^+$ ,  $\text{NH}_4^+$ ,  
87  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{C}_2\text{O}_4^{2-}$ , using ion chromatography (IC, Dionex ICS-3000, Dionex Corp.,  
88 Sunnyvale, CA, USA). Similar sample pretreatment procedures were used to determine soluble elements. While,  
89 10 ml of filtrate was taken and 0.187 ml  $\text{HNO}_3$  (mass fraction: 69%) was added to water extracts before measuring  
90 soluble elements, in case soluble Fe(II) was oxidized into an insoluble state. To determine total elements, sample  
91 pieces were placed into inner-tanks and subjected to digestion with a mixture of  $\text{HNO}_3 + \text{HF}$  (at a volume ratio of  
92 4:1) at  $180^\circ\text{C}$  for 48 h. The element concentrations were measured using inductively coupled plasma mass  
93 spectrometry (ICP-MS, Model: iCAP Qc, Thermo Fisher Scientific Inc., Germany). Carbonaceous materials,  
94 specifically organic carbon (OC) and elemental carbon (EC), were analyzed using a sunset OC/EC analyzer from  
95 Sunset Laboratory Inc. The detection limits of the analysis instruments used can be found in Table S1. The organic  
96 matter (OM) content was estimated with 1.6 times OC, as proposed by Turpin and Lim (2001). Further details  
97 about sample collection, pretreatment procedures, and chemical species detection can be found in our previous  
98 work (Li et al., 2023a; Li et al., 2023b).

99 Various weather conditions and air pollution characteristics were encountered during the observation period,  
100 including clean, slightly-polluted (SP), heavily-polluted, foggy, and dusty conditions. Due to the large deviations  
101 and uncertainties in the statistical results of dust-related samples, data from these samples were not considered.  
102 Additionally, samples from heavily-polluted periods ( $N = 6$ , defined by  $\text{PM}_{2.5} > 50 \mu\text{g m}^{-3}$  and  $\text{PM}_{2.5}/\text{PM}_{10} > 0.4$ )  
103 and fog-influenced samples ( $N = 12$ ) were also not included because of the limited sample number and the  
104 significant difference in fog durations between samples. In this paper, we focus on the results of the clean period  
105 samples ( $N = 19$ ) and the SP period samples ( $N = 32$ ). Clean periods samples were collected when  $\text{PM}_{2.5} < 30 \mu\text{g}$   
106  $\text{m}^{-3}$  and  $\text{PM}_{10} < 50 \mu\text{g m}^{-3}$ . The SP periods samples were those collected when  $30 \mu\text{g m}^{-3} < \text{PM}_{2.5} < 50 \mu\text{g m}^{-3}$  and  
107 those collected when  $\text{PM}_{2.5} < 30 \mu\text{g m}^{-3}$  while  $\text{PM}_{10} > 50 \mu\text{g m}^{-3}$ .

## 108 **2.2 Aerosol pH and liquid water content**

109 ISORROPIA thermodynamic equilibrium model (version II, [https://www.epfl.ch/labs/lapi/models-and-](https://www.epfl.ch/labs/lapi/models-and-software/isorrophia/iso-code-repository/)  
110 [software/isorrophia/iso-code-repository/](https://www.epfl.ch/labs/lapi/models-and-software/isorrophia/iso-code-repository/)) was employed to estimate gas concentrations and aerosol water pH (Song  
111 et al., 2018). The forward mode, which uses both gas and aerosol data as model input, was utilized for pH  
112 calculations. This approach was preferred to the reverse mode because the later, using only aerosol data, is very  
113 sensitive to the uncertainties of the measured WSIs concentrations (Hennigan et al., 2015; Song et al., 2018).

114 “Metastable-mode” was employed in ISORROPIA, assuming that solid precipitates did not form except for CaSO<sub>4</sub>.  
 115 The concentrations of gaseous species (i.e., NH<sub>3</sub>(g), HNO<sub>3</sub>(g), HCl(g)) were not measured at the site. In alignment  
 116 with the approach proposed by Sun et al. (2018), we devised a strategy to estimate the concentrations of these  
 117 gaseous species. Initially, the input of aerosol data was assumed as the sum of aerosol and gas data (specifically  
 118 for HNO<sub>3</sub>, HCl and NH<sub>3</sub>). This step provided us with the first set of gas and aerosol data outputs. For the second  
 119 run, the gas data output derived from the initial run was added to the original aerosol data, and it was considered  
 120 as the sum of gas data and aerosol data just like the first run to calculate HNO<sub>3</sub>(g), HCl(g) and NH<sub>3</sub>(g). The same  
 121 method was employed for subsequent iterations until the variance in the NO<sub>3</sub><sup>-</sup> output below the 1% threshold in  
 122 mass. The calculation processes can be described by the following equations:

$$123 \quad \text{Input}[C_{\text{Aerosol}}+C_{\text{Gas}}]_{N+1}=C_{\text{Aerosol}}+[C_{\text{Gas}}]_{N} \quad (1)$$

$$124 \quad L = \left| \frac{[C_{\text{NO}_3^-}]_{N+1} - [C_{\text{NO}_3^-}]_N}{[C_{\text{NO}_3^-}]_N} \right| \times 100\% \quad (2)$$

125 where C<sub>Aerosol</sub> is the observed concentration of NO<sub>3</sub><sup>-</sup> (or NH<sub>4</sub><sup>+</sup>, Cl<sup>-</sup>), C<sub>Gas</sub> is the concentration of gaseous species  
 126 of HNO<sub>3</sub>(g) (or NH<sub>3</sub>(g), HCl(g)), and [C<sub>Gas</sub>]<sub>N</sub> is the concentration of gaseous species of HNO<sub>3</sub>(g) (or NH<sub>3</sub>(g),  
 127 HCl(g)) output by ISORROPIA in the N<sup>th</sup> run (N ≥ 1). The iteration was stopped until L < 1%.

128 Finally, three times of iterations (N<sub>max</sub> = 3) were determined when L = 0.1%. The aerosol pH was calculated by  
 129 using aqueous H<sup>+</sup> concentration and aerosol liquid water content (ALWC) outputted by ISORROPIA, as described  
 130 by equation (3).

$$131 \quad \text{pH} = -\log_{10} \frac{1000 \times \text{H}^+(\text{aq})}{\text{ALWC}} \quad (3)$$

132 Significant correlations between the results of the first run and the fourth run were observed for pH (r<sup>2</sup> = 0.95) and  
 133 ALWC (r<sup>2</sup> = 0.99), indicating the stability and reliability in estimating the pH and ALWC by ISORROPIA II  
 134 (Figure S2). Moreover, the correlations of NO<sub>3</sub><sup>-</sup> (r<sup>2</sup> = 0.71), NH<sub>4</sub><sup>+</sup> (r<sup>2</sup> = 0.98) and Cl<sup>-</sup> (r<sup>2</sup> = 0.51) between the  
 135 simulated results and measured concentrations are significant, demonstrating the robust confidence level of the  
 136 simulated results (Figure S3).

137 In addition, the impact of organic matter (OM) on aerosol pH was determined to be minimal. This can be attributed  
 138 to the limited sensitivity of the predicted pH to the water uptake by organic species (ALWC<sub>org</sub>) when the OM  
 139 fraction in PM<sub>2.5</sub> is low (Guo et al., 2015; Liu et al., 2017). Following the methods of Guo et al. (2015), we

140 estimated  $ALWC_{org}$  and its influence on aerosol pH. Our analysis determined the  $ALWC_{org}$  to range between 0.83  
141 and  $3.31 \mu\text{g m}^{-3}$ , constituting merely 2.6–9.8% of the total ALWC. Aerosol pH was about 0.03–0.08 higher when  
142 considering OM, affirming the negligible effect of OM on aerosol pH (see Text S1 in the supporting information  
143 for more details).

