Abstract. Continents are formed by the amalgamation of numerous micro-terranes and island arcs, so they have spatially varying lithosphere strengths. The Crème brûlée (CB) model and the Jelly sandwich (JS) model have been commonly used to describe continental lithosphere strength-depth variations. Depending on the strength of continental lower crust, the CB and JS models can be further subdivided into two subclasses, in which the I subclass (CB-I and JS-I) and II subclass (CB-II and JS-II) respectively have a strong or weak lower crust. During continental collision, lithosphere deformation is the byproduct of the comprehensive interaction of multiple terranes. Here we used 2-D thermo-mechanical numerical models that contain three continental terranes to systematically explore the effects of terranes with various strengths on continental deformation, and studied the effects of different rheological assumptions on terrane deformation. We ~~found~~ four types of lithosphere deformation patterns: collision, subduction, thickening and delamination, and replacement. ~~Lithosphere structures, especially local pre-existing weaknesses, also have nonnegligible influences on lithosphere deformation.~~ These simulation patterns are seen in observed deformation patterns and structures in East Asia, suggesting they are likely to be naturally occurring modes of intracontinental orogenesis.

1. Introduction

Continents have undergone multiple break-up and assembly events during the past ~2 billion years, with the assembly events often being associated with the accretion and deformation of numerous micro-terranes (Mitchell et al., 2021). Accreted terranes have different ages ranging from ~3500 – 3000

29 Ma to 50 – 0 Ma, and diverse compositions and structures linked to their diverse continental, arc, or
30 oceanic origin, which often leads to them having distinct initial lithospheric thicknesses and strengths
31 (Artemieva, 2006; Audet and Bürgmann, 2011; Pasyanos et al., 2014; Morgan and Vannucchi, 2022).
32 The lithosphere of ancient continental terranes like cratons are usually thick and strong, while younger
33 lithosphere of continental margins and tectonically active regions is thin and weak (Audet and
34 Bürgmann, 2011; Burov, 2011), and deeply buried former oceanic fragments can have temperature and
35 strengths that vary over ~0.5 Gyr timescale (Morgan and Vannucchi, 2022).

36 Continental lithosphere strength conventionally been represented by two prevailing rheology models
37 —the Crème brûlée (CB) and the Jelly sandwich (JS) idealizations (Chen and Molnar, 1983; Jackson,
38 2002; Burov and Watts, 2006; Bürgmann and Dresen, 2008; Burov, 2011). The Crème brûlée scenario
39 suggests that lithosphere strength resides entirely in the crust, with the lithospheric mantle being much
40 weaker (with this strength contrast being the explanation for why little seismicity is typically seen in
41 the continental mantle, despite rock-mechanics arguments that it should usually be stronger than its
42 overlying crust). In contrast, the Jelly sandwich model is based on conventional rock mechanics
43 arguments which imply that in general the continental middle and lower crust should be weaker than
44 overlying cooler upper crust and underlying further-from-solidus lithospheric mantle (Figure 1a). The
45 rheology of the continental lower crust can also differ strongly in different continental terranes due to
46 the varieties in composition, temperature, water content, stress, and tectonic environment (Bürgmann
47 and Dresen, 2008; Hacker et al., 2015; Morgan and Vannucchi, 2022). Therefore, the CB and JS
48 conceptualizations can be further subdivided into CB-I and CB-II, JS-I, and JS-II subclasses that reflect
49 potentially variable strengths of the lower crust: CB-I and JS-I, CB-II and JS-II have strong and weak
50 continental lower crust, respectively (Fig. 1a). Observations in Eastern Asia show a wide variability in
51 terrane deformation styles that argue for the potential feasibility of all four of these rheological models
52 (Figure 1b).

53 Several previous numerical modelling studies have discussed the effects of rheological contrasts
54 between terranes in lithosphere deformation in a collisional system. Studies containing two terranes
55 have explored contrasts in crustal rheology, and found that this can greatly change the morphology, size
56 and deep lithosphere structure of collisional orogenic belt (Chen, 2021; Chen et al., 2017; Cook and
57 Royden, 2008; Faccenda et al., 2008; Sun and Liu, 2018; Vogt et al., 2018; Xie et al., 2021). Strong
58 crust also has the potential to protect its underlying lithospheric mantle from deformation and

59 destruction (Heron and Pysklywec, 2016). Studies containing three or more terranes in their models
60 have usually focused on the middle terrane which can play a crucial role in lithosphere deformation in a
61 collisional system (Kelly et al., 2016, 2020; Li et al., 2016; Huangfu et al., 2018, 2022; Sun and Liu,
62 2018; Xie et al., 2023). A weak middle terrane is easy to be thickened, to the point where eventually its
63 lithospheric mantle can be delaminated from the crust; while a moderate-strength middle terrane can
64 induce far-field orogenesis; and a strong middle terrane may prevent propagation of deformation and
65 facilitate underthrusting of the advancing terrane. In addition, some studies have also stressed the
66 importance of local pre-existing weak zones which can change the order and style of lithosphere
67 deformation (Chen et al., 2020; Heron et al., 2016; Sokoutis and Willingshofer, 2011; Xie et al., 2021).

68 ~~In modern Asia, the large-scale Alpine Himalaya~~ continental collisional system often involves the
69 multiple units of an indenting terrane, a middle terrane, and far-end backwall terranes. These terranes
70 have the different lithosphere rheologies and thicknesses, and they of these terranes collectively
71 contribute to several styles of continental deformation (Artemieva, 2006; Audet and Bürgmann, 2011;
72 Pasyanos et al., 2014; Morgan and Vannucchi, 2022). Here, we use a 2-D thermo-mechanical numerical
73 modeling method to systematically study the effects of terranes with various rheological properties on
74 continental deformation. Our numerical models simulate a continent-continent collisional system that
75 contains three continental terranes. They explore the effects of four groups of lithosphere deformation
76 patterns linked to the four rheological idealizations of CB-I, CB-II, JS-I, and JS-II applied to each
77 terrane. We will summarize the rheological features for each deformation pattern, and then apply the
78 simulations to better understand ongoing and past deformation histories of various orogenic belts in the
79 global, especially preserved in eastern Eurasia/Asia, such as the eastern Tien Shan orogenic belt, the
80 Tibetan Plateau and the Early Paleozoic Orogen in Southeastern China.

