Abstract.

We investigate the collection of dust particles in the mesosphere with the MESS (MEteoric Smoke Sampler) instrument that is designed to fly on a sounding rocket. We assume that the ice particles that form in the polar mesosphere between 80 and 85 km altitude in summer contain meteoric smoke particles; and these should be collected with MESS. The instrument consists of a collection device with an opening and closure mechanism, and an attached conic funnel which increases the sampling area in comparison to the collection area. Dust particles are collected either directly after passing through the instrument or indirectly after colliding with and fragmenting on the funnel wall. We calculate the dust and fragment trajectories in the detector to determine the collection efficiency for different particle sizes, rocket velocities and heights and we find the final velocities and the temperatures of the particles. The considered design has a sampling area of 62.78 mm diameter and a collection area of 20 mm diameter. For the conditions at the rocket launch site in Andøya, Norway, we estimate the collection of meteoric smoke particles contained in the ice particles to be $\sim 10^{12}$ - 10^{14} amu / mm^2. The estimated temperatures suggest that the composition of these smoke particles is not affected by the collection. Our calculations also show that keeping the instrument open above 85 km altitude increases the amount of small smoke particles that are directly collected. The directly collected smoke particles are heated as they decelerate, which can affect their composition.

1 Introduction

The upper atmosphere at the lower layer of the ionosphere contains small solid dust particles that take part in chemical processes (Plane et al., 2015). These particles, denoted as meteoric smoke particles (MSP), originate from cosmic dust material that remains in the upper atmosphere as a result of the meteor process. During their entry in the upper Earth's atmosphere, meteors are heated and ablated when they reach altitudes between 120 km and 80 km above the Earth's surface, e.g. (Mann, 2009). These remnants of the cosmic dust condense into nm-sized particles, the MSP. MSPs are a possible candidate to facilitate the formation of ice particles through heterogeneous nucleation that incorporates the MSP into large ice particles. Note that both MSP and ice particles, are referred to as mesospheric dust particles in this text. Homogeneous condensation has growth rates that are too low (Tanaka et al., 2022) to explain the ice particles that are observed during summer at mid and high latitudes around themesopause where the temperature reaches its global minimum. The ice particles notably cause mesospheric phenomena such as the Noctilucent Clouds (NLC) and the Polar Mesospheric Summer Echoes (PMSE) (Rapp and Lübken, 2004). NLC are associated to cloudy patterns that can be seen directly from the Earth's surface during the twilight when the sun light is reflected because of large ice particles, i.e. with a radius larger than about 20 nm. The ices particles are observed from space in the polar mesospheric clouds that occur at altitudes between 80 km and 85 km with a peak at around 82 km (Hervig et al., 2001; Bardeen et al., 2008) . Associated with the ice particles are also PMSE: strong coherent radar echoes that can be observed from around 30 MHz to 300 MHz and sometimes at even higher frequencies (Latteck et al., 2021). They are observed at altitudes ranging from 80 km to 90 km with a peak around 85 km. Both NLC and PMSE evidence the presence of ice particles in the mesosphere. The ice particles actually occur in summer at mid- and high-latitudes around the mesopause, where the temperature reaches its global minimum, but homogeneous condensation has growth rates too low to explain their formation (Tanaka et al., 2022).
There is little known about the MSP composition because of their altitude location. MSP, as well as the ice particles containing MSP, are located too high for high-altitudes balloons and too low for satellites. Satellite observations can be used to derive composition information from atmospheric extinction at different wavelengths, e.g. (Hervig et al., 2012). Sounding rockets with built-in instruments are the only means of in-situ measurements. Mass spectrometers on rockets have been measuring cluster ions for decades. Stude et al. (2021) have provided an overview of these measurements and describe their recent attempts to measure the composition of the mesospheric dust particles by using a mass spectrometer. Although they could confirm the presence of the larger particles, they were not able to address their composition. In addition to mass spectrometers, there have been several attempts to collect mesospheric dust particles with probes on rockets, but no conclusive results have been reported from their subsequent laboratory analysis for a long time. Early collection experiments to study ice particles in NLC were made with large detectors where aerodynamics was seen as a limiting parameter for the detection of small particles. For instance, it has been reported that the median diameter size of particles that can be collected with their instrument was 130 nm and most of the analysed particles had diameters between 100 nm to 200 nm (Farlow et al., 1970). They pointed out, however, that their optical analysis had missed a large number of small particles on the collector. From in-situ measurements with different dust instruments the composition of the MSP was estimated by using the material work function inferred from the charging

properties (Rapp et al., 2012; Havnes et al., 2014; Antonsen and Havnes, 2015). And the dust particles were collected with the MAGIC (Mesospheric Aerosol – Genesis, Interaction and Composition) instrument. With MAGIC the collector size was reduced down to the order of the molecular mean free path in order to minimize atmospheric shock effects due to the airflow around the payload (Hedin et al., 2014). In this paper, a new approach is considered. Motivated by the observations that the ice particles in the mesosphere most likely contain smaller MSP, the collection of ice particles can be a mean to collect and study the MSP embedded in those ice particles. Accordingly, a new sample collector is currently under development : the MESS (MEteoric Smoke Sampler) instrument (Havnes et al., 2015). Instead of trying to directly capture MSP, this instrument aims at collecting ice particles which contain MSP. The ice particles are larger than MSP and less likely to be deflected by the airflow in the vicinity of the instrument.
This current work presents the MESS instrument, the trajectories of the mesospheric dust particles, including both MSP and ice particles, calculated when they travel through the instrument, and an estimation of the collection efficiency of the instrument. The paper is organized as follows. Section 2 presents the design of the instrument. Section 3 describes the model that is used to evaluate the trajectories of the mesospheric dust particles. Section 4 is dedicated to the presentation of the results, including the airflow in the vicinity of the instrument, the mesospheric dust particles trajectories and the collection rates for different altitudes and rocket velocities, as well as a discussion about the final temperature and final speed of the dust particle. Finally, the conclusions are drawn and outlooks are given in Section 5, in particular by looking into the most suitable rocket conditions for an optimized collection of dust particles.

