13 Abstract

14 Forest wildfires in interior Alaska represent an important black carbon (BC) source for the Arctic and sub-Arctic. However,
15 BC observations in interior Alaska have not been sufficient to constrain the range of existing emissions. Here, we show our
16 observations of BC mass concentrations and carbon monoxide (CO) mixing ratios in the Poker Flat Research Range (65.12°
17 N, 147.43° W), located in central Alaska, since April 2016. The medians of the hourly BC mass concentration and CO mixing
18 ratio throughout the observation period were 13 ng m⁻³ and 124.7 ppb, respectively. Significant peaks in the BC mass
19 concentration and CO mixing ratio were observed at the same time, indicating influences from common sources. These BC
20 peaks coincided with peaks at other comparative sites in Alaska, indicating large BC emissions in interior Alaska. Source
21 estimation by FLEXPART-WRF confirmed a contribution of forest wildfires in Alaska when high BC mass concentrations
22 were observed. For these cases, we found a positive correlation ($r = 0.44$) between the observed BC/ Δ CO ratio and fire
23 radiative power (FRP) observed in Alaska and Canada. This finding indicates that the BC and CO emission ratio is controlled
24 by the intensity and time progress of forest wildfires and suggests the BC emission factor or/and inventory could be potentially
25 improved by FRP. We recommend that FRP be integrated into future bottom-up emission inventories to achieve a better
26 understanding of the dynamics of pollutants from frequently occurred forest wildfires under the rapidly changing climate in
27 the Arctic.

28

29 **1 Introduction**

30 Climate change in the Arctic region has been strongly accelerated compared to the global average (Box et al., 2019; Bonfils et
31 al., 2020). The near-surface air temperature increased between 1.8 and 3.1 °C in the period between 1971 and 2017 (Box et
32 al., 2019). This rapid temperature increase in the Arctic region caused significant decreases in the extent of sea ice (Aizawa et
33 al., 2021), resulting in the acceleration of Arctic warming (Cohen et al., 2014; Thackeray and Hall, 2019). Even if net CO₂
34 emission is controlled to zero until the end of the 21st century (SSP1-2.6 scenario), modelling studies predicted a more than
35 3.5 °C temperature increase (Cai et al., 2021; Xie et al., 2022). However, there are still some difficulties associated with climate
36 predictions based on global climate models because of the widespread use of different model hindcasts and forecasts (Overland
37 et al., 2014). Specifically, it is known that the Arctic amplification process causes a significant acceleration in Arctic warming,
38 but the process is highly complicated and is not sufficiently understood; this includes processes involved in aerosol
39 concentration changes and the deposition of black carbon (BC) on snow and ice surfaces (Cohen et al., 2014). Thus, more
40 research is required to understand Arctic climatic processes.

41 BC aerosols, which are formed by various incomplete combustion processes, such as fossil fuel and biomass burning (Bond et
42 al., 2013), strongly contribute to warming by absorbing solar radiation (Bond et al., 2013; IPCC, 2021). In addition, BC
43 deposited on snow and ice surfaces decreases surface albedo and contributes to snow melting and warming (Aoki et al., 2011;
44 Bond et al., 2013; Oshima et al., 2020; IPCC, 2021). BC can be transported over long distances (estimated lifetimes are 3–6
45 days globally (Wang et al., 2014; Lund et al., 2018)) and affect the climate and environment of remote regions, such as the
46 Arctic (Wang et al., 2011; Matsui et al., 2022). However, large discrepancies among model estimations for BC climate effects
47 on the Arctic remain (Gliß et al., 2021) because of a lack of observation data (IPCC, 2021) to constrain the models in terms of
48 dependence on emission inventories (Pan et al., 2020; Matsui et al., 2022) and/or removal rates (Ikeda et al., 2017; Lund et al.,
49 2018). For long-range transport from Asia to the Arctic, constraints on the major BC emissions from East Asia (Choi et al.,
50 2020; Kanaya et al., 2020), ship-based observations for BC transport to the Arctic (Taketani et al., 2016, 2022), evaluation of
51 the multimodel bias using these datasets (Whaley et al., 2022) and an improved understanding of transport mechanisms and
52 source attributions (Ikeda et al., 2017; Zhu et al., 2020) have been achieved. However, more observational constraints are
53 required for the characterization of BC emissions from boreal forest wildfires (Pan et al., 2020; AMAP, 2021).