81 **2. Numerical modelling method and model setup**

82 **2.1. Numerical modelling method**

83 Our thermo-mechanical models were performed with the I2VIS code of Gerya and Yuen (2003),
84 previously used in Xie et al. (2021, 2023). This code combines finite differences with marker-in-cell
85 techniques to solve the mass, momentum, and energy conservation equations for incompressible flow.
86 It incorporates the non-Newtonian visco-plastic rheologies for the lithosphere, as well as the possibility

87 to include parameterizations of the effects of surface processes like sedimentation and erosion.

88 2.1.1. Governing equations

89 The mass conservation equation for incompressible flow is:

$$90 \quad \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0, \quad (1)$$

91 The momentum conservation equations (Stokes equations) are:

$$92 \quad \begin{aligned} \frac{\partial \sigma'_{xx}}{\partial x} + \frac{\partial \sigma'_{xy}}{\partial y} &= \frac{\partial P}{\partial x}, \\ \frac{\partial \sigma'_{yy}}{\partial y} + \frac{\partial \sigma'_{xy}}{\partial x} &= \frac{\partial P}{\partial y} - g\rho \end{aligned} \quad (2)$$

93 The energy (heat) conservation equation is:

$$94 \quad \begin{aligned} \rho C_p \frac{DT}{Dt} &= -\frac{\partial q_x}{\partial x} - \frac{\partial q_y}{\partial y} + H_r + H_s + H_a + H_L \\ q_x &= -k \frac{\partial T}{\partial x} \\ q_y &= -k \frac{\partial T}{\partial y} \\ H_a &= T\alpha \frac{DP}{Dt} \\ H_s &= \sigma'_{xx} \dot{\epsilon}_{xx} + \sigma'_{yy} \dot{\epsilon}_{yy} + 2\sigma'_{xy} \dot{\epsilon}_{xy} \end{aligned} \quad (3)$$

95 where x and y represent the horizontal and vertical coordinate directions, and v_x and v_y are the
96 corresponding velocity components, respectively. σ'_{ij} and $\dot{\epsilon}_{ij}$ ($i, j = x, y$) are deviatoric stress and
97 strain-rate tensors, respectively; g is the gravitational acceleration; ρ is density. In the heat conservation
98 equation, q_x and q_y are the horizontal and vertical components of the heat flux, respectively; C_p is heat
99 capacity, and H_r , H_a , H_s , and H_L denote the radioactive, adiabatic, shear, and latent heat production,
100 respectively; k is the thermal conductivity.

101 The rheological constitutive relationship connects the deviatoric stress and strain rate:

$$\begin{aligned}
\sigma'_{xx} &= 2\eta_{eff} \dot{\epsilon}_{xx}, \quad \dot{\epsilon}_{xx} = \frac{\partial v_x}{\partial x} \\
\sigma'_{xy} &= 2\eta_{eff} \dot{\epsilon}_{xy}, \quad \dot{\epsilon}_{xy} = \frac{1}{2} \left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right), \\
\sigma'_{yy} &= 2\eta_{eff} \dot{\epsilon}_{yy}, \quad \dot{\epsilon}_{yy} = \frac{\partial v_y}{\partial y}
\end{aligned} \tag{4}$$

103 where η_{eff} is the effective viscosity.

104 2.1.2. Rheology

105 Here we make the conventional assumption that the crust and mantle have a visco-plastic rheology.

106 Viscous deformation is determined as a combination of diffusion and dislocation creep that depends on

107 temperature, pressure, and strain rate, expressed as (Gerya, 2019):

$$\begin{aligned}
\eta_{disl} &= \frac{1}{2} \frac{1}{(A_D)^{-1/n} (\dot{\epsilon}_{II})^{(n-1)/n}} \exp\left(\frac{E_a + V_a P}{nRT}\right) * S \\
\eta_{diff} &= \frac{1}{2} \frac{A_D}{\sigma_{cr}^{(n-1)}} \exp\left(\frac{E_a + V_a P}{RT}\right) * S
\end{aligned} \tag{5}$$

109 For mineral aggregates, both dislocation and diffusion creep occur simultaneously, with a combined
110 effective viscosity given by:

$$\frac{1}{\eta_{ductile}} = \frac{1}{\eta_{disl}} + \frac{1}{\eta_{diff}}, \tag{6}$$

112 where η_{disl} and η_{diff} are viscosities for dislocation and diffusion creep, respectively. σ_{cr} is the
113 critical stress for the dislocation to diffusion stress transition, and the parameters A_D , E_a , V_a , and n are a
114 material constant, activation energy, activation volume, and stress exponent, respectively, and R is the
115 universal gas constant. The strength scaling factor, S , is introduced as a simple parameter to vary the
116 lithospheric viscosity.

117 Plasticity is implemented using a conventional pseudo-viscous yield criterion first used to study rifting
118 (e.g. Chen and Morgan, 1990) that is extended to include a strain-weakening-like parameterization of
119 fracture-related strain weakening (Gerya et al., 2010; Vogt et al., 2017):

$$\eta_{plastic} = \frac{\sigma_{yield}}{2\dot{\epsilon}_{II}}$$

$$\sigma_{yield} = C + P\phi$$

$$C = \begin{cases} C_a + (C_b - C_a) \times \frac{\gamma}{\gamma_{cr}}, & \text{if } \gamma \leq \gamma_{cr}, \\ C_b, & \text{if } \gamma \geq \gamma_{cr} \end{cases}, \quad (7)$$

$$\phi = \begin{cases} \phi_a + (\phi_b - \phi_a) \times \frac{\gamma}{\gamma_{cr}}, & \text{if } \gamma \leq \gamma_{cr} \\ \phi_b, & \text{if } \gamma \geq \gamma_{cr} \end{cases}$$