### 144 **2.3 Weather conditions and air quality data**

145 The publicly released temperature, RH, surface pressure, wind speed, and wind direction recorded every 10  
146 minutes were obtained from a meteorological observatory of the Qingdao Meteorological Bureau (Figure S1).  
147 Hourly mass concentrations of  $PM_{2.5}$ ,  $PM_{10}$ ,  $SO_2$ ,  $NO_2$ ,  $O_3$  and CO were obtained from an adjacent air quality  
148 monitoring station in the Shinan District of Qingdao City (Figure S1), which is managed by Ministry of Ecology  
149 and Environment of the People's Republic of China (<http://www.mee.gov.cn/>).

150 To examine the relative abundance of chemical species in aerosols, we reconstructed the mass concentrations of  
151  $PM_{2.5}$  by equation (4) using the obtained concentrations of WSIs, OM, EC and elements.

$$152 \quad PM_{2.5R} = WSIs + OM + EC + Elements + Si + Ca \quad (4)$$

153 where  $PM_{2.5R}$  is the reconstructed  $PM_{2.5}$ , and WSIs consists of  $Na^+$ ,  $NH_4^+$ ,  $K^+$ ,  $F^-$ ,  $Cl^-$ ,  $SO_4^{2-}$ ,  $NO_3^-$  and  $C_2O_4^{2-}$ . As  
154 for elements, Mg, Al, V, Cr, Mn, Fe, Ni, Co, Cu, Zn, Ga, As, Se, Rb, Sr, Cd, Ba, Tl and Pb were considered. Si  
155 and Ca concentrations were estimated based on the mass ratio of Si/Al (3.43) following the methodology described  
156 by Huang et al. (2010) and the mass ratio of Ca/Al (0.80) suggested by Arimoto et al. (2004) and Wang et al.  
157 (2011). Because the nearby monitoring station is closer to the sea and less affected by human activities (yellow  
158 dot in Figure S1), the level of  $PM_{2.5R}$  is higher than the observations from the monitoring station. But the trends of  
159 variations of these two datasets were consistent, indicating the high confidence of the  $PM_{2.5R}$  dataset. In addition,  
160 any mention of ionic ratios or normalized parameters in the results and discussions of this paper indicates the data  
161 was divided by  $PM_{2.5R}$ .

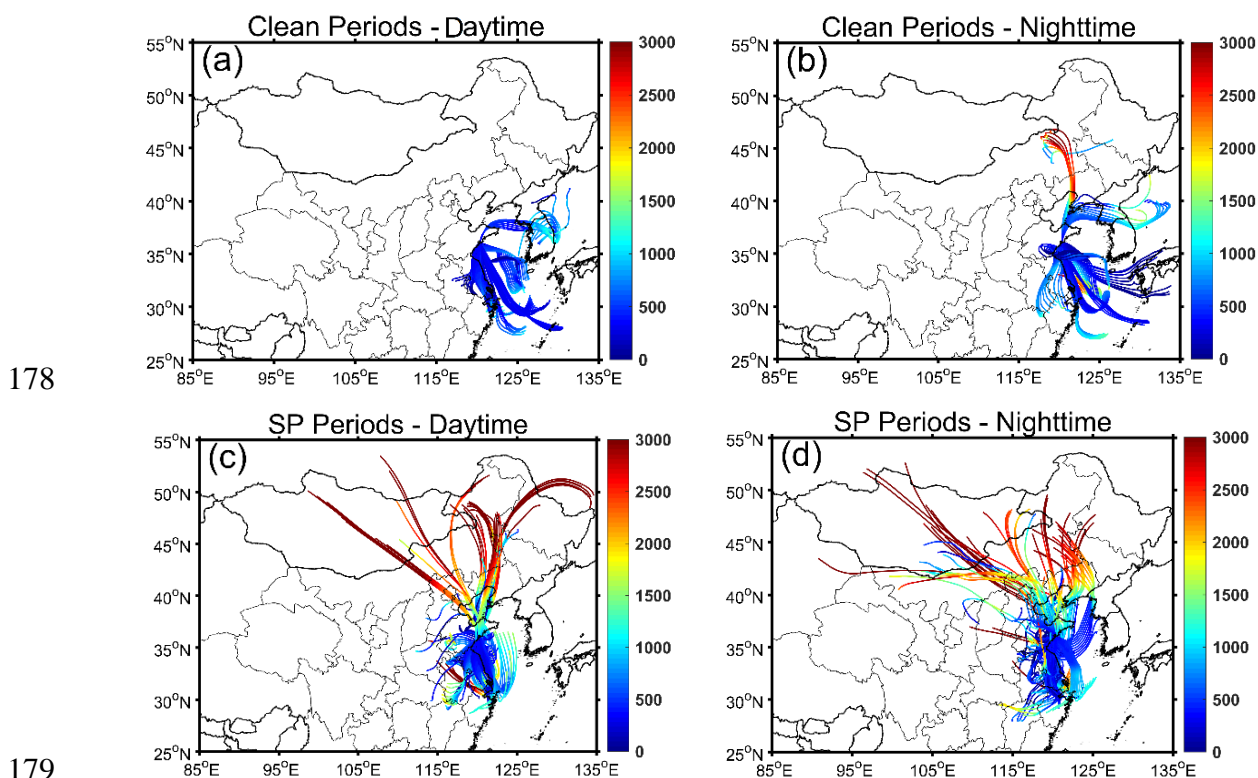

### 162 **2.4 Provenances of air masses**

163 The HYbrid Single-particle Lagrangian Integrated Trajectory (HYSPLIT) Model  
164 (<https://www.ready.noaa.gov/HYSPLIT.php>), developed by NOAA, was applied to calculate the origins of air  
165 masses from which  $PM_{2.5}$  samples were collected. Gridded GDAS data with a horizontal resolution of  $1.0^\circ \times 1.0^\circ$   
166 were used as the input. Backward trajectories were computed for a period of 48 h, with starting points located at  
167 300 m above ground level.

## 168 3 Results

### 169 3.1 Meteorological features of clean and SP periods

170 During clean periods, the backward trajectories reveal that the air masses mainly originated from sea areas (Figure  
171 1). The prevailing sea breeze resulted in high RH levels of  $81.5 \pm 4.9\%$  during daytime and  $86.6 \pm 8.8\%$  during  
172 nighttime (Table 1). The minimal temperature variance of about  $2^\circ\text{C}$  between daytime and nighttime further  
173 reflects the characteristics of marine atmosphere. In contrast, air masses during SP periods originated from various  
174 directions, with a significant number traversing terrestrial regions prior to arriving at the collection site.  
175 Temperature and RH exhibited noticeable diurnal variations. The daytime temperature was  $17.2 \pm 3.0^\circ\text{C}$  and  
176 decreased to  $13.2 \pm 3.7^\circ\text{C}$  during nighttime. The RH levels were  $62.1 \pm 9.4\%$  and  $76.8 \pm 9.4\%$  during daytime and  
177 nighttime, respectively.