2 Instrument design

MESS is a rocket instrument intended to collect dust particles in the mesosphere. It will be mounted on the top deck of the rocket and be exposed to the airflow caused by the rocket motion, which will carry the particles into the instrument. The experiment idea, first proposed in Havnes et al. (2015), is to collect large ice particles less influenced by the airflow around the payload and increase the amount of collected material by building the instrument with a funnel. Figure 1a shows the mechanical drawing of MESS, where the top figure shows a side view and the bottom figure shows a top view, and Figure 1b shows the simplified instrument used in the simulations. Thanks to the conical shape, it will be possible to collect dust fragments from the entire funnel area. The instrument dimensions are limited by other detectors placed on the payload platform which also need to be exposed to the direct flow of air and dust. The funnel opening has a diameter of 62.78 mm with a cone angle of 20°, corresponding to an opening area of $A_{opening}$=3096 mm^2. The funnel height is 120 mm, and the total height of the

(a) Technical drawing of the MESS detector

(b) Simplified drawing of the MESS detector used in the simulations

Figure 1. Drawings of the MESS detector

4

instrument is 180 mm. The bottom of the funnel is 20 mm in diameter, corresponding to a collection area of A_{coll}=314 mm^2. The funnel increases the sampling area by about a factor of 10. The collection area will consist of 8 TEM (Transmission Electron Microscope) grids distributed in a circle, as seen in the center of the bottom of Figure 1a. Identical reference grids will be located inside the instrument, not exposed to the airflow. TEM grids include a support mesh and a carbon foil, they are used in standard sample holders, and using them would facilitate easy handling of the samples. Note that TEM grids were also used in the MAGIC campaign (Hedin et al., 2014). The instrument will be sealed by a mechanical lid which will be opened shortly after the nose cone ejection and kept open until the apogee. When opened, the lid can be seen as an extension of the funnel and is, as a consequence, omitted in the simplified drawing and description used in the simulations. Such an approximation is discussed later. A pressure valve is located inside the instrument and is solely used for pumping before the rocket launch in order to make sure that the pressure in the instrument is similar to the ambient pressure at the opening altitude. A sudden change of pressure during the opening of the instrument could damage the collection grids. Similarly, the pressure must be adjusted before opening the instrument after recovery. At mesospheric altitudes, the air density is still significant, and rocket speeds are in the order of 1000 m.s^{-1}, consistent with supersonic speeds. As a result, a bow shock will form in front of the instrument, which will affect the airflow and cause deflection of the particles. The effect of this deflection will be addressed in this paper.

3   Model description

In order to track the dust particles in the instrument, their trajectories are calculated by solving numerically the equation of motion for each dust particle. Accordingly, the modeling of the dust particles trajectories is presented in Section 3.1. As the motion of the dust particles is mainly driven by the drag force that the dust particles undergo which depends on the characteristics of the background gas, i.e. the air in the upper atmosphere, Section 3.2 presents the evaluation of the flow of the air in the vicinity of the instrument. Finally, we assume here that the ice particles can break up when they collide with the funnel wall of the instrument and the fragmentation modeling along with the underlying assumptions are introduced in Section 3.3. Regarding the MSP, it is assumed that they do not fragment and that the collision of a MSP with the funnel wall results in a specular reflection.

3.1   Dust particle dynamics

Since both MSP and ice particles are considered, the trajectories of both of them have to be calculated. Since the ice particles are mostly composed of ice and MSP represent a small fraction, the bulk properties of the ice particles are determined from the ice characteristics. Note that it is assumed that ice particles contain 3% of MSP and 97% of ice. We assume that the dust particles are perfectly spherical, with a radius r_d and a mass density ρ_d. This is in particular true if the radius of the dust particles is larger than about 1 nm. For smaller radius, the geometry of the dust particles needs to be considered and the model presented in this section is no longer valid and cannot be used in that case. Then, the dust particles are assumed to be neutral, i.e. electric and magnetic effects can be neglected, and only subjected to the drag force and gravity. The drag force comes

5

from the collisions between the molecules of the background gas and the dust particles. It is incidentally assumed that the dust particles are by far more massive than the gas molecules. As a consequence, the dust particles are heated due to these collisions and their temperature may reach the sublimation temperature. At this moment, they dust particles will start to sublimate making necessary to consider their mass variation. Note that sublimation is a priori more likely to take place for ice particles rather than for MSP. Finally, by taking the rocket as the reference frame, the equation of motion of the dust particles having a velocity $\vec{v}_d$ reads (Baines et al., 1965; Smirnov et al., 2007; Antonsen and Havnes, 2015) :

$$\frac{d\vec{v}_d}{dt} = \frac{1}{m_d} \left[m_d \vec{g} + \chi \pi r_d^2 m_g n_g v_{th,g}^2 f(u) \frac{\vec{v}_g - \vec{v}_d}{|\vec{v}_g - \vec{v}_d|} - \frac{dm_d}{dt} \vec{v}_d \right] \tag{1}$$

with $m_d = 4\pi \rho_d r_d^3 / 3$ the mass of the dust particles. In the right hand side, the first term corresponds to gravity, with $\vec{g}$ the gravity acceleration, the second term corresponds to the drag force and the third term corresponds to the mass variation of the dust particles. Regarding the drag force, the parameter χ is associated to the geometry of the dust particles; for spherical dust particles $\chi = 1$. m_g, n_g and $v_{th,g}$ respectively correspond to the molecules mass, density and thermal speed of the background gas. The thermal speed is defined by $v_{th,g} = \sqrt{2k_B T_g / m_g}$ with k_B the Boltzmann constant as a function of the temperature of the background gas T_g. The function f is given by :

$$f(u) = \frac{1}{\sqrt{\pi}} \left(u + \frac{1}{2u} \right) e^{-u^2} + \left(1 + u^2 - \frac{1}{4u^2} \right) \mathrm{erf}(u) \tag{2}$$

in terms of the relative speed $u = |\vec{v}_g - \vec{v}_d| / v_{th,g}$ assuming specular reflection of background gas molecules during collisions with dust particles. Note that such a modeling of the drag force is valid for both subsonic and supersonic regimes. Because of the heating of the dust particles, that can be important enough to lead to the sublimation of the ice layer, the evolution of the dust particles temperature T_d has to be modeled. It is given by the energy balance that can be written as follows (Horányi et al., 1999; Antonsen and Havnes, 2015) :

$$\frac{dT_d}{dt} = \frac{1}{m_d c_d} \left(\frac{\pi}{4} r_d^2 n_g v_{th,g} k_B T_g g(u) - L_d \frac{dm_d}{dt} \right) \tag{3}$$

with c_d and L_d the dust particles specific heat and latent heat respectively. The first term of the right hand side corresponds to the heating due to the collisions with background gas molecules and the second corresponds to the modification of the internal energy due to the sublimation. Similarly to Eq.(2), the function g is defined as a function of the relative speed u and is given by :