121 where σ_{yield} is yield stress, P is dynamic pressure, γ is the integrated plastic strain, and γ_{cr} is the
 122 upper strain limit for fracture-related weakening. C and ϕ are cohesion and friction angle that depend
 123 on the plastic value. C_a and ϕ_a are the initial and C_b and ϕ_b are final strength values, respectively.
 124 This involves making the rheological assumption that deeply percolating fluids and high pore fluid
 125 pressures can significantly lower the plastic strength of fractured rocks.
 126 The final effective viscosity is determined by the minimum value between the ductile and plastic
 127 viscosities (Ranalli, 1995):

$$128 \quad \eta_{eff} = \min(\eta_{ductile}, \eta_{plastic}). \quad (8)$$

129 2.1.3. Surface processes

130 Topography in our models evolves according to a transport equation that is solved at each time step,
 131 with a crude local parameterization of effects of accounts for sedimentation and erosion:

$$132 \quad \frac{\partial y_{es}}{\partial t} = v_y - v_x \frac{\partial y_{es}}{\partial x} - v_s + v_e. \quad (9)$$

133 Where y_{es} is the vertical position of the surface as a function of horizontal distance x ; and v_x and v_y are
 134 the corresponding velocity components, respectively. v_s and v_e are the sedimentation and erosion rates,
 135 respectively, conforming to the relation:

136 $v_s = 0$ mm/yr, $v_e = 0.3$ mm/yr when $y_{es} > 5$ km;

137 $v_s = 0.3$ mm/yr, $v_e = 0$ mm/yr when $y_{es} < 5$ km.

138 2.2. Model Setup

139 The 2-D numerical model covers a rectangular computational domain of 3000 km \times 700 km and

140 consists of 1360×400 non-uniform grid cells with dozens of mobile markers in each grid cell to
141 transport physical properties (Figure 2a). Above 300 km, the cell-size of the grid in the middle of
142 model ($X = 1300 - 2200$ km) is $1 \text{ km} \times 1 \text{ km}$, and gradually widens towards the two sides to finally
143 become $5 \text{ km} \times 1 \text{ km}$. From the 300 km depth to the model bottom, each grid is stretched to 5 km in the
144 vertical direction. As a result, the grid in the middle of the model ($X = 1300 - 2200$ km) is $1 \text{ km} \times 5 \text{ km}$
145 and is $5 \text{ km} \times 5 \text{ km}$ in the other regions. Changing resolutions in different model regions can ensure the
146 model can finely depict lithosphere deformation in the region of interest while improving the
147 calculation's efficiency.

148 In the initial configuration, the model comprises three continental terranes — the Pro-, Mid- and
149 Retro-terrane — which refer to the indenting 'Pro-' terrane driven by plate convergence, an
150 intermediate 'Mid-' terrane, and a far-end backwall 'Retro-' terrane, respectively (Figure 2a). For the
151 purpose of simplification, The-the three terranes are assumed to have the same initial crustal structure
152 with 20 km thick upper and lower crust, respectively. In the meanwhile, to simulate lateral structure
153 differences within continental lithosphere (Pasyanos et al., 2014), Thicknesses-thicknesses of the initial
154 lithospheric mantle of the Pro-, Mid- and Retro-terrane are 160 km, 90 km, and 120 km, respectively.
155 ~~Variable lithosphere thicknesses for the Pro-, Mid- and Retro-terranes simulate lateral structure~~
156 ~~differences within continental lithosphere (Pasyanos et al., 2014).~~ The rest of the region is filled by
157 asthenosphere except along the model top, where a 20 km thick layer of "sticky air" with low viscosity
158 (1×10^{18} Pas) and low density (1 kg/m^3) is placed to simulate the effects of a free surface (Schmeling et
159 al., 2008). Flow laws and material properties for each lithospheric layer are listed in Table 1.

160 Mechanical boundary conditions of the model are that the top and sides are free-slip boundaries which
161 mean that the vertical velocity at the top boundary and horizontal velocity at the side boundaries are all
162 zero, ~~and-~~ The bottom is assumed to be a somewhat non-physical 'permeable boundary' that was
163 developed to reduce the required depth of the computational region (Burg and Gerya, 2005). For
164 top-driven flows like those considered here, this approximation has been shown to not affect
165 deformation in the upper parts of the region (Burg and Gerya, 2005). Finally, a constant convergence
166 rate of 20 mm/yr is assigned to the Pro-terrane ($X = 1000$ km) to drive the model.

167 Initial temperature conditions are set as follows: the model top is set to ~~at~~ 0°C , the two side boundaries
168 are adiabatic boundaries with zero horizontal heat fluxes, and the model bottom has an initial
169 temperature of 1593°C , and can dynamically adjust as the model evolves. The initial thermal gradient

170 in the crust is 15 °C/km in the three terranes, so their Moho temperature is 600 °C. A temperature of
171 1330 °C is applied at the bottom of the lithospheric mantle of the three terranes, which leads to the Pro-
172 and Mid-terrane having minimum and maximal thermal gradients in the lithospheric mantle,
173 respectively (see the right plane in Figure 2a). An adiabatic thermal gradient of 0.5 °C/km is assumed
174 within the asthenosphere. The temperature field would evolve over time, thus, although the three
175 terranes are not in thermal equilibrium at the start of the experiments, it has few effects on model
176 evolution. The initial setup of lithosphere structure and temperature field make the Mid-terrane weakest
177 when same rheology model is used for the three terranes. ~~Finally, a constant convergence rate of 20~~
178 ~~mm/yr is assigned to the Pro-terrane (X = 1000 km) to drive the model.~~

179 3. Simulation Results

180 The rheological models of CB-I, CB-II, JS-I, and JS-II ~~assumes~~result from different strength scaling
181 factors for the upper crust, the lower crust, and the lithospheric mantle in our numerical models (Figure
182 2b). We systematically test the effects of these rheological assumptions on the deformation of the Pro-,
183 Mid- and Retro-terranes. According to different behaviors of lithosphere deformation, these Simulation
184 simulation results can be categorized into four basic modes of ~~lithosphere deformation:~~ collision,
185 subduction, thickening and delamination, and replacement (Figures S1 and S2). In the deformation
186 mode of collision, the lithospheric mantle of the Mid-terrane is extruded out and the lithospheric
187 mantles of the two bounding terranes meet and collide together. In the deformation mode of subduction,
188 the lithospheric mantle of one of the bounding terranes subducts into the deep mantle below the
189 Mid-terrane while the other one keeps almost undeformed. In the deformation mode of thickening and
190 delamination, one of the bounding terranes is shortened by compression, and delamination may come
191 on the heels of thickening of lithosphere due to gravitational instability in some cases. In the
192 deformation mode of replacement, the bottom of weak and thick lithospheric mantle of the bounding
193 terrane is scraped off by the strong lithospheric mantle of the Mid-terrane, and replaced by the latter.
194 Here, w~~We~~ select a typical case for each mode of lithosphere deformation to ~~discuss~~describe more
195 details of these modes of model evolution.