54 Forest wildfires in the northern American region, especially those that occur in Alaska every summer (Picotte et al., 2020), are
55 one of the important BC emission sources in the Arctic and subarctic troposphere, and they result in depositional fluxes on
56 snow and ice over the Arctic and surrounding regions (Xu et al., 2017; AMAP, 2021; Williamson and Menounos, 2021; Matsui
57 et al., 2022). The occurrences of these forest wildfires in interior Alaska have increased since the 1980s (Sierra-Hernández et
58 al., 2022), and this increasing trend is predicted to continue (Hu et al., 2015; Box et al., 2019; AMAP, 2021); the emission of
59 aerosols, including BC from forest wildfires, is projected to severely affect the environment (Halofsky et al., 2020) and climate
60 (Schmale et al., 2021) in the future.

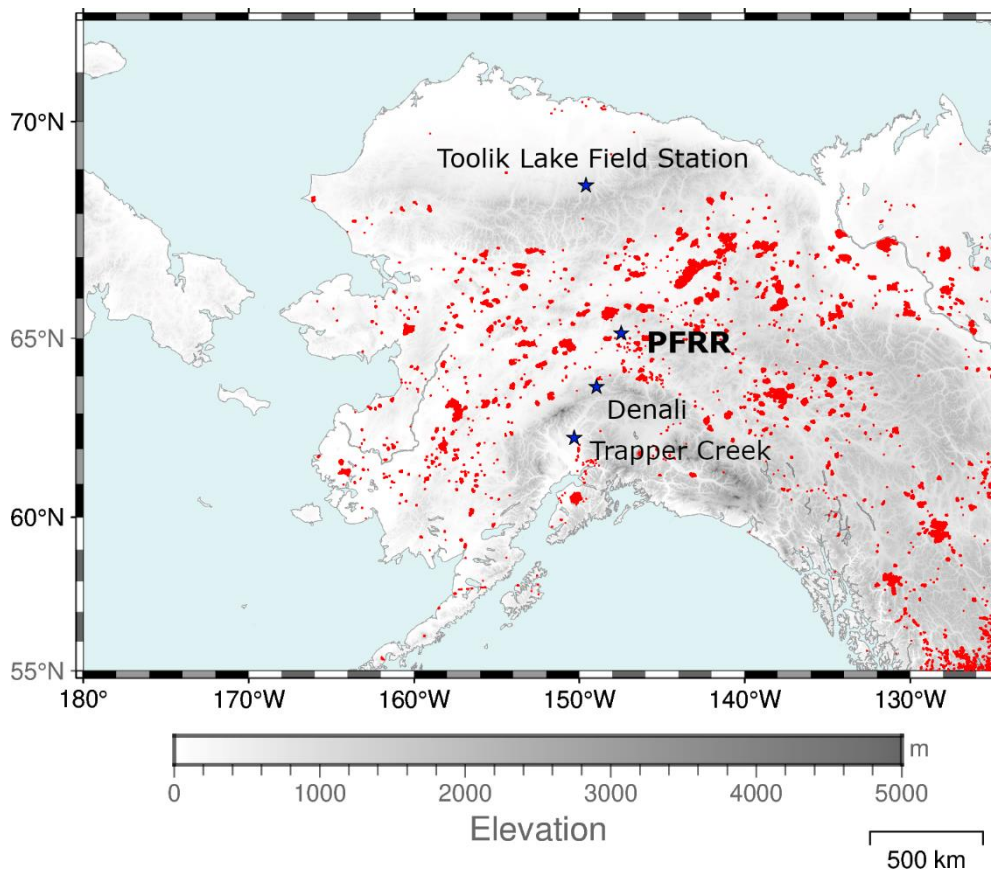

61 BC mass concentrations have long been observed in the atmosphere and snow at Utqiagvik (Barrow) (Eck et al., 2009; Garrett
62 et al., 2011; Mori et al., 2020), which is a high Arctic coastal tundra site. Campaign studies on atmospheric BC mass
63 concentrations were also conducted in interior Alaska using aircrafts (Kondo et al., 2011b; Bian et al., 2013; Creamean et al.,
64 2018). These campaign observations have provided an in-depth understanding of aerosol parameters related to wildfires.
65 However, separate long-term observations of BC mass concentrations are required to characterize annual trends and seasonality.
66 Fewer studies have reported atmospheric BC mass concentrations in interior and coastal Alaska (Polissar et al., 1996, 1998;
67 Eck et al., 2009; Mouteva et al., 2015) and the high Arctic coastal site (Alert, Canada) (Garrett et al., 2011). To understand the
68 long-term variations in BC mass concentration and their impacts on the climate and environment, more BC observation data
69 from interior Alaska are needed (AMAP, 2011). In this study, we aimed to investigate detailed variations in BC mass
70 concentration and its sources, with a focus on forest wildfires in interior Alaska, based on our monitoring of BC and CO at the
71 Poker Flat Research Range (PFRR), which is a University of Alaska Fairbanks (UAF) observational site in interior Alaska.
72

73 **2 Method**

74 **2.1 Observation site**

75 We conducted BC and CO monitoring at the PFRR (65.12° N, 147.43° W, 500 m a.s.l.) starting in April 2016. The PFRR is
76 located in the centre of interior Alaska (Figure 1), approximately 35 km northeast of Fairbanks. The PFRR is surrounded by a
77 predominant evergreen needled-leaved (black spruce; *Picea mariana*) forest with shrubland and herbaceous vegetation