180 **Figure 1: 48-h backward trajectories during daytime and nighttime during clean and slightly-polluted (SP) periods.**  
181 **Trajectories are color-coded based on the altitude (unit: m) above the ground.**

### 182 3.2 Concentrations of $\text{PM}_{2.5}$ and Fe, and %Fes

183 Table 1 presents the  $\text{PM}_{2.5}$  levels and aerosol Fe concentrations during both clean and SP periods. Under clean  
184 conditions,  $\text{PM}_{2.5}$  concentrations were similar during daytime and nighttime, with average values of  $16.9 \mu\text{g m}^{-3}$   
185 and  $16.4 \mu\text{g m}^{-3}$ , respectively. Compared to the nighttime,  $\text{Fe}_T$  and  $\text{Fe}_s$  concentrations were higher during the

186 daytime, which were  $289.2 \pm 223.4 \text{ ng m}^{-3}$  and  $20.0 \pm 10.5 \text{ ng m}^{-3}$ , respectively. Daytime levels of  $\text{Fe}_T$  and  $\text{Fe}_S$   
 187 were 1.5 times and 1.6 times as high as those observed at night, respectively. The increase in  $\text{Fe}_T$  and  $\text{Fe}_S$  during  
 188 daytime may be linked to heightened human activities. Furthermore, the elevated  $\text{Fe}_S$  during daytime could be  
 189 attributed to photochemical processes, which promoted the dissolution of aerosol Fe, a topic to be discussed further  
 190 in Section 4.2.  $\% \text{Fe}_S$  values ranged from 2.3% to 14.1% with an average of 8.7% during daytime, approximately  
 191 1.4 times the nighttime average of 6.3% (after removing an extreme point of 37.2%).

192

193 **Table 1. Meteorological parameters,  $\% \text{Fe}_S$ , aerosol pH, the concentrations (average  $\pm$  standard deviation) of  $\text{PM}_{2.5}$**   
 194 **and chemical species during clean and slightly-polluted periods.**

	Clean Periods		Slightly-polluted Periods	
	Daytime	Nighttime	Daytime	Nighttime
$\text{PM}_{2.5}$ ( $\mu\text{g m}^{-3}$ )	$16.9 \pm 3.1$	$16.4 \pm 5.6$	$30.3 \pm 7.0$	$28.3 \pm 7.7$
Temperature ( $^{\circ}\text{C}$ )	$16.6 \pm 2.8$	$14.3 \pm 2.3$	$17.2 \pm 3.0$	$13.2 \pm 3.7$
RH (%)	$81.5 \pm 4.9$	$86.6 \pm 8.8$	$62.1 \pm 9.4$	$76.8 \pm 9.4$
ALWC ( $\mu\text{g m}^{-3}$ )	$30.0 \pm 13.5$	$55.0 \pm 53.7$	$22.5 \pm 13.2$	$44.1 \pm 33.8$
$\text{Fe}_T$ ( $\text{ng m}^{-3}$ )	$289.2 \pm 223.4$	$186.7 \pm 122.2$	$938.3 \pm 850.5$	$520.3 \pm 496.1$
$\text{Fe}_S$ ( $\text{ng m}^{-3}$ )	$20.0 \pm 10.5$	$12.5 \pm 7.4$	$25.7 \pm 10.5$	$21.6 \pm 8.1$
$\% \text{Fe}_S$ (%)	$8.7 \pm 3.8$	$6.3 \pm 4.1$	$3.7 \pm 2.0$	$5.8 \pm 3.0$
pH	$0.46 \pm 0.83$	$1.06 \pm 0.96$	$1.16 \pm 0.88$	$0.98 \pm 0.75$
$\text{SO}_4^{2-}$ ( $\mu\text{g m}^{-3}$ )	$13.97 \pm 5.19$	$10.97 \pm 8.06$	$14.94 \pm 5.81$	$13.78 \pm 5.43$
$\text{F}(\text{SO}_4^{2-})^a$	$42.9\% \pm 14.0\%$	$36.8\% \pm 14.0\%$	$20.9\% \pm 3.6\%$	$23.0\% \pm 5.3\%$
$\text{NO}_3^-$ ( $\mu\text{g m}^{-3}$ )	$5.82 \pm 3.49$	$5.63 \pm 4.87$	$26.71 \pm 13.15$	$22.80 \pm 10.81$
$\text{F}(\text{NO}_3^-)^b$	$15.7\% \pm 6.0\%$	$17.7\% \pm 11.3\%$	$35.4\% \pm 9.0\%$	$35.6\% \pm 9.0\%$
$(2[\text{SO}_4^{2-}] + [\text{NO}_3^-]) / \text{PM}_{2.5R}$ ( $\mu\text{mol } \mu\text{g}^{-1}$ )	$0.0115 \pm 0.0026$	$0.0105 \pm 0.0023$	$0.0101 \pm 0.0017$	$0.0106 \pm 0.0016$

195 <sup>a</sup>  $\text{F}(\text{SO}_4^{2-})$  is the fraction of  $\text{SO}_4^{2-}$  in  $\text{PM}_{2.5}$  mass, which was calculated by using  $\text{SO}_4^{2-}$  concentrations divided by  $\text{PM}_{2.5R}$   
 196 concentrations. <sup>b</sup>  $\text{F}(\text{NO}_3^-)$  is the fraction of  $\text{NO}_3^-$  in  $\text{PM}_{2.5}$  mass. The calculation method is the same as  $\text{F}(\text{SO}_4^{2-})$ .

197

198 Under SP conditions,  $\text{PM}_{2.5}$  was at similar levels during daytime and nighttime with the average values of  $30.3 \mu\text{g}$   
 199  $\text{m}^{-3}$  and  $28.3 \mu\text{g m}^{-3}$ , respectively. However, the daytime  $\text{Fe}_T$  ( $938.3 \pm 850.5 \text{ ng m}^{-3}$ ) was much higher than the  
 200 nighttime  $\text{Fe}_T$  ( $520.3 \pm 496.1 \text{ ng m}^{-3}$ ), which was approximately threefold higher than during clean periods.  
 201 Similarly, the daytime  $\text{Fe}_S$  concentration of  $25.7 \pm 10.5 \text{ ng m}^{-3}$  was also slightly higher than the nighttime  
 202 concentrations of  $21.6 \pm 8.1 \text{ ng m}^{-3}$ , which was 1–2 times higher than that during the clean period. Different from

203 the clean period, %Fes was markedly higher at night ( $5.8\% \pm 3.0\%$ ) compared to the daytime %Fes ( $3.7\% \pm 2.0\%$ )  
204 during the SP period, ranging from 1.0% to 12.3%.

### 205 3.3 Chemical characteristics of PM<sub>2.5</sub>

206 Figure 2 illustrates the mass fractions of various chemical species present in the reconstructed PM<sub>2.5</sub> (PM<sub>2.5R</sub>).

207 During the clean period, WSIs were the dominant components, constituting about 75.0% and 74.1% of PM<sub>2.5</sub> mass

208 during daytime and nighttime, respectively. SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup> were the main contributors to WSIs. During

209 daytime, SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> were  $13.97 \pm 5.19 \mu\text{g m}^{-3}$  and  $5.82 \pm 3.49 \mu\text{g m}^{-3}$ , respectively, serving as the major

210 acidic species and accounting for 42.9% and 15.7% of the PM<sub>2.5</sub> mass (Table 1 and Figure 2). At night, SO<sub>4</sub><sup>2-</sup> and

211 NO<sub>3</sub><sup>-</sup> concentrations decreased slightly, which were  $10.97 \pm 8.06 \mu\text{g m}^{-3}$  and  $5.63 \pm 4.87 \mu\text{g m}^{-3}$ , respectively,

212 representing 36.8% and 17.7% of the PM<sub>2.5</sub> mass (Table 1 and Figure 2). In other words, the two main acid species,

213 SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup>, occupied slightly larger fractions of the PM<sub>2.5</sub> mass during the daytime (58.7%) compared to the

214 nighttime (54.6%), along with the lower ALWC, resulting in the lower aerosol pH of  $0.46 \pm 0.83$  during daytime

215 (Table 1). At night, aerosol pH ( $1.06 \pm 0.96$ ) increased by a factor of 2.3 compared to daytime.