196 3.1. Case 1: Lithosphere Collision

197 Case 1 represents the scenario of lithosphere collision ~~between the Pro- and Retro-terranes~~ (Figure 3).

198 In this model, the assumed rheological models for the Pro-, Mid- and Retro-terrane are JS-I, JS-II, and
199 JS-I, respectively, which means that the Mid-terrane has a significantly weaker lower crust relative to
200 the Pro- and Retro-terrane. The lithospheric mantle of the Mid-terrane is also slightly weaker due to its
201 thinner lithosphere and correspondingly higher initial temperature field. ~~Strength profiles on the right~~
202 ~~top of Fig. 3 show t~~he lithosphere strength ~~profiles~~ of the three terranes are shown in Figure 3g.

203 The Mid-terrane is the first to deform when the Pro-terrane begins to collide, absorbing plate
204 convergence in the form of lithosphere thickening (Figures 3a and 3d). The upper crust of the
205 Mid-terrane breaks due to strain weakening, and several reverse faults ~~with opposite dip directions are~~
206 ~~formed~~ to absorb crustal shortening. The lower crust folds, and strain diffusely distributes within it.
207 Since the Retro-terrane is relatively strong, it prevents crustal deformation from propagating into this
208 terrane, and restricts the bulk of deformation to the Mid-terrane. With continuous advance of the
209 Pro-terrane and resistance of the Retro-terrane, the crust of the Mid-terrane is intensively shortened,
210 leading to more thrusting structures in the upper crust and a “flower-like” structure in the lower crust
211 (Figures 3b and 3e). Thrust structures and crustal deformation also expand toward the Pro- and
212 Retro-terrane at this stage. Topography also grows towards the two bounding terranes (Figure 7a).
213 Ultimately, the weak lithospheric mantle of the Mid-terrane is squeezed out, and the Pro- and
214 Retro-terrane's lithospheric mantles meet and so start to collide beneath the overlying crust of the
215 Mid-terrane (Figures 3c and 3f).

216 ~~Crustal deformation and topographic uplift first occur in the middle terrane, then expand towards the~~
217 ~~bounding terranes. Ultimately, the lithospheric mantles of the bounding terranes begin to collide after~~
218 ~~extruding/removing the lithospheric mantle beneath the middle terrane.~~

219 3.2. Case 2: Lithosphere Subduction

220 Case 2 shows lithosphere subduction of the Pro-terrane (Figure 4). In this model, the assumed
221 rheological models for the Pro-, Mid- and Retro-terrane are JS-II, JS-I, and JS-I, respectively. The
222 Mid-terrane has a stronger lower crust ~~and weaker lithospheric mantle than compared with~~ the
223 Pro-terrane, but its lithospheric mantle is a little weaker than the Pro-terrane due to higher temperature
224 field resulting from its thinner lithosphere structure (Figure 4g)(see the strength profiles on the right top
225 of Figure 4). When convergence begins, the weak lower crust of the Pro-terrane is blocked by the
226 stronger lower crust of the Mid-terrane. This induces it to stack in a collisional front to form a

227 remarkable folding structure (Figures 4a and 4d). The strong lithospheric mantle of the Pro-terrane
228 continues to move forward and underthrusts beneath the Mid-terrane. As the Pro-terrane advances, its
229 crust gradually enters the Mid-terrane, inducing shortening and thickening of the upper crust of the
230 Mid-terrane, while the strong lower crust of the Mid-terrane almost keeps undeformed (Figures 4b and
231 4e).

232 Meanwhile, the lithospheric mantle of the Pro-terrane continues to underthrust ~~and serapesscraping~~ off
233 part of the lithospheric mantle of the Mid-terrane. Eventually, the crust of the Pro-terrane wedges a
234 long distance into the Mid-terrane, and the lithospheric mantle of the Pro-terrane subducts into the
235 deeper mantle (Figures 4d and 4f). In this example, crustal deformation and topography gradually
236 propagate from the Pro-terrane to the Mid-terrane, whereas the Retro-terrane remains nominally
237 'undeformed' at all times (Figure 7b).

238 In some experiments, the lithospheric mantle of the Retro-terrane can subduct beneath the Mid-terrane
239 (Figure S1). ~~In this deformation pattern, (1) crustal deformation and topography gradually propagates~~
240 ~~from one of the bounding terranes into the other bounding terrane through the middle terrane, and (2)~~
241 ~~the lithospheric mantle of bounding terrane subducts into the deep mantle beneath the middle terrane.~~

242 3.3. Case 3: Lithosphere Thickening and Delamination

243 Case 3 illustrates the thickening and delamination of the lithospheric mantle of the Pro-terrane (Figure
244 5). In this case, the rheological models for the Pro-, Mid- and Retro-terrane are CB-II, JS-I, and JS-I,
245 respectively (Figure 5j). The Pro-terrane has a ~~more fragile rheologically weaker~~ lower crust and
246 lithospheric mantle, making it relatively easy to deform once the collision has started. The lithospheric
247 ~~mantle~~ of the Pro-terrane is first ~~shortened and~~ thickened, ~~and the in which leads to crustal~~ starts to
248 form folding fold in two discrete zones (Figures 5a and 5f)ing. The lower part of the thickened
249 lithospheric mantle is denser than its ambient mantle owing to lower temperature, which causes it to
250 drip downwards (Figures 5b-5h). After delamination of the thickened lithosphere, subduction of the
251 Pro-terrane's lithospheric mantle along one of the deformation localization zones absorbs the plate
252 convergence (Figures 5e and 5i)initiation occurs within the lithospheric mantle of the Pro-terrane.
253 Crustal deformation is restricted in the ~~Mid~~Pro-terrane until lithosphere delamination, after which
254 crustal strain and topography rapidly spread from the Pro-terrane to the Mid-terrane (Figure: 7c). Like
255 case 2, the Retro-terrane stays essentially undeformed at all times.