78 (Buchhorn et al., 2020). In this study, BC and CO monitoring results were analysed between April 2016 and December 2020.
79

80

81 Figure 1. A map that shows the location of the PFRR and other sites compared in section 3.2 (Trapper Creek, Denali, and
82 Toolik Lake Field Station). All hot spots (larger than 0.3 (MW) in fire radiative power (FRP)) observed in the USA and Canada
83 by the Visible Infrared Imaging Radiometer Suite (VIIRS) between 2016 and 2020 are shown in red colour.

84

85 2.2 Measurements

86 BC was measured by a Continuous Soot Monitoring System (BCM3130, Kanomax, Japan) with a flow rate of 0.78 L min^{-1} at
87 standard temperature and pressure (STP; 273 K and 1013 hPa). Sample air was introduced using an approximately 10 m
88 conductive silicone tube (1/2" i.d.) from a height of 5.5 m above the ground. To minimize interferences from scattering particles,
89 coarse mode particles (approximately $>1.0 \mu\text{m}$), such as mineral dust, were removed by a PM1.0 cyclone (URG-2000-30ED,
90 URG, USA) operated with a small flow regulation pump ($\sim 4.5 \text{ L min}^{-1}$ at STP). In addition, to remove nonrefractory particles,
91 such as sulfate and organics, the sample air was heated to approximately $300 \text{ }^\circ\text{C}$ using a heated inlet before it was introduced
92 into the instrument. More details of the instrument are described elsewhere (Miyazaki et al., 2008; Kondo et al., 2009, 2011a).

93 One-minute observation data were averaged to hourly data as the primary data. The limit of detection value (LOD) for hourly
94 BC mass concentration was estimated to be 2 ng m^{-3} , which is the sum of average hourly data and $3\text{-}\sigma$ values using 18 hours
95 of particle-free air measurements.
96 The CO mixing ratio was measured by an infrared absorption photometer (48iTLE, Thermo Fisher Scientific, USA) with a
97 flow rate of 0.5 L min^{-1} . Sample air was introduced using an approximately 10 m PFA tube from a height of 5.5 m above the
98 ground. Internal zero measurements were carried out for 20 minutes every hour, and the CO mixing ratio was estimated from
99 the difference in absorption between the sample and the zero measurements. Span gas (0.99 ppm CO/N₂, Taiyo-Nissan, Tokyo,
100 Japan) calibration was performed in April 2016. We calculated ΔCO as the enhancement in CO from background levels (14
101 days moving 5-percentile values of observation results). Cases with hourly ΔCO larger than $3\text{-}\sigma$ (13.9 ppb in median, $1\text{-}\sigma$ was
102 derived from zero mode measurements before and after the hourly ambient air observations) were only used for analysis.
103