216 The aerosol pH calculated in this work was evidently lower than many other areas of China (Liu et al., 2017; Wang

217 et al., 2019; Xu et al., 2020). During the clean period, air masses mainly originated from the seas. Therefore, the

218 aerosol pH can be very acidic because of the lack of sources of alkaline substances over the ocean, such as NH<sub>3</sub>,

219 Ca<sup>2+</sup>, et al. (Zhou et al., 2018). Compared to the inland areas, much lower aerosol pH in coastal areas is reasonable

220 (Wang et al., 2022). For instance, Zhou et al. (2018) reported that the pH of aerosols near the Bohai Sea can be as

221 low as around 1.0. Moreover, they also found that the daytime aerosol acidity was significantly stronger than that

222 during the nighttime in coastal areas. This observation aligns with the findings during clean periods in our study,

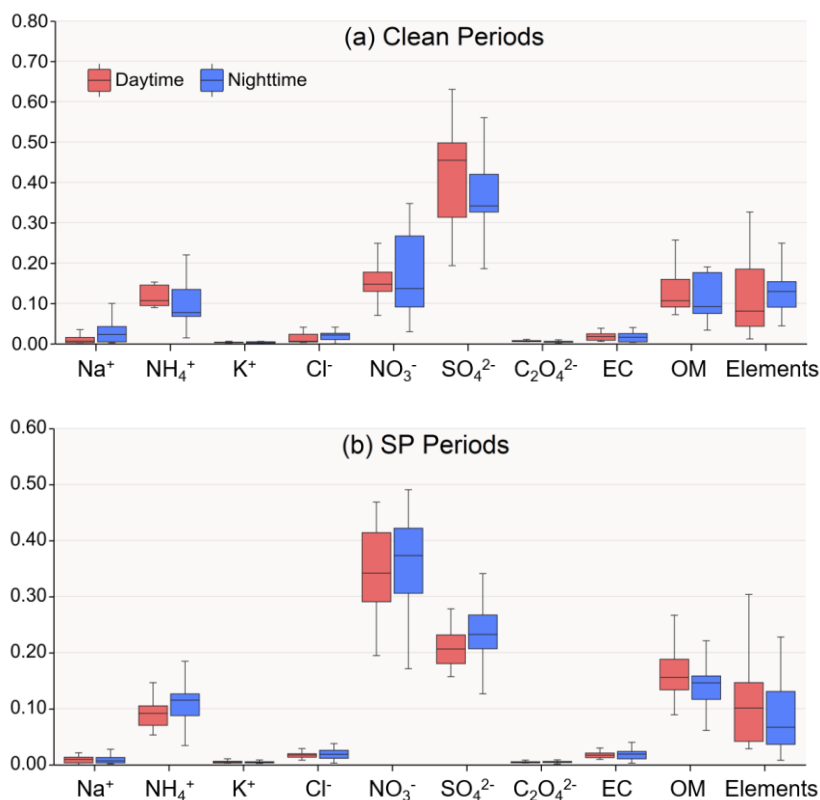

223 which were characterized by the predominance of sea breezes. In this study, we employed the ratio of acidic

224 substances to PM, namely,  $(2[\text{SO}_4^{2-}] + [\text{NO}_3^-])/\text{PM}_{2.5R}$ , to characterize the level of acidic substances in a unit of

225 PM<sub>2.5</sub>, because SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> were predominant acidic species within WSIs (>75% in mass). It was  $0.0115 \pm$

226  $0.0026 \mu\text{mol } \mu\text{g}^{-1}$  and  $0.0105 \pm 0.0023 \mu\text{mol } \mu\text{g}^{-1}$  in PM<sub>2.5</sub> mass during daytime and nighttime, respectively (Table

227 1).

228

229

230 **Figure 2: Mass fractions of chemical species in reconstructed PM<sub>2.5</sub> mass during daytime and nighttime in clean and SP**  
 231 **conditions. Mg<sup>2+</sup> and Ca<sup>2+</sup> are not shown in the above pictures, because total Mg is included in elements data and total**  
 232 **Ca is assessed by 0.8 times Al.**

233

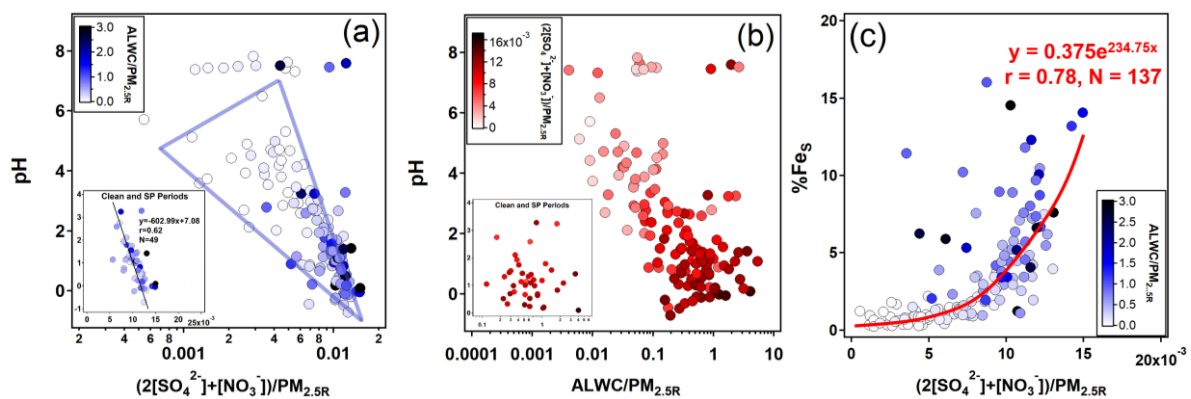

234 During the SP period, WSIs retained similar proportions in PM<sub>2.5</sub> as during the clean period, accounting for 70.5%  
 235 and 74.3% during daytime and nighttime, respectively. SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup> were also the main contributors to  
 236 WSIs. In the daytime, the concentrations of SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> were  $14.94 \pm 5.81 \mu\text{g m}^{-3}$  and  $26.71 \pm 13.15 \mu\text{g m}^{-3}$ ,  
 237 respectively, showing a marginal elevation over nighttime levels (Table 1). However, SO<sub>4</sub><sup>2-</sup> had evidently lower  
 238 contributions to PM<sub>2.5</sub> compared to the clean period, which were only 20.9% and 23.0% during daytime and  
 239 nighttime, respectively (Table 1 and Figure 2). In contrast, NO<sub>3</sub><sup>-</sup> had a noticeably higher contribution to PM<sub>2.5</sub>  
 240 compared to the clean period, exhibiting little diurnal variation, with percentages of 35.4% and 35.6% during  
 241 daytime and nighttime, respectively (Table 1 and Figure 2). In total, the ratio of acids to PM (i.e.,  
 242  $(2[\text{SO}_4^{2-}] + [\text{NO}_3^-]) / \text{PM}_{2.5\text{R}}$ ) was  $0.0101 \pm 0.0017 \mu\text{mol } \mu\text{g}^{-1}$  during daytime and  $0.0106 \pm 0.0016 \mu\text{mol } \mu\text{g}^{-1}$  during  
 243 nighttime (Table 1). Even though the ALWC ( $44.1 \pm 33.8 \mu\text{g m}^{-3}$ ) was significantly more abundant at night  
 244 compared to the daytime ( $22.5 \pm 13.2 \mu\text{g m}^{-3}$ ), the aerosol pH was lower at night. Specifically, the nighttime  
 245 aerosol pH was  $0.98 \pm 0.75$ , while the daytime aerosol pH was slightly higher at  $1.16 \pm 0.88$ , indicating weaker  
 246 aerosol acidity during daytime with a 18.4% increase in pH compared to nighttime aerosols.