256 ~~If the lithosphere of the Pro- or Retro- terrane is extremely weak, for example, its rheology model is~~
257 ~~CB-II, then lithosphere thickening and delamination may occur. In this deformation pattern, (1) the~~
258 ~~weak lithosphere of the bounding terrane first thickens by compression and then delaminates due to its~~
259 ~~density, while (2) crustal deformation rapidly propagates from the thickened bounding terrane into the~~
260 ~~middle terrane following lithosphere delamination.~~

261 3.4. Case 4: Lithosphere Replacement

262 Case 4 illustrates ~~how~~ the lithospheric mantle of the Pro-terrane ~~can be~~is replaced by that of a
263 neighboring stronger Mid-terrane (Figure 6). In this case, the rheological models for the Pro-, Mid- and
264 Retro-terrane are CB-I, JS-II, and JS-I, respectively. The Pro-terrane has a strong lower crust and a
265 thick and weak lithospheric mantle, while the Mid-terrane has a weaker lower crust and a strong
266 lithospheric mantle (Figure 6g). This lithosphere configuration between the Pro- and the Mid-terrane
267 causes deformation to be primarily distributed in the Pro-terrane's lithospheric mantle and the
268 Mid-terrane's crust. As a result, the Mid-terrane's crust becomes intensely shortened by fold and thrust
269 structures, but its strong lithospheric mantle wedges into the Pro-terrane's thick and weak lithospheric
270 mantle (Figures 6a, 6b, 6d and 6e). The strong lithospheric mantle of the Mid-terrane scrapes off the
271 lower part of the weak lithospheric mantle of the Pro-terrane and so replaces it (Figures 6c and 6f).
272 Similar to case 1, crustal deformation and topography expand from the Mid-terrane towards its side
273 terranes (Figure 7d).

274 The lithospheric mantle of the Retro-terrane can also be replaced in some cases (e.g. Figure S1). ~~In this~~
275 ~~deformation pattern, the significant deformation features are that: (1) part of the weak lithospheric~~
276 ~~mantle of the bounding terrane is replaced by the strong lithospheric mantle of the middle terrane; (2)~~
277 ~~crustal deformation and topography expand from center towards the two sides.~~

278 4. Discussion

279 4.1. Rheological Characteristics for Distinct Lithosphere Deformation Patterns

280 Distinct lithosphere deformation patterns in our simulation ~~results result~~ arise from rheological
281 contrasts between neighboring continental terranes. Figure 8 summarizes the rheological characteristics
282 of these distinct deformation patterns ~~(Figure 8)~~. When the Mid-terrane's lithospheric mantle is
283 weakest (typified by models in which the rheological model of the Mid-terrane is CB-II), it is easy for

284 its mantle to be extruded out, leading to collision between the lithospheric mantles of its surrounding
285 Pro- and Retro-terrane. When one of the two bounding Pro- or Retro-terrane²s has extremely weak
286 lithospheric mantle-is weakest, its lithosphere is first to be thickened by compression, and then
287 delamination may follow due to the resulting density-driven instability. When the lower crust of the
288 Mid-terrane is relatively strong (CB-I or JS-I), while the lower crust is weaker in the Pro- or
289 Retro-terrane (CB-II or JS-II), then the lithospheric mantle of the Pro- or Retro-terrane will tend to
290 subduct into the deep mantle, e.g. leading to intracontinental subduction. Finally, when the Mid-terrane
291 has a weak lower crust and strong lithospheric mantle (JS-II), while the Pro- or Retro-terrane has a
292 strong lower crust and weak lithospheric mantle (CB-I), then the lithospheric mantle of the former may
293 replace the lithospheric mantle of the latter.

294 ~~In-When~~ the deformation patterns involve the collision and replacement of lithosphere, continental
295 deformation involves all three terranes (Figures 3 and 6). In contrast, the other deformation patterns
296 only involve two terranes, the Pro- or Retro-terrane and the Mid-terrane (Figures 4 and 5). The
297 rheological properties of the Mid-terrane are responsible for these differences. Like previous numerical
298 studies (Kelly et al., 2016, 2020; Li et al., 2016; Huangfu et al., 2018, 2022; Sun and Liu, 2018), our
299 simulations show that a weak a-Mid-terrane is easier to deform, and that in this case lithosphere
300 deformation will expand from center to its neighboring sides; while a relatively strong Mid-terrane
301 prevents deformation from propagating far, so that lithosphere deformation is constrained to occur
302 within two terranes. ~~The simulation results also highlight the potential effects of differences in~~
303 ~~rheological stratification between different terranes to lithosphere deformation (Figures 4 and 6).~~

304 Although our multi-terrane numerical models mainly focus on the impact of the lateral strength
305 differences between different terranes in a continental collisional system, rheological models of CB-I,
306 CB-II, JS-I, JS-II also involve vertical rheological variation (Figure 1a). It seems difficult to summarize
307 how vertical strength variation affects lithosphere deformation of the continental collisional system.
308 For example, in some cases, only changing the rheological models of the Pro- or Retro-terrane may
309 produce distinct deformation modes such as collision, subduction, thickening and delamination, and
310 displacement (e.g., the first and third rows, the third column in the upper left panel in Figure 8 and the
311 third column in the lower right panel in Figure 8). However, changing the rheological models of the
312 Pro- or Retro-terrane seems to have less impact on the deformation mode of the continental collisional
313 system, according to the simulation results of models which are connected by several cross-shaped

314 solid lines with different colors in Figure 8. Thus, it is difficult to determine whether the horizontal
315 strength contrasts between terranes or the vertical strength variation of a single terrane plays the
316 dominant role in a multi-terrane collisional system. This is also the significance and necessity of our
317 study.