104 **2.3 Model calculation**

105 The FLEXPART (FLEXible PARTicle dispersion model)-WRF (Weather Research & Forecast) model was used in backward
106 mode to characterize the source areas and sectors for the sampled air masses at the PFRR. FLEXPART-WRF version 3.3
107 (Brioude et al., 2013) and WRF version 4.4 (Skamarock et al., 2019) were employed for this study. The FLEXPART-WRF
108 model was driven by mass weighted wind fields and perturbation within the PBL calculated by WRF, which covers the
109 Northern Hemisphere with a 45-km horizontal resolution. The ERA5 global reanalysis (Hersbach et al., 2020) was used as the
110 initial and lateral boundary conditions of WRF, and the meteorological field of WRF was also nudged to ERA5 with e-folding
111 times of 3 hours and 12 hours for wind fields and temperature, respectively. Wet deposition is the major removal process for
112 BC, and the deposition process in FLEXPART version 10 (Grythe et al., 2017) was applied to the FLEXPART-WRF model
113 and was used in this study, with values of 10.0, 1.0, 0.9, and 0.1 employed as the collection efficiencies for wet deposition by
114 rain and snow and the activation efficiencies of cloud condensation nuclei (CCN) and ice nuclei (IN) (C_{rain} , C_{snow} , CCN_{eff} , and
115 IN_{eff}), respectively. The FLEXPART-WRF calculation was conducted every 6 hours from April 2016 to December 2020. For
116 each simulation, 40000 particles were released at 0.5×0.5 degrees (horizontally) and 200 m AGL (vertically) centred at the
117 PFRR. The particles were tracked for 20 days at 6-hour intervals. The primary output of the FLEXPART-WRF backward
118 calculations was the potential emission sensitivity (PES), which expresses the residence time of particles at a given location
119 and is used to characterize the transport pathways of the sampled air masses. The concentration of BC was estimated by
120 multiplying PES and emissions based on a procedure reported by Sauvage et al. (2017). ECLIPSE (Evaluating the Climate
121 and Air Quality Impacts of Short-Lived Pollutants) version 6b (Klimont et al., 2017) and GFED (Global Fire Emission
122 Database) version 4.1 (Daily) (van der Werf et al., 2014) were used as the anthropogenic and biomass burning emissions,
123 respectively. Note that the Chinese BC emissions from ECLIPSE version 6b with the monthly profile of version 5 are certified

124 with downwind atmospheric BC observations (Kanaya et al., 2020), while other bottom-up inventories might result in a factor
125 of ~2 overestimation. The PES fields were calculated with a horizontal resolution of 0.5×0.5 degrees. The contribution of
126 particles within 100 m from the surface was considered for the calculation of PES for anthropogenic emissions. The plume
127 height of the GFAS (Global Fire Assimilation System) (Di Giuseppe et al., 2017) was also used for the estimation of the
128 injection height for biomass burning emissions. The fractional contribution of anthropogenic emissions was considered using
129 eight sectors in the ECLIPSE emission, and the anthropogenic and biomass burning emissions were divided into eight regions.
130 The mean age of BC was also estimated by the mean lag time between release and observed time weighted by the amount of
131 emission at each time period within the 20-day backward calculations.

132

133 **2.4 Analysis of the effect of forest wildfire on the BC mass concentration at the PFRR**

134 We characterized the observed BC/ Δ CO ratios, which are known to be valuable indicators of emission sources and combustion
135 conditions (Kondo et al., 2011b; Pan et al., 2017; Selimovic et al., 2019), in terms of fire radiative power (FRP), which accounts
136 for forest fire intensity. To do this, we compared the BC/ Δ CO ratio in high BC mass concentration cases observed in summer
137 and FRP observed by the Visible Infrared Imaging Radiometer Suite (VIIR) on the Suomi NPP satellite. Airmasses were traced
138 for 4 days at the most using the Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPPLIT; Stein et al., 2015))
139 with GDAS1 meteorological datasets (3 h archived $1^\circ \times 1^\circ$ Global Data Assimilation System) from the National Centers for
140 Environmental Prediction (<http://ready.arl.noaa.gov/gdas1.php>; accessed on 2 November 2023). The calculation started from
141 500 m AGL at the PFRR site, and fire spots were searched along with the trajectories.