## 247 4 Discussion

248 We found that daytime %Fes was much higher than nighttime %Fes during the clean period, while the opposite  
249 pattern emerged during the SP period. This section delves into the primary factors driving the distinct diurnal shifts  
250 in aerosol %Fes during clean and SP periods, based on the aspects of aqueous-phase conversions and  
251 photocatalysis reactions.

### 252 4.1 Aqueous-phase conversions promoted by acid processes

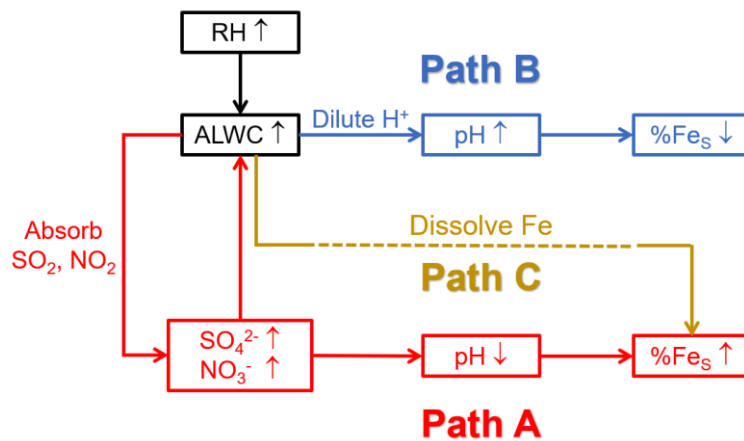

253 The %Fes was dependent on the acidification of the aerosol particles, and high %Fes was associated with low  
254 aerosol pH (Table 1). The pH of aerosols is controlled by ALWC and  $H^+$  contents. The predominant acidic species,  
255 i.e.,  $SO_4^{2-}$  and  $NO_3^-$ , play crucial roles in promoting the dissolution of insoluble Fe through proton-promoted  
256 reactions. As shown in Figure 3a, there was a significant negative correlation between the aerosol pH and the  
257 relative content of these two acidic species when the pH was below 4. Especially during clean and SP periods ( $r =$   
258 0.62, Figure 3a), the slope of the regression line was approximately  $-602.99$ , indicating that a variation of  $1.0 \text{ nmol}$   
259  $\mu\text{g}^{-1}$  of the acidic species content in  $PM_{2.5}$  can lead to a noticeable fluctuation of aerosol pH (about 0.60). For  
260 instance, the daytime aerosol pH was 0.60 lower than that of the nighttime during the clean period, even though  
261 the difference of the two acidic species content was only about  $1.0 \text{ nmol } \mu\text{g}^{-1}$ .

262  
263 **Figure 3: Relationships among pH, the normalized relative abundance of ALWC (unit:  $\mu\text{g m}^{-3}$ ) and main acidic species**  
264 **(=  $2[SO_4^{2-}] + [NO_3^-]$ , unit:  $\mu\text{mol m}^{-3}$ ) with respect to the reconstructed  $PM_{2.5}$  (i.e.,  $PM_{2.5R}$ , unit:  $\mu\text{g m}^{-3}$ ), and %Fes. The**  
265 **subgraph at the bottom-left of figures (a) and (b) show scatter plots during clean and SP periods with the linear**  
266 **regression line obtained by using the Igor Pro-based program developed by Wu and Yu (2018).**

267  
268 There was no prominent correlation between pH and ALWC when the pH exceeded 6 (Figure 3b). When the pH  
269 was smaller than 6, the increasing ALWC facilitated the heterogeneous reactions of  $SO_2$  and  $NO_2$  to generate more

270  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ , lowering the aerosol pH and enhancing the %Fes. The formation of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  will further  
 271 facilitate the growth of ALWC due to their remarkable hygroscopicity, establishing a positive feedback (Path A in  
 272 Figure 4), referred to as the “ALWC-acid” feedback (Wang et al., 2016; Wu et al., 2018b). On the other hand,  
 273 ALWC dilutes  $\text{H}^+$  in aerosol water. This process weakens the aerosol acidity and inhibits the particles from %Fes  
 274 elevation (Path B in Figure 4). In addition, the increasing ALWC served as a medium for loading water-soluble  
 275 components may promote the formation of Fes (Path C in Figure 4). The profound influence of acidic species on  
 276 the aerosol pH indicates the predominance of the “ALWC-acid” feedback in modulating the aerosol pH and  
 277 augmenting %Fes (Figures 3a, 3c and S4). The high %Fes we observed during daytime and nighttime can be  
 278 attributed to the relatively higher content of acidic species in  $\text{PM}_{2.5}$ .

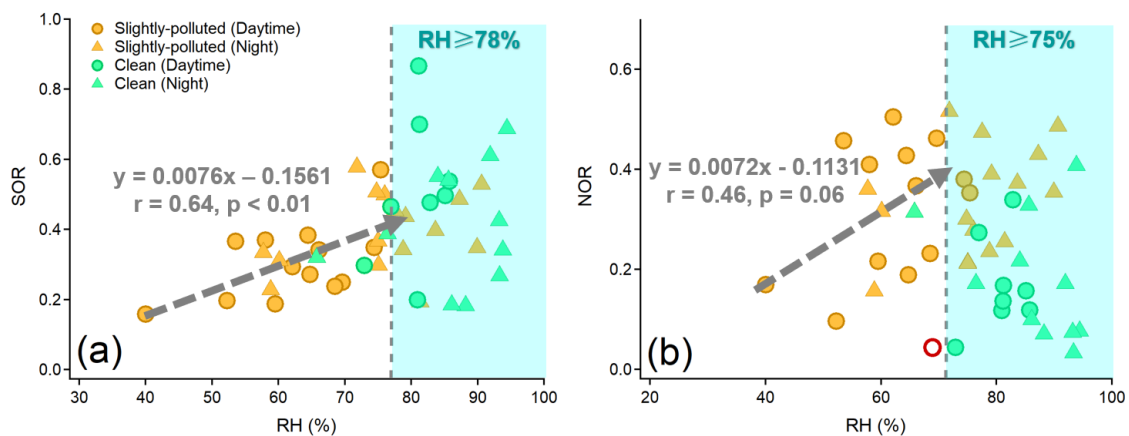

279  
 280 **Figure 4: Schematic diagram of ALWC affecting pH and %Fes. Path C is challenging to observe and quantify because**  
 281 **of the Fes extraction using MilliQ water in the sample pretreatment.**

282  
 283 RH is a key factor in the formation of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  through heterogeneous/aqueous-phase reactions within  
 284 aerosols (Wang et al., 2016; Liu et al., 2020; Hou et al., 2022). As demonstrated in Figure 5, the strong dependency  
 285 of the oxidation rate of sulfur (SOR, defined as  $[\text{SO}_4^{2-}]/([\text{SO}_4^{2-}] + [\text{SO}_2])$ ) on RH was observed under moderate  
 286 humid conditions ( $r = 0.64, p < 0.01$ ). But the oxidation rate of nitrogen (NOR, defined as  $[\text{NO}_3^-]/([\text{NO}_3^-] + [\text{NO}_2])$ )  
 287 had a poor dependence on RH ( $r = 0.46, p > 0.05$ ). A decrease of 10% in RH resulted in a notable reduction of  
 288 7.6% in SOR (Figure 5). Such a striking RH dependence was observed mainly during the SP period, indicating the  
 289 significant role of heterogeneous reactions in controlling the formation of  $\text{SO}_4^{2-}$ . Therefore, the facilitation of  
 290 aqueous-phase conversions leading to the formation of  $\text{SO}_4^{2-}$  was more pronounced at night during the SP period,  
 291 attributed to the high RH. This, in turn, resulted in a high proportion of  $\text{SO}_4^{2-}$  and acidic species, as well as the

292 elevated SOR (Table 1, Figures 2b and S5). The nighttime aerosol pH was approximately 0.18 units lower than  
293 that during daytime, but this slight variation did not hinder the efficient formation of Fes during nighttime in SP  
294 periods.