$$g(u) = \frac{2}{\sqrt{\pi}} \left(5 + 2u^2 \right) e^{-u^2} + \frac{3 + 12u^2 + 4u^4}{u} \mathrm{erf}(u) \tag{4}$$

so that the modeling the heating of the dust particles is valid for both subsonic and supersonic regimes. It can be pointed out that radiative processes, such as thermal emission of the dust particles, solar radiation and terrestrial radiation, are neglected in Eq.(3) (Rizk et al., 1991). The mass variation of the dust particles $d_t m_d$ appearing in Eq. (1) and Eq. (3) associated to the mass loss due to the sublimation corresponds to a flux of molecules constituting the dust particles out of their surface. Thus, the mass variation of the dust particles is defined by :

$$\frac{dm_d}{dt} = -4\pi \rho r_d^2 \frac{dr_d}{dt} \tag{5}$$

where the radius variation is evaluated by assuming that dust particles molecules leave the surface diffusively. It is given by the Hertz-Knudsen equation (Skorov and Rickman, 1995; Kossacki and Leliwa-Kopystynski, 2014; Antonsen and Havnes, 2015) which can be written as :

$$\frac{dr_d}{dt} = -\frac{P_{vap}}{\rho_d}\sqrt{\frac{m_D}{2\pi k_B T_d}} \tag{6}$$

with m_D the mean mass of dust particles. P_{vap} corresponds to the vapor pressure and is given by (Podolak et al., 1988) :

$$P_{vap} = P_0 \exp\left(-\frac{T_0}{T_d} + \frac{2\gamma_d m_D}{\rho r_d k_B T_d}\right) \tag{7}$$

where P_0 and T_0 are constants depending on the type of dust particles, i.e. ice particles or MSP. The second term in the exponential corresponds to a correction of the vapor pressure so that spherical mass ejection for very small surfaces is considered (Evans, 1994). This correction term is given in terms of the specific surface energy γ_d of the dust particles.

3.2 Airflow model

In order to calculate the trajectories and the heating of the dust particles, the number density, the temperature and the velocity of the background gas have to be evaluated. Such an evaluation is done by using the DS2V program developed by Bird and Brady (1994). It is a 2D numerical software based on Direct Simulation Monte Carlo (DSMC) methods which are commonly used to study rarefied gas dynamics. The mesosphere and the lower thermosphere are characterized by a Knudsen number usually between 0.01 and 1 for standard size of instrument collecting mesospheric dust particles, which corresponds to a rarefied gas (Antonsen and Havnes, 2015). The Navier-Stokes equations which are suitable for a continuous flow (when $Kn \ll 0.1$) can not be used anymore and probabilistic methods should be preferred.

3.3 Fragmentation model

Because of the conical shape of the detector, a large number of the incoming dust particles can collide with the funnel walls. We assume that during the collision, MSP are reflected without breaking up while the ice particles can break into fragments. Little is known of this fragmentation process and we refer to results obtained from ice collision experiments and molecular simulations (Tomsic et al., 2003). It was found that a large fragment is likely to be created during the collision of pure ice particles onto a metal wall with a large angle with respect to the normal direction of the surface. Accordingly, it is assumed for our case that a large fragment is created having a mass equal to half of the mass of the incoming ice particle and the same composition as the incoming ice particle, i.e. 3% of MSP and 97% of ice. The other half of the mass is divided between a large number of smaller fragments. They are assumed to be small enough so that the ice sublimates immediately. According to the mass conservation and by assuming that the radius distribution $\omega(r)$ the MSP fragments scale as $\omega(r) \propto r^{-3}$ supported by results from in-situ measurements (Antonsen et al., 2020), it can be deduced that the mean radius of these fragments is mostly smaller than 0.8nm, see Appendix A. This means that the model presented in the previous section is no longer suitable and cannot track the MSP fragments. Finally, the description of the fragmentation process that is used in this work to investigate the trajectories of the MSP fragments is summarized in Figure 2. We consider only the large fragment if $r_d < 6$ nm right before
Figure 2. Drawing of the modeling of the ice particles fragmentation process having a mass m_d and a radius r_d when they collide with the funnel wall. The size scales are not respected for the sake of clarity. When $r_d > 6$ nm, the angle associated to the two fragments is the same as the angle of the incident particle with respect to normal direction of the surface. Different angles are displayed for the sake of clarity.

the collision, and we consider the large fragment plus one MSP fragment having a radius of 1nm if $r_d > 6$ nm right before the collision. For both the large fragment and the MSP fragment, it is assumed that the angle after collision is the same as the angle of the incident ice particle due to specular reflection.

Another kind of collisions happens when the mesospheric dust particles hit the top of the funnel or the collection area. In those cases, the collision is head-on and the model we just described is not suitable. For head-on collisions of ice particles, it is assumed that the ice particles entirely break up where the ice vaporizes and the MSP are released because the speed of the ice particle during the collision is about several hundreds of meters per second. For head-on collisions of MSP, it is assumed that the MSP rebounds without being destroyed.

4 Results

This section is dedicated to the presentation of the results coming from simulations performed for different altitudes and different rocket speeds.The altitudes of 80 km, 82 km, 85 km and 90 km are considered as they correspond to the borders and centers of the region of interest as mentioned in Section 1. The rocket velocity varies with the altitude and depends on the rocket apogee. For a mesospheric rocket, the apogee lies between 110 to 130 km and it can be expected a speed around 1000 m.s^{-1} at an altitude between 80 km and 90 km. Accordingly, rocket speeds of 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1} are considered. It can be pointed out that such speeds are associated to supersonic flows The airflow of the background gas in the vicinity of the instrument is first presented in Section 4.1. Then, the trajectories of dust particles are presented in Section 4.2 with two illustrative examples. In order to evaluate in a more comprehensive way the dust particles motion in the instrument, the detection rates are presented in Section 4.3 for the different altitudes, different rocket velocities and different dust particles initial radii. These detection rates are then used to estimate the mass of dust particles collected during a rocket flight. Finally, the final temperatures and speeds of the dust particles when they reach the collection area are presented in Section 4.4 and Section 4.5 respectively.