142 The BC/ Δ CO ratio is also affected by atmospheric processes (Kanaya et al., 2016; Choi et al., 2020), as only BC is lost via
143 wet removal processes. To extract observation results that were not affected by wet removal processes, we used accumulated
144 precipitation along the trajectory (APT) as an indicator of wet removal processes. Previous studies showed that the BC/ Δ CO
145 ratio can be significantly changed when APT is larger than 1 mm (Choi et al., 2020; Kanaya et al., 2016; Kondo et al., 2011b).
146 Therefore, the duration for the accumulation of fire spots was shortened when APT reached 1 mm or when the trajectory
147 reached ground level. Rectangles were defined with $\pm 0.5^\circ$ in the longitudinal direction and $\pm 0.25^\circ$ in the latitudinal direction
148 centring around hourly air mass positions. Then, the FRP and the number of hot spots were accumulated for individual
149 rectangles over the duration of the trajectories. Finally, the total accumulated FRP (\sum FRP) was divided by the detected total
150 spot number to yield an index describing the conditions of fires affecting the observed airmasses. As hot spot datasets, VIIRS
151 375 m (VNP14IMG_TML_NRT) archived datasets from the Fire Information for Resource Management System (FIRMS)
152 website (<https://earthdata.nasa.gov/firms>; accessed on 2 November 2023) were used in this study. The selected confidence
153 levels were ‘nominal’ or ‘high’, and the selected type attributed to thermal anomalies was ‘presumed vegetation fire’. In

154 addition, we used FRP values greater than 0.3 MW because hot spots smaller than 0.3 MW included outliers (Figure S1). Only
155 hot spots that were observed within the previous 24 hours were considered.

156

157 **3 Results and discussion**

158 **3.1 Time series of observed BC and CO concentrations**

159 The time series of BC mass concentration and CO mixing ratio are shown in Figure 2, and those of annual median, 10th, and
160 90th percentile values are summarized in Table 1. The hourly median BC mass concentration and 10th and 90th percentile
161 values throughout the observation period were 13, 3, and 56 ng m⁻³, respectively. No significant increase in annual median BC
162 mass concentration was observed (Table 1). Abrupt peaks (up to 5540 ng m⁻³) were occasionally observed during summer.
163 This seasonality differed from BC observational reports at Utqiagvik (Barrow), which showed BC mass concentration over
164 the long term using the same instrument (BCM3130) employed in this study (Sinha et al., 2017; Mori et al., 2020). The previous
165 report showed that the BC mass concentration increases in winter and early spring and decreases in summer. These differences
166 are possibly caused by a difference in location. The PFRR is located in interior Alaska, while Barrow is located on the
167 northernmost coast of Alaska, suggesting that large BC emissions occurred around the PFRR.

168 The median, 10th, and 90th percentiles of hourly CO mixing ratios throughout the observation period were 124.7, 99.0, and
169 148.2 ppb, respectively. Similar to BC, significant increases in the annual median CO mixing ratio were not observed, but
170 contrary to the BC mass concentration, the CO mixing ratio showed clear seasonal variation, high in spring (between February
171 and April, 143.5 ppb in the median) and low in summer (July and August, 103.3 ppb in the median) (Figure 2(b)). These
172 observed CO mixing ratios and seasonal variations were consistent with the aircraft observation results (less than 500 m AGL
173 above the PFRR) provided by the NOAA Global Monitoring Laboratory (<https://doi.org/10.15138/39HR-9N34>; accessed on
174 2 November 2023) (Figure S2) and previous studies that reported the CO mixing ratio at the PFRR (Kasai et al., 2005;
175 Yurganov et al., 1998). In summer, CO peaks coincident with BC mass concentration were found, suggesting a common
176 emission source for both BC and CO.

177

178 Table 1. Annual summary of the observed hourly BC mass concentration and CO mixing ratio at the PFRR.

Year	BC (ng m^{-3})			CO (ppb)		
	Median	10th percentile	90th percentile	Median	10th percentile	90th percentile
2016 ^a	11	2	49	109.7	93.1	130.3
2017	15	3	65	128.2	100.5	148.8
2018	14	3	53	118.2	93.3	149.4
2019	15	3	63	128.4	113.1	150.8
2020	13	3	50	131.3	107.5	150.6

179 ^a Observations started on 28 April 2016.

180

181

182 Figure 2. Time series of (a) BC mass concentration and (b) CO mixing ratio. Grey lines, blue points, and red triangles show
 183 hourly, daily, and monthly averages, respectively.