295 In contrast, RH was generally above 80% during daytime and nighttime in clean periods. The SOR was 0.49 on  
296 average and did not exhibit a clear correlation with RH beyond 78% (Figure 5a). Similar phenomena have been  
297 observed in previous studies, suggesting the existence of a saturation point in the promotion of RH on the aqueous-  
298 phase formation of  $\text{SO}_4^{2-}$  (Wang et al., 2019; Wang et al., 2021). High RH (> 70%) can cause water-soluble species  
299 to deliquesce and form an aqueous layer on the particle surface. Once the aqueous layer forms, the influence of  
300 RH variations becomes minimal (Shi et al., 2022). Hence, the degree of aqueous-phase processes promoting  $\text{SO}_4^{2-}$   
301 formation during clean periods was similar across both daytime and nighttime.

302  
303 **Figure 5: The dependence of SOR (a) and NOR (b) on RH during clean and slightly-polluted periods. The fitting of the**  
304 **regression line between SOR and RH was fitted when  $\text{RH} < 78\%$ . The fitting of the regression line between NOR and RH**  
305 **was fitted when  $\text{RH} < 75\%$  and one deviation point (the red circle in (b)) was removed.**

306

## 307 4.2 Daytime enhancement by photocatalysis reactions

### 308 4.2.1 The influence of photochemical processes on sulfate formation

309 Photochemical reactions can enhance the formation of acidic species and increase the aerosol %Fes through aerosol  
310 acidification (Tao et al., 2020; Liu et al., 2021a). The large proportion of acidic species during the daytime of the  
311 clean period was attributable to  $\text{SO}_4^{2-}$ , which was 6.1% higher than the nighttime  $\text{SO}_4^{2-}$  (Table 1 and Figure 2a).  
312 Despite similar levels of  $\text{SO}_2$  observed during daytime and nighttime, the daytime SOR reached as high as  $0.50 \pm$

313 0.20 (Figure S5). The conversion rates in the aqueous phase were similar during daytime and nighttime in clean  
 314 periods. Therefore, the substantial fraction of  $\text{SO}_4^{2-}$  was most likely caused by photochemical reactions.

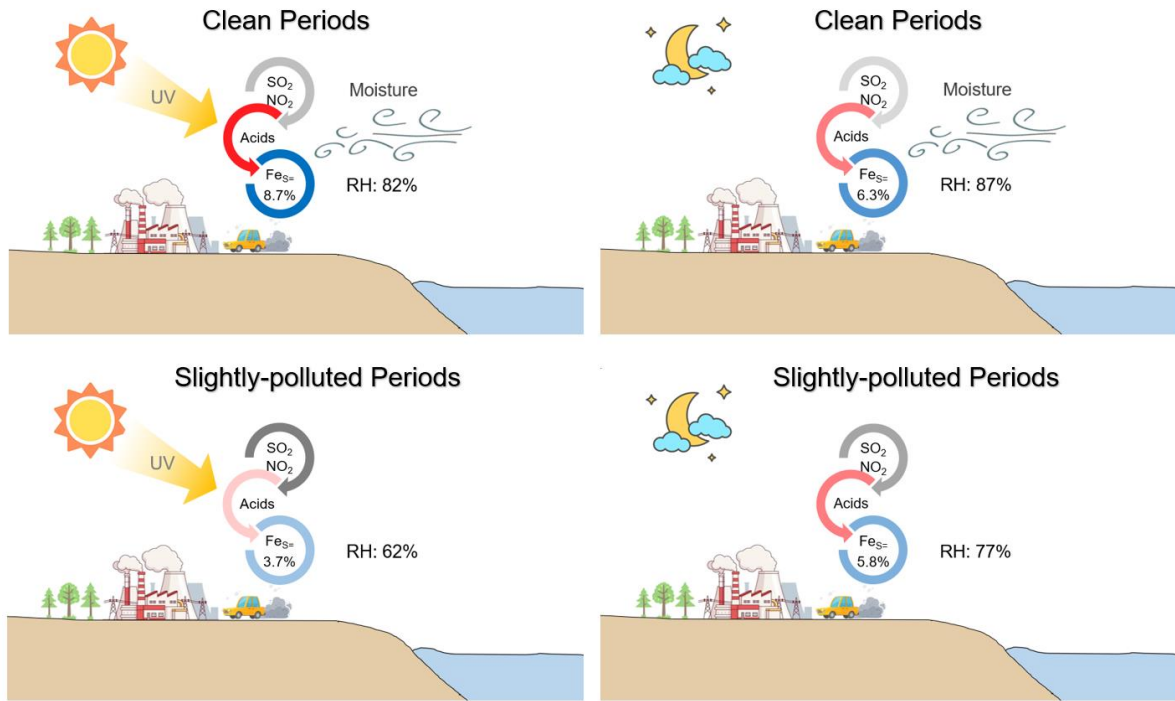

315  $\text{O}_x$  (described by the sum of  $\text{O}_3$  and  $\text{NO}_2$ ) was investigated to quantify the potential of photochemical reactions,  
 316 following the method of Wu et al. (2018a). The daytime  $\text{O}_x$  concentration ( $56.1 \pm 6.4$  ppb) was about 5.1% higher  
 317 than that of nighttime  $\text{O}_x$  ( $53.4 \pm 9.3$  ppb) during the clean period. The substantial SOR occurred under the extreme  
 318  $\text{O}_x$  conditions (Figure 6a), suggesting a significant contribution of the photochemical reactions during the clean  
 319 period. The enhancement of daytime photochemistry and aqueous chemistry on aerosol %Fes was more  
 320 pronounced than that of the nighttime aqueous reactions solely during the clean period (Figure 7a and 7b).

321  
 322 **Figure 6: RH- $\text{O}_x$  image plots colored by SOR during clean and SP periods. The last rows and columns of the matrices**  
 323 **represent the average value of SOR in the corresponding ranges of RH and  $\text{O}_x$ .**

324  
 325 During the SP period, the extent of SOR was more influenced by RH than by  $\text{O}_x$ , especially when RH was below  
 326 80% (Figure 6b). Nighttime SOR ( $0.37 \pm 0.12$ ) was approximately 1.2 times higher than the daytime SOR ( $0.31 \pm$   
 327  $0.11$ ) even though the daytime  $\text{O}_x$  was higher than that during nighttime (Figure S5), indicating a greater  
 328 contribution of liquid/heterogeneous reactions to the  $\text{SO}_4^{2-}$  formation than photocatalytic reactions. Similar  
 329 findings were reported by Hou et al. (2022), who highlighted the dominant role of humidity rather than  $\text{O}_x$  in  $\text{SO}_4^{2-}$   
 330 formation in haze intensification. The nighttime exhibited a more significant "ALWC-acid" feedback compared to  
 331 the daytime during the SP period. The influence of daytime photochemistry combined with aqueous-phase  
 332 reactions was comparatively weaker than nighttime aqueous chemistry, leading to the higher %Fes at night (Figure  
 333 7c and 7d). Notably,  $\text{O}_x$  concentrations were significantly higher during the SP period in comparison to the clean

334 period (Figure S5), indicating more active daytime photocatalytic reactions. However, the impact of aqueous-  
 335 phase conversions during the SP nighttime period was relatively weak compared to the nighttime of the clean  
 336 period. These results suggest that the role of photocatalytic reactions in  $\text{SO}_4^{2-}$  formation, and subsequently in the  
 337 elevation of aerosol %Fes, was feeble compared to aqueous-phase conversions.