4.1 Neutral gas flow

The flow of the background gas around the rocket depends on its density and temperature. These parameters, and in particular the density, can vary over short spatial and temporal scales. Variations by roughly a factor of 2 were observed for the density during previous rocket campaigns (Lübken et al., 1993; Strelnikov et al., 2003). However, such variations are neglected in a first approximation and because it is out of the scope of the present work. Thus, mean values provided by the NRLMSISE-00 atmospheric model are used to evaluate the initial densities and temperatures of the background gas (NRL). The model has been used to look at the data in July at a place of GPS coordinates 69° N 16° E in order to estimate the atmospheric conditions in the summer near the Andøya Space Center. These values are gathered in the Table 1 for the four different altitudes.

Altitude [km]	80	82	85	90
Density $[\text{m}^{-3}]$	5.909×10^{20}	4.115×10^{20}	2.220×10^{20}	6.697×10^{19}
Temperature [K]	160.5	150.0	139.4	138.7

Table 1. Initial densities and temperatures of the background gas for the four different altitudes coming from the NRLMSISE-00 atmospheric model(NRL).

The Figure 3 shows the airflow and the gas density around the instrument at altitude of 82 km and rocket speed of 1000 m.s^{-1}. The airflows associated to the other altitudes and rocket speeds are in Appendix B since they are relatively similar to the one shown in Figure 3. It can be seen that a bow shock with a thickness of about 4 cm is created at the top of the detector. This is because the rocket speed is always higher than the sound speed of the background gas. The gas density in the bow shock
Figure 3. Results of the DSMC simulations showing (left) the background gas density n_g and stream around the detector and (right) a lineout of the background gas density n_g with respect to the height from the bottom of the detector for an altitude of 82 km and a rocket speed of 1000 m.s^{-1}.

is higher than the initial density by a factor of 3 to 4 depending on the rocket speed. Below the bow shock, the gas density reaches its highest value in the funnel, where it is higher than the initial density by about one order of magnitude depending on the rocket speed. The increase of the gas density in these two regions implies that the dust particles can be slowed down by undergoing the drag force twice, first during the bow shock crossing and then, and in a more important way, when being inside the funnel. Finally, it can be observed that the stream is mainly laminar around the detector but becomes turbulent inside the detector which means that the trajectories of the dust particles may be modified because of these turbulence. Given the slow-down that dust particles can experience when crossing the bow shock or being in the funnel and given the turbulence taking place in the detector, it can be expected that a significant fraction of the small particles do not reach the collector. When looking at the influence of the rocket speed on the gas density for a given altitude, it appears that the gas density of the bow shock and inside the detector gets higher with the rocket speed, which means that a higher rocket speed leads to a stronger drag force. Thus, increasing the rocket speed does not necessarily entail a more efficient collection of dust particles as they would be influenced more importantly by the drag force and being possibly decelerated more than for a lower rocket speed. This will be addressed in Section 4.3.
10

4.2 Dust particle trajectories

The previous results providing the airflow of the background gas in the vicinity of the instrument can now be used to evaluate the motion of the dust particles. To do so, equations (1)-(6) are solved numerically using the 4th order Runge-Kutta method. These equations are function of the mass density ρ_d, the specific heat c_d, the latent heat L_d, the mean mass m_D, the specific surface energy γ_d, and the parameters P_0 and T_0 of dust particles that are different for ice particles and MSP. The values of these parameters are gathered in Table 2 for both ice particles and MSP (Podolak et al., 1988; Antonsen and Havnes, 2015). The particles tracking in the simulation is stopped either when the particle reaches the detector, or when the particle is no longer in the simulation box, i.e. the particle is taken away from the instrument by the airflow and does not reach the detector, or when the particle is stopped due to the slowing down coming from the drag force. i.e. the particle does not reach the detector, or, for ice particles, when the particle radius becomes smaller than 0.8 nm where the model is no longer valid. In that case, the particle does not reach the detector because it is completely sublimated. This section aims at presenting the results obtained from these simulations for both ice particles and MSP through the evaluation of their trajectories. For the sake of clarity, it has been chosen to present only one representative example for both ice particles and MSP showing the typical trajectories of the dust particles in the instrument instead of an exhaustive list. To investigate the trajectories of the dust particles in a comprehensive way, the evaluation of the trajectories should be done for different altitudes, different rocket velocities and different initial radius leading to the very large number of cases. The presentation in the next section of the collection rates as a function of these parameters aims at addressing this question and study the efficiency of the instrument for different altitude and rocket speeds.

	ρ_d $\left[\text{kg.m}^{-3}\right]$	c_d $\left[\text{J.kg}^{-1}.\text{K}^{-1}\right]$	L_d $\left[\text{J.kg}^{-1}\right]$	m_D [a.m.u.]	γ_d $\left[\text{J.m}^{-2}\right]$	P_0 $\left[\text{J.m}^{-3}\right]$	T_0 [K]
Ice particles	980	$90+7.5T_d$	2.78×10^6	18	0.19	3.9×10^{11}	4845
MSP	3000	1000	6×10^6	140	0.20	1.5×10^{13}	56655

Table 2. Values of the mass density ρ_d, the specific heat c_d, the latent heat L_d, the mean mass m_D, the specific surface energy γ_d, and the parameters P_0 and T_0 for ice particles and MSP. It is reminded here that P_0 and T_0 do not represent the pressure or the temperature of any dust particles but they are constants that have the dimension of a pressure and a temperature. Note that for the ice particles, the specific heat is expressed in terms of the ice particle temperature T_d.

Instead of giving an extensive list of trajectories for different altitudes, different rocket speeds, and different initial radius, we prefer instead to show an illustrative case gathering the different trajectories that can be exhibited by the dust particles when they cross the instrument. The dependence of the trajectories on the altitude, the rocket speed and the initial radius of the dust particle is discussed in the next section by looking at the collection rates. Accordingly, Figure 4 shows the trajectories of ice particles that have an initial radius of 13 nm and the trajectories of MSP that have an initial radius of 7 nm. In both cases, a rocket velocity of 1000 m.s^{-1} and an altitude of 82 km are considered. Different trajectories can be identified. First, dust particles starting near the central axis of the instrument. It can be seen that an ice particle with an initial radius of 13 nm and a MSP with an initial radius of 7 nm cross entirely the instrument and reach the collection area. However, if some dust particles

(a) Ice particles with an initial radius of 13nm. The white lines represent the ice particle trajectories. The blue lines represent the trajectories of the fragments constituted of pure MSP created during each collision of an ice particle with a funnel wall.

(b) MSP with an initial radius of 7nm.