318 **4.2. Influences of Lithosphere Structure**

319 Lithospheric thickness is one of the critical factors that controls its strength (Burov, 2011), ~~this and it~~
320 can strongly vary between tectonic regions (Pasyanos et al., 2014). In our models, we assume different
321 lithospheric thicknesses for the Pro-, Mid- and Retro-terrane to explore these effects. Complex effects
322 are seen. When changing the lithospheric thicknesses of the Mid-terrane, or of all three terranes,
323 remarkable variations in lithosphere deformation appear in cases 1 and 2, but smaller variations are
324 seen for cases 3 and 4 (Figure 9). Cases 1 and 2 assume a Jelly sandwich rheology for the Pro-, Mid-
325 and Retro-terrane, so the strength of the lithospheric mantle of three terranes is comparable. Strength
326 variations produced by differences in lithospheric thickness may alter the relative strength of the three
327 terranes, resulting in distinct lithospheric deformations. For example, if the Pro- and Mid-terranes have
328 same lithosphere thickness, deformation mode in Case 2 would change from subduction to thickening
329 (subplot 3 vs. subplot 8 in Figure 9); if the Mid-terrane is thickest or the three terranes have same
330 thickness of lithosphere, deformation mode in Case 1 would change from collision to replacement
331 (subplot 2 vs. subplot 17 and 22 in Figure 9), and the polarity of the subduction of Pro-terrane's
332 lithospheric mantle would be reversed in Case 2 (subplot 3 vs. subplot 18 and 23 in Figure 9). Instead,
333 in cases 3 and 4, the Pro-, Mid- and Retro-terrane have two regions with stronger Jelly-sandwich-like
334 rheological structures and one with a weaker Crème brûlée structure, and deformation preferentially
335 concentrates in the weaker terrane ~~with a weak mantle Crème brûlée rheology~~. In comparison to the
336 large strength difference implied for the lithospheric mantle between the Crème brûlée and Jelly
337 Sandwich rheological models, the strength variations associated with the differences in lithosphere
338 thickness are relatively small. Therefore, changing the thicknesses of the lithosphere has much smaller
339 effects on the lithosphere deformation, as seen in cases 3 and 4 (also see the subplots in 3rd and 4rd rows
340 of Figure 9).

341 In addition, the weak zones that suture two terranes are generally preserved during continental
342 amalgamation (Burker et al., 1977; Vink et al., 1984; Yin and Harrison, 2000). These local pre-existing

343 lithosphere weaknesses would be preferentially activated if the continental lithosphere were subjected
344 to compression, and could play a key role in concentrating deformation, adjusting deformation
345 sequences, and inducing lithosphere subduction (Sokoutis and Willingshofer, 2011; Heron et al., 2016;
346 Chen et al., 2020; Xie et al., 2021, 2023). Comparing the simulation results of models with and without
347 weak zone, we find that a weak zone will facilitate lithosphere subduction in earlier stages of model
348 evolution, resulting in more diverse lithosphere deformation patterns during the later stage (Figure
349 ~~S210~~).

350 **4.3. Implications for the Tectonics of East Asia Eurasia**

351 **4.3.1. Lithosphere Collision beneath the Eastern Tien Shan**

352 The eastern Tien Shan is an ideal region to study the deformation patterns linked to long-term
353 lithosphere collision (Figure 11a). The eastern Tien Shan ~~is located east of the geographic longitude of~~
354 ~~80° E and~~ is bounded by the Tarim Basin to the south, and the Junggar Basin to the north (~~Figure 10a~~).
355 It is composed of a series of former island arcs and small continental blocks that amalgamated during
356 the late Paleozoic (Han and Zhao, 2017). The lithosphere of the eastern Tien Shan is weaker and
357 thinner in comparison to its neighboring ~~Tarim Basin and Junggar Basin~~ (Kumar et al., 2005; Lei and
358 Zhao et al., 2007; Zhang et al., 2013; Deng and Tesauro, 2016). At ~20 – 25 Ma, the eastern Tien Shan
359 became a reactivated orogeny in response to ongoing India-Asia collision (Yin et al., 1998).
360 Compression linked to the India-Asia collision induced the Tarim lithosphere to underthrust northward
361 (Xu et al., 2002; Guo et al., 2006; Lei and Zhao et al., 2007; Lü et al., 2019; Hapaer et al., 2022; Sun et
362 al., 2022). In the northern part of the eastern Tien Shan, significant high-velocity anomalies and Moho
363 overlap are also imaged, which are conventionally explained as being due to the southward
364 underthrusting of the Junggar lithosphere (Xu et al., 2002; Guo et al., 2006; Li et al., 2016; Lü et al.,
365 2019). High-velocity anomalies in the Tarim and Junggar lithosphere appear to connect beneath the
366 eastern Tien Shan, suggesting the lithosphere of the Tarim and Junggar Basins has converged and
367 collided together in this region (~~10b-11band-11e~~; Lü et al., 2019). Bidirectional underthrusting
368 of the Tarim and Junggar lithosphere leads to intense crustal shortening and thrust faults on both flanks
369 over the adjacent basins, as well as attendant fold and reverse fault zones along the range fronts (Yin et
370 al., 1998; Wang et al., 2004).

4.3.2. Lithosphere Thickening and Delamination in the Tibetan Plateau

The deformation pattern arising from lithosphere thickening and delamination has been applied to the Tibetan Plateau (Figure 11c). Tibetan lithosphere may have been significantly weakened by hydration, metasomatism, and partial melting of the lithospheric mantle during a series of oceanic closure and terrane accretion events before the India-Asia collision (Yin and Harrison, 2000; Zhang et al., 2014; Ma et al., 2021). It was then pushed northward by the Indian craton and was blocked by the Tarim/Qaidam craton during India-Asia collision, leading to double crustal thickness (Zhao and Morgan, 1985; Zhang et al., 2011). The lithosphere beneath the Tibetan Plateau does not thicken significantly like its crust, especially beneath northern Tibet (Owens and Zandt, 1997; Tunini et al., 2016). Numerous observations instead suggest that the Tibetan lithosphere has been detached from the crust and has sunk into deeper mantle, consistent with the presence of high-velocity regions in the deep mantle in western, southern and southeastern Tibet (Li et al., 2008; Chen et al., 2017; Feng et al., 2021). A significant depression of the 660-km discontinuity beneath the Himalaya terrane and the uplift of 410-km discontinuity in western Tibet have also attributed to the presence of delaminated Tibetan lithosphere (Wu et al., 2022). In northern Tibet, anomalously high temperatures are assumed to be linked to a region of inefficient S_n propagation indicating a thin or absent lithospheric mantle lid in this region, while a remarkable low-velocity zone in the mantle and ultra-potassic volcanics also suggest lithosphere thinning (Barazangi and Ni, 1982; Turner et al., 1996; Owens and Zandt, 1997; Guo et al., 2006; Liang et al., 2012; Tunini et al., 2016). After lithosphere thinning commenced in the Miocene, the Tibetan Plateau rapidly grew outwards ~~rapidly~~ (Lu et al., 2018 and references therein; Molnar et al., 1993; Xie et al., 2023).