184

185 3.2 Comparisons with other observation sites

186 We compared the BC observation results from the PFRR to those from other Alaskan sites (Table 2 and Figure S3), i.e.,
187 Trapper Creek (TRCR), Denali (DENA), and Toolik Lake Field Station (TOOL), using datasets for 24-hour filter samples
188 collected every three days. The datasets were from the thermal/optical reflectance method at DENA, TRCR, and TOOL
189 (<http://views.cira.colostate.edu/fed/QueryWizard/>; accessed on 2 November 2023). A systematic bias might be present in terms
190 of the methods used, but it is most likely within a factor of 2 from the actual conditions based on comparisons with recent data
191 at various sites (Miyazaki et al., 2008; Kondo et al., 2009; Kanaya et al., 2008; Kondo et al., 2011a; Ohata et al., 2021; Sinha
192 et al., 2017). For the BC mass concentration observed at TRCR, DENA, and TOOL, datasets flagged V0 (valid value) were
193 selected.

194 The BC mass concentration peaks were nearly coincided for the PFRR, DENA, TRCR, and TOOL (Figure S3). The median
195 and maximum daily BC mass concentrations observed at each site are summarized in Table 2. The median BC mass
196 concentrations at DENA, TRCR, and TOOL were larger than those at the PFRR by 6–19 ng m⁻³ (Table 2), but the significance
197 of the difference is unclear considering methodological differences and associated uncertainties (precision). Here, the
198 uncertainties of the thermal/optical reflectance method varied between 12 and 14 ng m⁻³ in median values during the whole
199 observation period. Note that our BC observation, which had a better LOD (2 ng m⁻³) and higher temporal resolution (1 hour),
200 could provide more reliable data in this low range. On the other hand, the maximum BC mass concentrations were higher at
201 the PFRR within the period with common BC peaks than at TRCR and TOOL but similar at DENA (Table 2). This indicates
202 that significant BC emissions in central Alaska were better captured at the PFRR than at other observation sites. We will
203 discuss source and emission ratio characterization in Sections 3.4 and 3.5 by fully utilizing the superior temporal resolution
204 and accuracy of our observations.

205

206 Table 2. Summary of site locations and measurement results at PFRR (this study), TRCR, DENA, and TOOL.

Site	Latitude (°N)	Longitude (°W)	Altitude (m a.s.l)	Daily BC mass concentration (ng m ⁻³)	
				Median	Maximum
PFRR ^a	65.12	147.43	500	18	920
TRCR	62.32	150.32	155	37	570
DENA	63.73	148.97	658	24	1044
TOOL ^b	68.64	149.61	740	28	643

207 ^aData were selected from the same date at PFRR, TRCR, and DENA.

208 ^b Observations started on 13 November 2018.

209

210 **3.3 Comparison of observation and model simulations and possible BC sources**

211 Figure 3(a) shows a time series of 6-hour averages of the observation data and 6-hourly BC mass concentrations estimated by
212 FLEXPART-WRF simulations. FLEXPART-WRF could capture the high BC mass concentration peaks (Figure 3(a)) with a
213 correlation coefficient of 0.7 (Figure S4). The median of the simulated/observed ratio (observation data > LOD in this case)
214 was 1.0 for the whole observation period, indicating good agreement between the model simulation and observations.

215 The source region and source sector contributions derived from the FLEXPART-WRF simulation are shown in Figure 3(b)
216 and (c). Source regions were classified into 8 categories, i.e., Europe, Central Asia, Russia, East Asia, Canada, Alaska, USA
217 (excluding Alaska), and Others (Figure 3(b)). Source sectors were classified into 9 categories, i.e., biomass burning, ship, gas
218 flaring, waste incineration, transport, industry, energy, domestic, and agriculture (Figure 3(c)). The BC source sectors and
219 regions varied significantly according to the season (Figure 3(b) and (c)). In the warm season (between May and September),
220 the possible BC source regions were Russia (3.6–74% in the 10–90 percentile) and Alaska (12–85% in the 10–90 percentile)
221 (Figure 3(b)), and the possible source sector was estimated to be biomass burning (8.1–88% in the 10–90 percentile) (Figure
222 3(c)), especially when BC mass concentration was high, suggesting that BC contributions from biomass burning that occurred
223 in Russia and Alaska are both significant for BC mass concentrations at the PFRR. As snow cover disappears from the ground
224 and the atmospheric conditions become drier, forest wildfires caused by lightning increase in these warm seasons (Reap, 1991;
225 Kaplan and Lau, 2021), resulting in increases in BC emissions from biomass burning (AMAP, 2021). We will focus on these
226 high BC mass concentration cases from Alaska and discuss the relationship between forest wildfire intensity and the BC/ Δ CO
227 ratio in the following section.