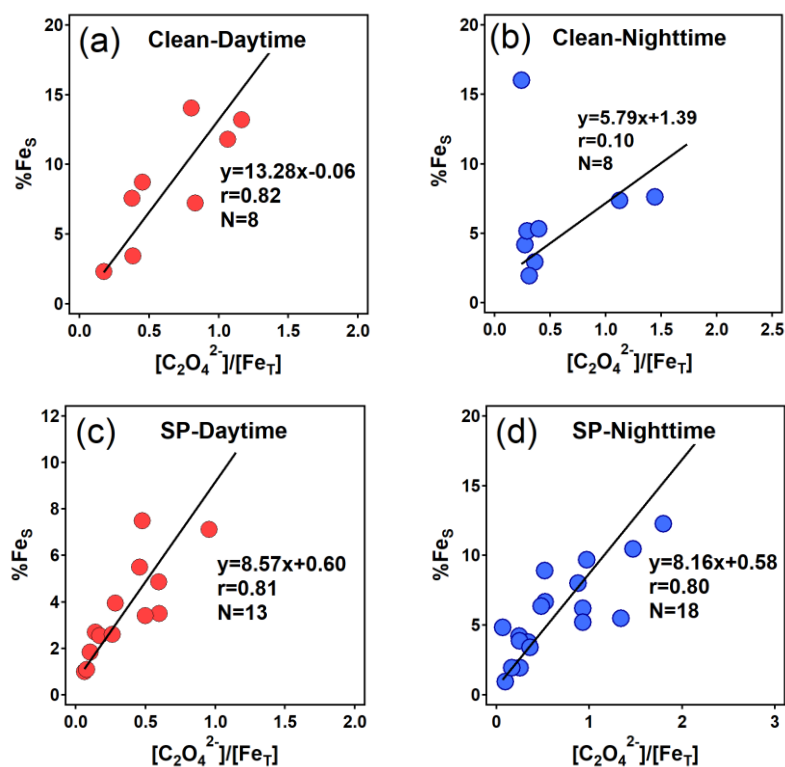

338  
 339 **Figure 7: Conceptual diagram showing the Fe dissolution influenced by acid processes at the coastal city during daytime**  
 340 **and nighttime in clean and SP periods.**

341  
 342 Enhancing aerosol %Fes through direct photocatalysis pathways is indeed possible. Iron oxides in minerals can  
 343 generate conduction band electrons upon irradiation, causing the reductive dissolution of Fe(III)-containing solid  
 344 phases to Fe(II) species (Zhang et al., 1993; Fu et al., 2010). However, structural Fe(III), which is the major iron-  
 345 related mineral in dust and coal fly ash, does not readily undergo direct reduction upon UV irradiation (Fu et al.,  
 346 2012; Fu et al., 2010; Xie et al., 2020). Another pathway for photolysis-conducted iron dissolution involves the  
 347 reduction by reactive oxygen species (ROS, e.g.,  $\text{O}_2^-$ ,  $\text{HO}_2^*$ , and  $\text{H}_2\text{O}_2$ ). These ROS can be generated from  
 348 dissolved oxygen accompanied by conduction band electrons, enhancing the Fe dissolution by reducing the solid-  
 349 phase Fe(III) into the more soluble Fe(II) form (Zhu et al., 1997; Hettiarachchi and Rubasinghege, 2020). Aerosol  
 350 water is necessary for the above reactions, and the proton-promoted dissolution by acid species is indispensable to  
 351 dissolve the solid-phase Fe(II) into aerosol solutions. We suppose that the observed weak influence of

352 photocatalysis on %Fes was because of the extreme aerosol acidity. The acidity of aerosols, such as a pH as low  
 353 as 2.0 during daytime of the present study, can suppress the contribution of photochemical catalysis in the  
 354 formation of Fes (Zhu et al., 1993; Fu et al., 2010; Fu et al., 2012). In addition, studies have suggested that Fe  
 355 dissolution can be inhibited in H<sub>2</sub>SO<sub>4</sub> systems under irradiation compared to dark conditions, which could be  
 356 another reason for the low %Fes during daytime although the exact mechanism remains unclear (Fu et al., 2010;  
 357 Hettiarachchi et al., 2018).

#### 358 4.2.2 The enhancement of %Fes promoted by oxalate-related conversions

359 Oxalate can form complexes with Fe(III) and participate in photochemical reactions through photoinduced charge  
 360 transfer. Oxalate transfers its charge to the Fe(III) surface via photolytic reactions during daytime, resulting in the  
 361 reduction of Fe(III) to Fe(II), followed by the dissociation of the formed Fe(II) from the surface and hence the  
 362 dissolution of aerosol Fe (Zuo and Hoigne, 1992; Zhang et al., 2019; Lueder et al., 2020). Shi et al. (2022)  
 363 identified the oxalate/Fe<sub>T</sub> ratio as an excellent predictor for aerosol %Fes through machine learning, underscoring  
 364 its remarkable effectiveness. However, field observations rarely confirm its influence on Fes from the perspective  
 365 of oxalate-Fe photochemistry.

366

367

368 **Figure 8: Relationships between %Fes and the molar ratio (unit:  $\mu\text{mol } \mu\text{mol}^{-1}$ ) of oxalate to Fe<sub>T</sub> during daytime and**  
 369 **nighttime in clean and SP periods. An extreme point (%Fes = 37.2%) in (b) was removed.**

370

371 In this study, significant correlations were observed between %Fes and the molar ratio of [oxalate]/[Fe<sub>T</sub>] during  
372 daytime in both clean periods ( $r = 0.82$ ) and SP periods ( $r = 0.81$ ) (Figure 8a and 8c). Similarly, a striking  
373 correlation was also found in nighttime during the SP period ( $r = 0.80$ ), although with a lower slope of 8.16 in the  
374 regression line (Figure 8d). Noteworthy is the strong dependence of %Fes (or Fes) on oxalate concentration at  
375 night (Figures 8d, S6b and S6d). Field observations highlight the pivotal role of organic compound complexation  
376 in stabilizing Fe (Sakata et al., 2022). Additionally, as illustrated by Figure 8a and 8c, the variation in %Fes induced  
377 by each unit variation in daytime [oxalate]/[Fe<sub>T</sub>] was greater than its nighttime equivalent. The most notable  
378 increase was observed during the clean period, with a daytime slope of 13.28, marking a 1.5-fold increase over the  
379 SP period (daytime slope = 8.57). Similarly, the concentration of Fes per unit of oxalate showed a parallel trend,  
380 marking the highest daytime slope of the clean period during the campaign (Figure S6). Such patterns imply that  
381 enhanced sunlight in clean days may have catalyzed photochemical processes involving daytime oxalate-Fe,  
382 leading to elevated Fes and %Fes. While these outcomes have only been discussed through laboratory simulations  
383 (Chen and Grassian, 2013), or indirectly by examining oxalate degradation or sulfate formation (Zhou et al. 2020),  
384 and they have been empirically discovered through field observations now in this study.