Figure 4. Trajectories of ice particles and MSP in the MESS instrument for rocket velocity of 1000 m.s^{-1} and an altitude of 82 km.

are smaller and lighter, they are likely not to reach the collection area. They are slowed-down because of the drag force and will eventually float in the instrument. This leads to a sort of threshold initial radius for the dust particles above which they should always reach the collection area. The largest value for this threshold initial radius is reached for a rocket speed of 1200 m.s^{-1} and an altitude of 80 km corresponding to the highest rocket speed and the lowest altitude, this case being associated to

245 the most important increase of the gas density in the bow shock and in the funnel. In that case, the minimum initial radius is about 11 nm for ice particles, and is about 9 nm for MSP. Then, dust particles starting a bit farther from the central axis. They enter the instrument and, if they are large enough, collide with the funnel wall otherwise they are progressively stopped by being slowed down due to the drag force. This corresponds to the trajectories ending in the middle of the instrument. This will be further investigated in the Section 4.5 dealing with the final speeds of the mesospheric dust particles. In the case of an ice

250 particle, the collision leads to a rebound during which the radius of the ice particle is divided by a factor of $2^{1/3}$ and a formation

12

of a fragment constituted of pure MSP as it can be observed on Figure 4a. In the case of a MSP, the collision only leads to a rebound as it can be seen on Figure 4b. In both cases, starting relatively far from the central axis means that dust particles can bounce several times and travel over a larger distance than a dust particle starting near the central axis. They undergo the influence of the drag force during a longer time and are more slowed down. Moreover, ice particles colliding several times

255 see their radius divided by a factor of $2^{1/3}$ at each collision, become smaller and slowed down more importantly by the drag force. Therefore, it is possible that they don't reach the collection area. In addition, fragments resulting from the collision of an ice particle with a funnel wall are quickly slowed down because they are very small, ∼1 nm, and only those created near the collection area are likely to reach it. If the fragments are created far from the collection area, they will float in the instrument after being entirely slowed down. Finally, dust particles starting far from central axis of the instrument. These particles cannot

260 be collected since they either are taken away by the airflow or hit the top of the funnel. For ice particles in that case, they will explode in a large number of small fragments. Unlike the collisions that are considered in the fragmentation process presented in Section 3.3, the collision here is head-on and any large fragment is created. All of the fragments are small and are taken away by the airflow, even those heading toward the central axis of the instrument, because of the stream existing in that region, see Figure B1 to Figure B4.

265 It appears from Figure 4 that particles entering the instrument are either slowed down and float in the instrument, the trajectories end in the middle of the instrument in this case, or reach the collection area, the trajectories end at the bottom of the instrument in that case. The case where particles entering the instrument and then go out by being taken away the airflow, as it could have been expected when looking at the streams, especially on Figure B1 and Figure B2, does not happen, except for small fragments created by head-on collision on the top of the funnel wall. In addition, it was observed by looking at

270 the airflow streams that turbulence take place in the instrument. It appears that these turbulence don't have any influence of the dust particles trajectories. These conclusions are drawn by evaluating the trajectories of ice particles and MSP having an initial radius of 13 nm and 7 nm respectively. However, they can be generalized to other radius. Even though trajectories of dust particles having a different initial radii are not shown here for the sake of clarity, a large number of simulations have been performed to evaluate the trajectories of dust particles that have an initial radius ranging from 1 nm to 20 nm for ice

275 particles and ranging from 1 nm to 10 nm for MSP. The simulations are then used to evaluate to the collection efficiency of the instrument for different altitudes, different rocket speeds and different initial radius for the dust particles.

4.3 Collection rates

It has been observed in the last section that when entering the instrument, some of the dust particles can reach the bottom of the instrument and be collected but others are sufficiently slowed down to be completely stopped and eventually float in

280 the instrument. This section is dedicated to the presentation of the collection rates of the ice particles and MSP reaching the collection area. These rates are obtained by calculating the ratio between the number of particles reaching the collection area and the number of particles entering the instrument. The rates are calculated for different initial radius for the dust particles, different rocket speeds and different altitudes. In each case, about 150 dust particles are considered as a compromise between a number that is large enough to be relevant for statistics and a number not too large regarding computational capabilities.

13

285   Figure 5 shows the collection rates of ice particles as a function of their initial radius. They are shown for different rocket speed, 800 m.s^{-1}, 1000 m.s^{-1}, 1200 m.s^{-1}, and different altitudes, 80 km, 82 km, and 85 km. As mentioned in Section 1, most of the ice particles are located between 80 km and 85 km with a peak around 82 km. Similarly, Figure 6 shows the collection

Figure 5. Ice particles collection rates as a function of their initial radius for three different rocket speeds 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1} and three different altitudes 80km, 82km and 85km. Each point of the graphs has been obtained by calculating the trajectories of about 150 ice particles.

Figure 6. MSP collection rates as a function of their initial radius for three different rocket speeds 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1} and three different altitudes 80km, 85km and 90km. Each point of the graphs has been obtained by calculating the trajectories of about 150 MSP.

14

rates of MSP as a function of their initial radius. They are also shown for different rocket speed, 800 m.s^{-1}, 1000 m.s^{-1}, 1200 m.s^{-1}, as for ice particles, and different altitudes, 80 km, 85 km, and 90 km, which are different for the altitudes considered for ice particles. As seen in Section 1, most of the MSP are located between 80 km and 90 km with a peak around 85 km. Overall conclusions are basically the same for both ice particles and MSP. First, it can be observed that the collection rates increase with the initial radius. Larger dust particles are more likely to reach the collection area as their trajectories are less influenced by the drag force. Then it can be seen that the collection rates are more important for higher altitudes and smaller rocket speed. At higher altitudes, the density of the background gas is smaller leading to a weaker drag force, this latter can be assumed as proportional to the background density in a first approximation, see Section 3.1, and a larger number of particles are likely to reach the collection area. Similarly, it appears that a slower rocket leads to a more efficient collection of ice particles. Although it could be expected that a faster rocket would lead to a better collection because the dust particles would faster cross the bow shock and the instrument, and being decelerated due to the drag force over a shorter period of time, it rather appears that the ice particles trajectories are more importantly driven by the drag force rather than by the rocket speed. This answers the question on the competition between drag force and initial particles speed raised in Section 4.1. Finally, it can be observed that particles smaller than a certain size don't reach the collection area. This creates a sort of threshold radius ranging from 2 nm to 10 nm for ice particles and from 1 nm to 8 nm for MSP depending on the rocket speed and altitude. A smaller rocket speed or the flight of the rocket a lower altitude leads to a weaker drag force allowing smaller particles to reach the collection area. Such an effect may have to be considered during the design of the rocket mission with respect to the apogee. Those particles having a radius smaller than the threshold radius are slowed down and stopped in the instrument and eventually float. Even if these particles don't reach the collection area, they could still be collected when the closing system is activated as they would remain inside the instrument. Thus, the instrument will have to be open carefully during the sample analysis so that there is no loss of the these potential particles floating in the instrument. In addition, the walls of the funnel should be inspected as dust particles could be stuck onto them. Overall, it appears that the MESS instrument presented in this work can collect dust particles over a large range of size. This instrument should efficiently collect ice particles larger than 10 nm and MSP larger than 8 nm. In addition, it should be able to collect a significant number of ice particles larger than 2 nm and MSP larger than 1 nm, even though the collection rates are the most important at the highest altitude where dust particles are less numerous (Megner et al., 2006; Baumann et al., 2013).