228 On the other hand, in the cold seasons (between October and April), the domestic (24–48% in the 10–90 percentile) and
229 transport sectors (25–48% in the 10–90 percentile) were estimated to be possible dominant BC source sectors (Figure 3(c)).
230 The dominant source region was Alaska (19–88% in the 10–90 percentile), and occasionally, Russia (0.89–31% in the 10–90
231 percentile) and East Asia (1.2–41% in the 10–90 percentile) were significant (Figure 3(b)).

232

233

234 Figure 3. Time series of (a) BC mass concentrations from observations at the PFRR (6-hour average) and FLEXPART-WRF
235 estimates (6 hours). Black circles and red triangles show the observed and simulated BC mass concentrations, respectively.
236 Time series of simulated 6-hourly (b) contributions from BC source regions and (c) contributions from BC source sectors
237 estimated by FLEXPART-WRF simulation. Individual colours show the source regions and sectors.

238

239 3.4 Biomass burning contribution for high BC concentration cases

240 Hereafter, we focus on high BC mass concentration cases at the PFRR (647 hours in total), which were selected with the 98
241 percentile value (171 ng m^{-3}) as the threshold for the hourly BC mass concentration. The cumulative BC mass concentration
242 observed in these high BC mass concentration cases accounted for 5.7–43% of the annual BC mass concentration, although
243 the duration of these periods was very short (17–187 hours in a year). Most of these high BC concentration cases
244 (approximately 90%) were observed in warm seasons (between June and September) and were related to forest wildfires in
245 Alaska. The median CO mixing ratio for the high BC concentration cases (174.7 ppb) was also significantly higher than that
246 in other periods (124.7 ppb), suggesting that both BC and CO were emitted from forest wildfires (see Section 3.3).