4.3.3. Lithosphere Subduction in Southeastern China

An example of intracontinental subduction is the Early Paleozoic Orogen in Southeastern China which appears to have not been preceded by oceanic subduction (Figure 11d; Faure et al., 2009). The Early Paleozoic Orogen of Southeastern China is located on the Wuyi-Yunkai Fold Belt. Arguments against it being a collisional orogenic belt are its lack of preserved ophiolites, a magmatic arc, subduction complexes, and high-pressure metamorphism. Instead, structural, metamorphic, and sedimentary elements indicate that this orogen was an intracontinental orogen controlled by the northward subduction of Cathaysia (Faure et al., 2009). A weak suture/failure zone inherited from previous

400 tectonic events contributed to the internal subduction of Cathaysia, during which ductile decollements
401 accommodated horizontal shortening by folding and thrusting. The tectonic development of this orogen
402 appears similar to the deformation mode of lithosphere subduction (Figure 4).

403 So far, we have yet to find a suitable region to apply the model deformation pattern of lithosphere
404 replacement. In this deformation pattern, crustal deformation and topographic evolution are similar to
405 those in the deformation pattern of lithosphere collision (Figures 7a and 7c). Thus, it is not easy to
406 identify this pattern by geological and geophysical techniques when the replaced and original
407 continental lithosphere has similar properties. Improved imaging observations with better resolution
408 may allow this deformation pattern to be identified in the future.

409 **5. Model Limitations**

410 Although we can obtain four deformation modes of continental lithosphere by changing the rheologies
411 of different terranes in a collisional model, we must keep in mind that our results are based on some
412 simplifications and assumptions, which may affect the model results. For example, in our model three
413 terranes are directly collaged together, but in nature different terranes are often connected through weak
414 sutures which may preferentially deform when they are subjected to compression (Burker et al., 1977;
415 Yin and Harrison, 2000). These local pre-existing weak zones have non-negligible influences on
416 lithospheric deformation, and their role were widely discussed in previous studies (Sokoutis and
417 Willingshofer, 2011; Heron et al., 2016; Chen et al., 2020 ; Xie et al., 2021, 2023). We also discussed
418 the effects of local pre-existing weak zones in Section 4.2. In addition, lithosphere thicknesses of the
419 Pro-, Mid- and Retro-terranes are chose arbitrary in our models, but they also has important influences
420 on lithosphere deformation (Figure 9). Some studies believe that differences in crustal strength will
421 also cause different lithospheric deformation (Faccenda et al., 2008; Vogt et al., 2017, 2018), but the
422 three terranes are set same crustal structure in our model for the aim of simplification. As well, some
423 studies believe that the convergence rate will greatly affect the deformation of orogenic belts (Chen et
424 al., 2016; Vogt et al., 2017), but in this study, the impact of the convergence rate almost can be ignored.

425 **6. Conclusions**

426 The continental lithosphere is likely to have strong lateral variations in its strength. We explored 2-D

427 numerical models that contain three diverse types of continental terranes to study the responses of
428 continental terranes with different strengths to compression. Four rheological models were respectively
429 applied to each of the Pro-, Mid- and Retro-terranes, and simulation results can be grouped into four
430 distinct deformation styles: lithosphere collision, subduction, thickening and delamination, and
431 replacement. These deformation styles arise from the rheological contrasts between these terranes: (1)
432 when the middle terrane is the weakest, its lithosphere is easily extruded, which leads to lithosphere
433 collision between its two bounding terranes; (2) when the middle terrane has a strong lower crust, while
434 the lower crust of a bounding terrane is weak, then subduction of the lithosphere of the bounding
435 terrane will occur; (3) when a bounding terrane is the weakest, its lithosphere would tend to be
436 thickened by lateral compression, followed by lithosphere delamination due to the resulting
437 density/gravitational instability; (4) when a bounding terrane has a strong lower crust and weak
438 lithospheric mantle, while the middle terrane has a weak lower crust and strong lithospheric mantle,
439 then lithosphere replacement will ~~again~~ occur. These simulation patterns are seen in observed
440 deformation patterns and structures in the eastern Tien Shan, and the Tibetan Plateau, the Early
441 Paleozoic Orogen of Southeastern China, suggesting they are likely to be naturally occurring modes of
442 intracontinental orogenesis.

674 **Figure 1. Four rheological models of continental lithosphere.** (a) Crème brûlée model (CB) and Jelly sandwich
675 model (JS). The two rheological models can be further subdivided into CB-I, CB-II, JS-I, and JS-II according to
676 the strength of the lower crust (modified from Jackson, 2002). (b) Observations of four distinct lithosphere
677 rheological structures implied for East Asia (modified from Zhang et al., 2013). Locations of strength profiles are
678 pointed out by dots with numbers in the topography map. Dots filled with different colors indicate different models
679 of lithospheric rheology. These strength profiles are calculated based on observed geothermal structure and
680 lithospheric structure, and assumed that compositions of the upper and lower crust and lithospheric mantle are wet
681 quartzite, undried granulite and dry olivine, respectively. Here Variations of temperature and upper and lower
682 crustal lithospheric compositions lead to a diverse suite of strength profiles vs. depth. —ORB: Ordos Basin; COB:

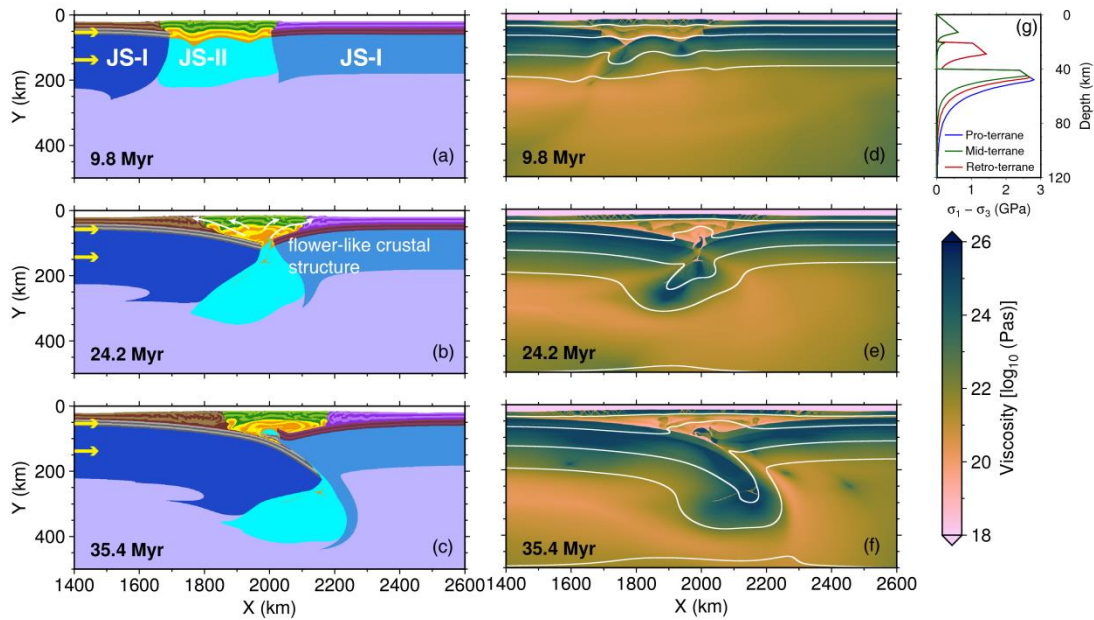

683 Central Orogenic Belt; JB: Junggar Basin; ST: South Tibet; TI: Tibet INDEPTH III; NET: Northeastern Tibet; SET:
 684 Southeastern Tibet; QB: Qaidam Basin; SB: Sichuan Basin; NCC: North China Craton; SLB: Songhiao Basin; DB:
 685 Qinling-Dabie Orogen; TB: Tarim Basin; SC: South China.
 686

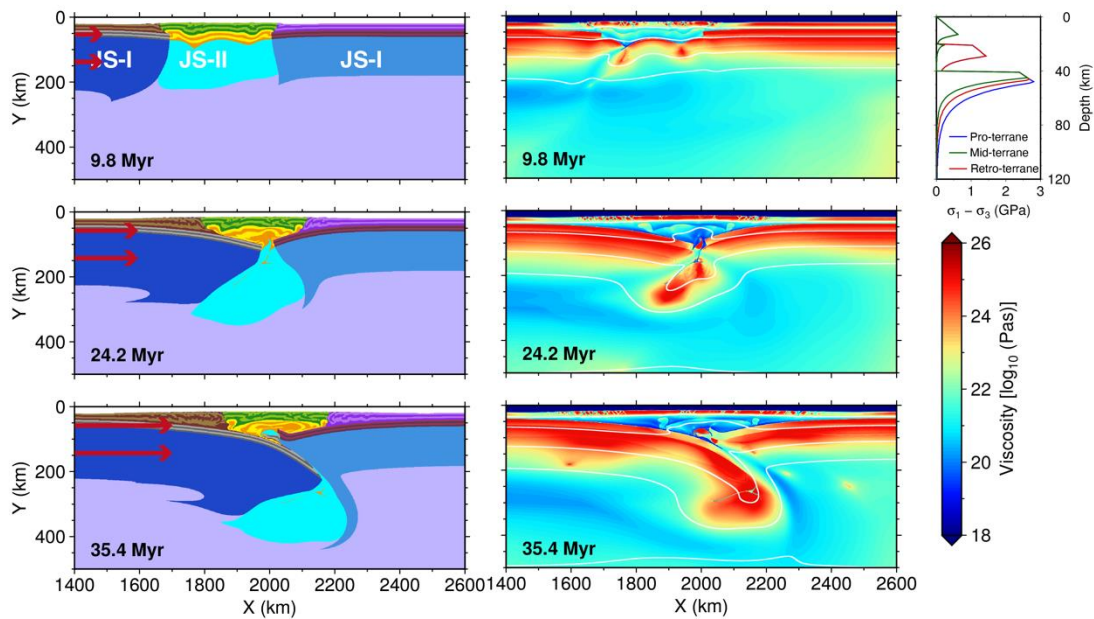

687
 688 **Figure 2. Initial model setup.** (a) Initial model configuration. The model size is 3000 km × 700 km, and size of
 689 study region is 1500 km × 500 km. Three continental terranes of the Pro-, Mid- and Retro-terrane are contained
 690 in the numerical model, and they are 200 km, 130 km, and 160 km thick, respectively. White lines are isotherms
 691 with an interval of 600 °C. Yellow arrows indicate the convergence rate of 20 mm/yr. Colored grids: 1 – sticky air;
 692 2 – sediments; 3 – weak zone; 4, 6, 8 – the upper crust of the Pro-, Mid- and Retro-terrane, respectively; 5, 7, 9 –
 693 the lower crust of the Pro-, Mid- and Retro-terrane, respectively; 10, 11, 12 –lithospheric mantle of the Pro-,
 694 Mid- and Retro-terrane, respectively; 13 – asthenosphere. (b) Initial temperature structure for the three terranes.
 695 The Pro- and Mid-terrane respectively have a coldest and warmest lithospheric mantle due to their differences of
 696 lithosphere thicknesses. (c) Four rheological models with contrasting lithospheric strength profiles. These are
 697 derived from different strength scaling factor (S) combinations for the upper crust, lower crust, and lithospheric
 698 mantle (Table S1). Strength profiles are calculated based on the Pro-terrane's initial lithospheric structure,
 699 composition, and temperature field. The prescribed strain rate is $1 \times 10^{-14} \text{ s}^{-1}$. CB-I and CB-II, the crème brûlée

700 model with strong and weak lower crust, respectively; JS-I and JS-II, the jelly sandwich model with strong and
 701 weak lower crust, respectively.

702