4.4 Estimate of the final temperatures

During their entry in the instrument, dust particles can be heated until undergoing mass loss when they start to sublimate. This heating that cannot be avoided with the current rocket speed may lead to modification of the chemical composition of the dust particles which would complicate the laboratory analysis.. This section aims at addressing this question by looking at the final temperature of the dust particles, i.e. the temperature of the dust particles when they reach the collection area.

Figures 7 and 8 show the final temperatures of ice particles and MSP respectively as a function of their initial radius for the three rocket speeds 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1}, and different altitudes. Similarly to the previous section, the final temperatures of ice particles are shown for an altitude of 80 km, 82 km and 8 5km, and the final temperatures of MSP are
15

Figure 7. Evolution of the final temperatures of the ice particles, i.e. when they reach the collection area, with respect to the their initial radius for different rocket velocities and different altitudes.

Figure 8. Evolution of the final temperatures of the MSP, i.e. when they reach the collection area, with respect to the their initial radius for different rocket velocities and different altitudes.

shown for an altitude of 80 km, 85 km and 90 km. The particles that are considered here are those starting in the central axis of the instrument for purpose of illustration. It has been checked that there are no relevant variations for the final temperatures depending on the initial position of the dust particles. In addition, ice particles starting at the center are those that are heated the most, which should provide the upper limit of the final temperatures. It can be seen for ice particles that there is no drastic change for the final temperatures. The largest difference is about 25 K overall between 170 K and 195 K. The heating due to

325

16

the drag force leads to a melting of the outer surface of the ice particles that remains relatively cold. The fact that the final temperature range from 170 K to 190 K also means that crossing the instrument results in a relatively small increase of their temperature. It is about a few tens of kelvins since the initial temperature of the dust particles is between about 140 K and 160 K, see Section 4.1. This means that the MSP located inside the ice particles are not significantly heated during their collection and the ice can be considered as acting like a thermal shield. Finally, the trends with respect to the rocket speed and the altitude are once again due to the drag force. A lower altitude and a faster rocket are associated to a stronger drag force resulting in a more important heating. Concerning pure MSP, it can be seen they are heated significantly, up to 1800 K. Although the first term in Equation 3 associated the heating induced by the drag force is about the same order of magnitude for MSP and ice particles, the second term associated to the mass variation is much smaller for MSP than for ice particles. The parameter T_0 taking part of the expression of the vapor pressure that is used to evaluate the mass variation is very different between MSP and ice particles. One has $T_0 = 56655$ K for MSP and $T_0 = 4845$ K for ice particles leading to a difference by a factor about 10. Thus, for MSP, the heating is not counterbalanced by the mass variation and MSP can reach large temperatures. Said differently, this can be interpreted by the fact that the melting temperature of the MSP is much higher than the melting temperature of the ice. Since the temperature increases up to the melting temperature, the MSP have a much higher temperature than the ice particles. In both cases, the high temperature for the MSP means that their chemical composition can be altered during their crossing of the instrument and the chemical composition of MSP reaching the collection can be different from the chemical composition of MSP before they enter the instrument, i.e. when they are present in the mesosphere. Finally, it appears that a slower rocket and a higher altitude lead to a final temperature that is significantly smaller. This can thus be an additional reason to prefer slower rockets as they are less likely to induce a change in the chemical composition of MSP.

4.5 Estimate of the final speeds

When reaching the collection area, the dust particles have a nonzero speed. Depending on that speed, the dust particles may damage the TEM grids, the walls of the collection area, and the instrument more generally. Additionally, they may also break up when eventually hitting the collection area or bouncing off. This section aims at addressing this question by looking at the final speed of the dust particles.

Figures 9 and 10 respectively show the final speeds of the ice particles and MSP as a function of their initial radius, for the same rocket speeds and altitudes as previously. We can see that the final speed of the ice particles and MSP quickly increases and most of the dust particles have a final speed of several hundreds of meters per second. For low altitude, it can be seen that a slower rocket leads to larger final speed for the dust particles. Said differently, a faster rocket leads to a more efficient deceleration of the dust particles, which comes from the bow shock created by the rocket that is strong enough to slow down the dust particles efficiently. At higher altitudes, a slower rocket leads on the contrary to smaller final speeds. In that case, the density of the atmosphere is such that the bow shock created by the rocket is not strong enough to slow down larger dust particles. Then, the final speed is driven by the rocket speed. Differently to the last section where it has clearly appeared that slower rockets would be more beneficial, the situation seems more ambiguous here. A slower rocket would be more beneficial at higher altitude but a faster rocket would be more beneficial at lower altitude. However, for all the rocket speeds, the number
Figure 9. Evolution of the final speeds of the ice particles, i.e. when they reach the collection area, with respect to the their initial radius for different rocket speeds and different altitudes.