385 Simultaneously, Fes species redox reactions can facilitate the formation of oxalate in return if the precursors are  
386 abundant, particularly with aqueous-phase reactions playing a pivotal role when RH exceeds 60% (Zhang et al.,  
387 2019). This may elucidate one of the main reasons behind the significant correlations observed between Fes and  
388 oxalate. Notably, oxalate concentration was higher during the daytime compared to the nighttime in this study  
389 (Figure S5), concomitant with elevated Fes concentrations. The photocatalytic degradation of oxalate-Fe,  
390 promoting Fe dissolution during daytime, was unlikely to be the predominant pathway influencing the oxalate  
391 concentration, otherwise a decrease in oxalate concentration would occur (Dou et al., 2021). Therefore, the oxalate  
392 formation process catalyzed by Fes could yield a higher production rate of oxalate during the daytime than at night.  
393 Figure S7 portrays the conceptual diagram of these conversion processes. Similar scenarios might unfold for SO<sub>4</sub><sup>2-</sup>  
394 formation due to the heightened Fe redox reactions during daytime (Zhou et al., 2020). Owing to the extremely  
395 low aerosol pH (< 2), transition-metal ions (TMIs, e.g., Fes)-catalyzed pathway could primarily influence the  
396 secondary formation of SO<sub>4</sub><sup>2-</sup>, leading to potent aerosol acidity (Liu et al., 2021b). The elevated aerosol acidity, in

397 turn, fostered the formation of  $\text{Fe}_s$ , thus furthering the generation of  $\text{SO}_4^{2-}$  and oxalate under high RH conditions.  
398 The resulting oxalate could then be complexed with  $\text{Fe}_s$ , sustaining % $\text{Fe}_s$  at a high level at night.

399 To summarise, the findings of this study suggest that daytime photochemical processes indeed facilitated the  
400 dissolution of aerosol Fe, consequently elevating % $\text{Fe}_s$  during the clean period. This mechanism, in turn, may  
401 foster the secondary formation of oxalate and  $\text{SO}_4^{2-}$ . The complexation of organic compounds significantly  
402 contributed to maintaining the high % $\text{Fe}_s$  at night. While during SP periods, the diurnal variation in aerosol % $\text{Fe}_s$   
403 mainly resulted from the differing levels of aerosol acidity between daytime and nighttime rather than oxalate-  
404 related conversions, a conclusion strongly supported by the higher % $\text{Fe}_s$  observed at night compared to daytime  
405 (Figure 8c and 8d).

#### 406 **4.3 Environmental implications**

407 Limited research has explored the diurnal variation of aerosol % $\text{Fe}_s$ . Only an early case investigated the diel  
408 variability of Fe species at an island located in the Caribbean Sea and highlighted the photochemical processing  
409 of Fe (Zhu et al., 1997). This study found a pronounced correlation between  $\text{Fe}_s$  and acid species within an aerosol  
410 pH range of 0 to 1, emphasizing the considerable influence of aerosol acidification on Fe dissolution. These  
411 findings align with the results of our study. Our results suggest that acid-driven aqueous-phase transformations  
412 could have a more crucial role in altering aerosol % $\text{Fe}_s$  than photochemical reactions under certain conditions in  
413 coastal urban areas.

414 Previous studies pinpointed robust % $\text{Fe}_s$  of anthropogenic aerosols, especially for combustion-related fly ash  
415 (Oakes et al., 2012; Wang et al., 2015; Baldo et al., 2022; Li et al., 2022). Unlike urban air, RH tends to be  
416 considerably higher over open oceans, fostering an environment where heterogeneous reactions and the secondary  
417 formation of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  are prevalent. In such cases, photochemical reactions and precursors' concentrations  
418 will determine the formation of salts. Given that the air mass of the clean period comprised a mix of marine and  
419 local urban air, it is expected that the Fe dissolution in aerosol particles is an effective way to produce  $\text{Fe}_s$  during  
420 daylight hours. Air masses moving from densely populated land areas carry substantial amounts of  $\text{SO}_2$ ,  $\text{NO}_2$  and  
421  $\text{NH}_3$  to offshore areas, aiding in the formation of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  and conducting to the acidic dissolution of Fe in  
422 aerosol particles. Subsequently, the solubilized Fe, through proton-promoted dissolution, can be further stabilized  
423 by the organic complexation of Fe in the marine atmosphere, as indicated by Sakata et al. (2022).

424 Additionally, the dearth of ammonia sources in the marine atmosphere may hinder the formation of  $\text{SO}_4^{2-}$  and  
425  $\text{NO}_3^-$  to some extent on the one hand (Wang et al., 2017; Guo et al., 2018). The limited availability of ammonia  
426 may be also conducive to enhancing the aerosol acidity and elevating aerosol %Fes on the other hand. Considering  
427 that concentrations of HCl in remote marine atmospheric boundary layer are typically higher than in the continent  
428 of East Asia, the influence of chloride on aerosol pH may therefore play a conspicuous role in regulating %Fes  
429 (Tobo et al., 2010), on which knowledge is very limited.

## 430 **5 Summary**

431 This study investigated the daytime and nighttime %Fes in  $\text{PM}_{2.5}$  in a coastal city of China under clean and SP  
432 conditions. Under clean conditions, %Fes was higher during daytime (8.7%) compared to the nighttime (6.3%,  
433 after removing an extreme point of 37.2%). On the contrary, under SP conditions, %Fes was higher at night (5.8%)  
434 than during daytime (3.7%). Significant correlations were observed between the main acidic components ( $\text{SO}_4^{2-}$   
435 and  $\text{NO}_3^-$ ), aerosol pH, and %Fes, indicating that the acid process played a dominant role in influencing  
436 aerosol %Fes.

437 The RH consistently exceeded 80% during both daytime and nighttime in clean periods. Aqueous-phase reactions  
438 were found to be most effective in promoting the secondary formation of acid species, with photochemical  
439 processes further enhancing  $\text{SO}_4^{2-}$  formation during daytime. Together with the lower ALWC, the aerosol pH was  
440 much lower during daytime ( $0.46 \pm 0.83$ ) compared to nighttime ( $1.06 \pm 0.96$ ) during the clean period, which  
441 exerted a more significant influence on aerosol Fe dissolution. In contrast, RH was much higher at night (76.8%)  
442 than that during daytime (62.1%) in the SP period. The dry conditions during daytime notably restricted the  
443 secondary formation of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ . The acid content in  $\text{PM}_{2.5}$  was much higher at night under the promotion  
444 of heterogeneous processes, resulting in stronger aerosol acidity and higher aerosol %Fes. Furthermore,  
445 photochemical reactions associated with oxalate likely played a considerable role in enhancing %Fes during  
446 daylight hours, a trend more noticeable during the clean period. Oxalate might also be crucial in sustaining  
447 elevated %Fes at night during the SP period.

448 This study provides insights into the mechanisms of aerosol %Fes modulation in the coastal city. The robust  
449 promotion of aqueous-phase processes and the comparatively weaker influence of photochemistry on enhancing  
450 aerosol %Fes were observed. In urban air, RH was a crucial factor in controlling %Fes through modulating the  
451 heterogeneous reactions of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ . In contrast, in the oceanic atmospheric boundary layer, precursors'

452 levels and photochemical processes may be the decisive manipulators on aerosol %Fes. Therefore, the content of  
453 bioavailable Fe in urban-related aerosols may be greatly elevated after intrusion into the marine atmosphere, which  
454 holds significant importance for future research.