Figure 10. Evolution of the final speeds of the MSP, i.e. when they reach the collection area, with respect to the their initial radius for different rocket speeds and different altitudes.

of dust particles bouncing off should be very small because most of them have a final speed higher larger 100 m.s^{-1}. Although the impact of nanometers-sized particles on carbon foils has not been studied to the best of our knowledge, the collision of larger aggregate particles have been both theoretically and experimentally investigated during the evaluation of the particles growth in protoplanetary disks. It was found that bouncing happens for collision speeds smaller than 10 m.s^{-1} for particles with the same material (Blum and Wurm, 2008; Wada et al., 2011). Bouncing is prevented when the kinetic energy of the impacting

365

It can be pointed out that Figures 9 and 10 show the final speeds of dust particles starting in the central axis of the instrument. Unlike the final temperatures, the final speed of the dust particles strongly depends on their initial position with respect to the central axis. Accordingly, Figures 11a and 11b respectively show the profile of the final speeds of ice particles and MSP with respect to the radial direction. For ice particles, these radial profiles are shown for an altitude of 82km and an initial radius of 20 nm. For MSP, the radial profiles are shown for an altitude of 85km and an initial radius of 10 nm. In both cases, they are shown for the three rocket speeds 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1}. It has been chosen to show the profiles associated to only one altitude and one initial size as a purpose of illustration. The altitudes of 82 km and 85 km have been chosen as a mean altitude. The initial radii of 20 nm and 10 nm have been chosen because they correspond to the maximum radii which are considered in this work. Such dust particles should be the least decelerated leading the upper limit of the final speed. It can be seen that the dust particles incoming near the central axis have the largest final speed. On the contrary, the dust particles incoming relatively far from the central axis have much smaller final speed. This is due to the collision of the dust particles on the funnel wall. As a result of the collision, the dust particles have a much larger transverse speed and becomes more sensitive to the turbulence taking place in the instrument, see Section 4.1, leading to a deceleration of the dust particles.

(a) Radial profiles of the final speed of ice particles associated to an altitude of 82km and an initial radius of 20 nm.

(b) Radial profiles of the final speed of MSP associated to an altitude of 85km and an initial radius of 10 nm.

Figure 11. Profiles of the final speed of ice particles and MSP along the radial dimension for three different rocket speeds.

4.6 Estimate of collected mass

We now estimate the total mass of mesospheric dust particles, i.e. MSP, collected with the MESS instrument, although the numbers are subject to great uncertainty. Our assumptions are for conditions during the summer near Andøya since this corresponds to the time and location of a future experimental campaign. We first estimate the amount of MSP contained in the ice particles that reach the detector. We then estimate the amount of MSP that is collected directly and is not contained in the ice.

In contrast to previous experiments, MESS aims at collecting the dust material contained in ice particles. We base our estimate for this collection on the number densities in NLC, which represent the large ice particles and their observations at the Andøya rocket launch site. The particle densities are from a study (Kiliani et al., 2015) based on several years of UV, VIS and IR lidar observations (Baumgarten et al., 2007, 2010) and with size distributions obtained from models (Berger and Lübken, 2015). For a given dust number density, the mass of collected particles $m_{collected}$ is evaluated by :

$$m_{collected} = A_{coll} \, \Delta h \, n_d \, V_{dust} \, \rho_{d,msp} \, \alpha \, \sigma \tag{8}$$

where A_{coll}, Δh, n_d and $\rho_{d,msp}$ are the collection area, the sample altitude, the dust particles number density and the mass density of MSP respectively. The dust volume V_{dust} is calculated from the radius r_d, by assuming spherical particles. The collection efficiency, σ we investigated above. The filling factor α denotes the mass fraction of the particle that consists of MSP, we assume $\alpha = 0.03$. With these assumptions, we find that the mass of MSP collected in ice particles amounts to 0.9620 10×10^{16} amu, $1.001 \, 10 \times 10^{16}$ amu, and $1.042 \, 10 \times 10^{16}$ amu for the rocket velocities 800 m.s^{-1}, 1000 m.s^{-1} and 1200 m.s^{-1}, respectively. This corresponds to a MSP deposition at the collection area around 3×10^{13} amu / mm^2 for a filling factor of 0.03 particle. With filling factors between 0.001 and 0.1, the deposited MSP are $\sim \times 10^{12}$ - 10^{14} amu / mm^2. These values are based on NLC observations near the Andoya rocket range. For comparison, a numerical global model study of polar mesospheric clouds (Yu et al., 2023) assumes for the water ice particles an average column ice content of the order of 400 μg / m^2. This latter value would correspond, for filling factor 0.03, to a MSP collection of 7×10^{12} amu / mm^2 which is in the range of our estimate.

To estimate the MSP that are directly collected, we rely on a global model, in particular to results from a model run of WACCM/CARMA carried out by W. Feng at the University of Leeds, UK. The results of this model run were applied in a recent study of the D-region incoherent scatter spectrum by Gunnarsdottir et al. (2023) and a further description can be found there. WACCM, the Whole Atmosphere Community Climate Model (Hervig et al., 2017) in combination with CARMA, the Community Aerosol and Radiation Model for Atmospheres (Bardeen et al., 2008) are used to simulate the growth, sedimentation and transport of meteor ablation products. The simulation run uses model parameters described in Brooke et al. (2017), a meteoric influx of 7.9 t /day, meteoric material density is 2 g / cm^3 and covers a 22-year period. It provides monthly averaged height profiles of the MSP in 28 size- bins ranging from 0.2 nm to 102.4 nm. However, particles larger than $\sim$ 10 nm have negligible number densities at mesosphere heights. The model results show little variation after 1 to 2 years (Gunnarsdottir et al., 2023; Greaker, 2023) and the results for the months June, July and August are similar. We combine the average dust number densities for the month of June and the collection efficiencies of MESS presented in this work to calculate the cumulative number of impacts and MSP mass per surface area at the MESS instrument. The values for June conditions and a rocket

speed of 1000 m.s^{-1} are shown in Figure 12. The values were derived according to Greaker (2023). The same work showed that by extending the sampling area to 95 km the amount of directly collected MSP increases further to 10^5 / mm^2. As such, it could prove beneficial to sample a larger area, in an attempt increase the amount of collected MSP. We note that the used MSP number densities are small in comparison to other WACCM/CARMA model runs. This is partly, but not only, due to the meteorite influx assumed in the model run, which is relatively small. Higher meteorite influx can lead to higher number densities of MSP, but the relationship is not linear (Bardeen et al., 2008).

(a) Elevation profile of the cumulative number of directly sampled MSP per detection surface area.

(b) Elevation profile of the cumulative mass of directly sampled MSP per detection surface area

Figure 12. Elevation profiles for estimates of the cumulative amount of directly sampled MSP reaching the detection surface, with a sampling area from 80 to 90 km and a rocket speed of 1000 m.s^{-1}. The labels indicates the MSP size-bin, and the black line shows the combined values for all size-bins. Similarly the black dashed line shows total value, however with a collection efficiency fixed at 100% at all altitudes

5   Conclusions

Our calculations suggest that the MESS design for collecting dust during rocket flight through a PMSE layer can return of the order of 10^{16} amu of refractory MSP material assuming that the rocket samples a 0.5 - 4 km height interval of PMSE and that the collected ice particles contain a 3 percent volume fraction of refractory MSP. We estimate the range of the deposited MSP at the sample collecting surface is $\sim \times 10^{12}$ - 10^{14} amu / mm^2. It if found that the MESS instrument can efficiently collect both MSP and ice particles with an initial radius of order of magnitude of 10 nm and at heights above 85 km also smaller particles can be collected. While MSP that are directly collected can reach temperature larger than 1000 K due to heating induced by the

drag force ice particle temperatures remains smaller than 200 K and the chemical composition of the MSP embedded in those ice particles is unchanged. Our calculations are based on model assumptions on the fragmentation at the funnel wall. We did not consider the cases that particles can stick at the funnel surface, nor did we consider charge effects. Dust particles can carry an initial charge and can also be charged during fragmentation. Including charged dust particles could result in an enhanced sticking to the walls and changes in the particle trajectory. In addition, the rocket payloads tend to become charged in their trajectory through the ionosphere. However, it has been shown that this charging in the mesosphere is small (Lai, 2011).

A further unknown is the orientation of the instrument and the rocket with respect to the flight direction, i.e. the angle of attack. Our calculations and estimations have been made by assuming a normal incidence corresponding to a zero angle of attack and the best case scenario. However, an angle of attack can not be avoided during the flight of sounding rockets. When the rocket is tilted, the airflow and the flux of dust particles through the instrument are modified as well as the fragmentation process since the hypothesis of large angle of incidence is no longer valid, see Section 3.3. We expect that an angle of attack of a few degrees may lead to modifications that lie within the uncertainties due to model assumptions. When modelling the case of a larger angle of attack, it becomes necessary to include the lid, the other instruments located near the MESS instrument and the overall shape of the rocket payload which is out of the scope of the present work.

In summary, the discussed design of a sample collector combined with a funnel increases the amount of collected dust mass by up to a factor of 7 because it has a larger sampling area. There is a cut-off for small particles that will not be collected. At 85 km, MESS will collect particles larger than roughly 4 nm radius. The cut-off for small particles is lower in the absence of a funnel, but the sampling area would be reduced. Dust collection with MESS should aim toward the higher altitude of PMSE. Our simulations suggest that for the same amount of dust in the atmosphere, a significantly higher amount of particles reach the collecting area at an altitude of 85 km in comparison to 80 km. With increasing rocket velocity, the amount of background gas in the instrument increases and so does the deceleration of particles in the instrument.

Competing interests. The authors declare that they have no conflict of interest.

Appendix A: Calculation of the MSP fragments radii

According to the fragmentation modeling presented in Section 3.3, the mass conservation during the collision reads :

$$m_d = m_{1/2} + \sum_{f=1}^{n} m_f \tag{A1}$$

where $m_{1/2} = m_d/2$ corresponds to the mass of the large fragment that is supposed to be half of the mass of the incoming dust particle m_d and n the number of fragments constituted of MSP having a mass m_f. The composition of the dust particles gives :

$$m_d = \frac{4}{3}\pi \left(x_{MSP}\rho_{MSP} + x_{ice}\rho_{ice} \right) r_d^3 \tag{A2}$$

where $x_{MSP} = 3\%$ and $x_{ice} = 97\%$ respectively corresponds to the MSP and ice mass fraction of the dust particle. The small fragments are supposed to be small enough so that the ice they can contain sublimates immediately. This leads to :

$$\sum_{f=1}^{n} m_f = \frac{1}{2} x_{MSP} m_d \tag{A3}$$

according to the mass conservation and the dust particle composition. Assuming that all the fragments can be characterized by a radius r_f, one has by using Equation (A2) :

$$\sum_{f=1}^{n} r_f^3 = \bar{\rho} r_d^3 \tag{A4}$$

where it has been defined $\bar{\rho} = x_{MSP} \left(x_{MSP}\rho_{MSP} + x_{ice}\rho_{ice} \right) / 2\rho_{MSP}$. By writing this equation in terms of the the radius distribution of the MSP fragments $\omega(r)$, it becomes :

$$\sum_{r=r_{min}}^{r=r_{max}} \omega(r)r^3 = \bar{\rho} r_d^3 \tag{A5}$$

where r_{min} and $r_{max} = \bar{\rho}^{1/3} r_d$ represent the radius of the smallest and largest MSP fragments respectively. The largest MSP fragment corresponds to the MSP fragment existing if only one is created. If the number of MSP fragments is large enough so that the radius distribution can be assumed as continuous over the fragments radius, we end up with :

$$\sum_{r=r_{min}}^{r=r_{max}} \omega(r)r^3 = \frac{\int_{r_{min}}^{r_{max}} \omega(r)r^3 \, dr}{\int_{r_{min}}^{r_{max}} r^3 \, dr} \tag{A6}$$

Finally, based on previous works focusing on fragmentation size distribution (Antonsen et al., 2020), the radius distribution can be assumed to scale as $\omega(r) \propto r^{-3}$. The integrals in the previous equation can be calculated analytically leading to :

$$\sum_{r=r_{min}}^{r=r_{max}} \omega(r)r^3 = 2 \frac{r_{max}^2 r_{min}^2}{r_{max} + r_{min}} \tag{A7}$$

485   from which we defined :

$$r_{mean} = \left(2\frac{\bar{\rho}^{2/3}r_d^2 r_{min}^2}{\bar{\rho}^{1/3}r_d + r_{min}}\right)^{1/3} \tag{A8}$$

as the mean radius of the MSP fragments. The Figure A1 shows this mean radius as a function of the dust particle radius for the different and relevant values of r_{min}. It appears that $r_{mean} < 0.8$ nm for most the dust particles radii which means that the geometry of the MSP fragments has to be considered if one wants to track them.

Figure A1. Mean MSP fragment radius as a function of the dust particle radius for three different value of r_{min}.

490   **Appendix B: Airflows around the instrument for different altitudes and rocket speeds**

The Figures B1, B2, B3 and B4 show the densities and the streams of the background gas around the detector for 80 km, 82 km, 85 km and 90 km respectively and for the three different rocket speeds in each case. The airflow are very similar. For all cases, a bow shock is created on top of the funnel leading to an increase of the air density which becomes even more important in the instrument where it is the highest. These two increases of density will lead to a stronger drag force slowing down the 495   mesospheric dust particles. Increasing the rocket speed leads to higher densities and stronger bow shocks while and a higher altitude leads to smaller densities and a weaker bow shocks.