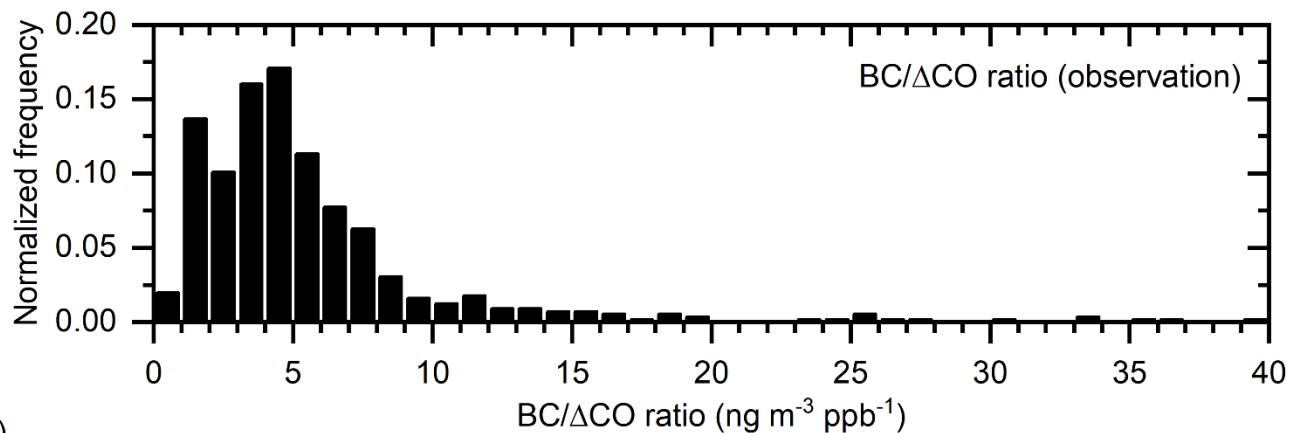

247 The normalized frequency distribution of the BC/ Δ CO ratio for the high BC mass concentration cases is shown in Figure 4(a).
248 The median, 10th, and 90th percentile values of the BC/ Δ CO ratio during these periods were 4.7, 1.8, and 18 ng m⁻³ ppb⁻¹,
249 respectively. These observed BC/ Δ CO ratios in the high BC mass concentration cases were in the same range or sometimes
250 higher than those in previous studies that reported the BC/ Δ CO ratios from boreal forest wildfire emissions in Canada (Kondo
251 et al., 2011b) and Siberia (Paris et al., 2009; Chi et al., 2013; Vasileva et al., 2017). Increases in biomass burning derived
252 BC/ Δ CO ratios with combustion efficiency were suggested from a boreal forest wildfire study (Kondo et al., 2011b) and from
253 laboratory-scale burning experiments of crop residues (Pan et al., 2017); however, in-depth studies examining variabilities in
254 BC/ Δ CO ratios based on long-term, near-forest observations have not been conducted. To consider the possibility that
255 combustion conditions (flaming and smouldering) primarily control the BC/ Δ CO ratio, we will investigate the relationship
256 between the BC/ Δ CO ratio and forest wildfire intensity in the following section.

257 The medians of the contributions of biomass burning and the mean age of BC estimated by the FLEXPART-WRF simulation
258 in these high BC mass concentration cases were higher and shorter (95.5% and 2.6 days) than those in other periods (7.6% and
259 6.9 days) (Figure 4(b) and (c)), indicating a strong contribution of BC from neighbouring forest wildfires. We also calculated
260 the 6-hourly mass-weighted biomass burning contributions from individual source regions (5 categories based on Figure 3(c),
261 Canada and USA are categorized as North America and East Asia, Central Asia, and Europe are included in Others) to the BC
262 mass concentrations at the PFRR (Figure 5). As a result, we found that large peaks, such as those observed between June and
263 August in 2017, 2018, and 2019, coincided well with the peaks of BC contributions from forest wildfires in Alaska. These
264 results confirmed that the observed high BC mass concentration cases were primarily affected by local forest wildfires in
265 Alaska. These peaks were widely observed in Alaska (Section 3.2) and imply a large impact of local forest wildfires on BC
266 mass concentration in this region. However, when these high BC mass concentration cases were selected, the median of the
267 simulated/observed ratio was 0.30, indicating underestimation in the model simulation (possibly due to insufficient spatial
268 resolution for neighbouring forest wildfires and difficulties in representing the vertical profiles of BC emissions) or/and in
269 emission inventories in the high BC mass concentration cases. Several studies have indicated that differences in different
270 inventories cause large uncertainties in model estimates of BC emissions, atmospheric concentrations, and radiative impacts,
271 especially in boreal North America (Carter et al., 2020; Pan et al., 2020). The impact of different inventories on model estimates
272 will be discussed in the future.

275 Figure 4. (a) A histogram of the observed BC/ Δ CO ratio at the PFRR in high BC mass concentration cases. Histograms of the
276 (b) contributions of biomass burning and (c) mean age of BC simulated with the FLEXPART-WRF model in high BC
277 concentration cases and other cases. Black and red bars used in (b) and (c) indicate high BC concentration cases and other
278 cases, respectively. Hourly results are shown for the observed BC/ Δ CO ratio (a), and 6-hourly results are shown for the
279 FLEXPART-WRF simulation ((b) and (c)).
280

281
282 Figure 5. A stacked graph of the 6-hourly mass-weighted biomass burning contributions for BC mass concentration at the
283 PFRR estimated with FLEXPART-WRF simulations. Grey bars indicate the total BC mass concentration for all sources, and
284 the colours show the individual source regions.
285

286 3.5 Relationship between the BC/ Δ CO ratio and FRP

287 In the previous section, we showed that most high BC mass concentration cases were related to forest wildfires in Alaska. We
288 selected 406 hourly cases between June and September from the data selected in Section 3.4 as high BC cases from forest
289 wildfires and chose 184 cases of hourly BC observations results from forest wildfires detected in Alaska and western Canada
290 by back trajectory analysis. Note that we also confirmed that no back trajectories could suggest forest wildfires in other seasons.
291 We found a positive correlation ($r = 0.44$, $p < 0.0001$, $n = 184$, Figure 6) between the BC/ Δ CO ratio and \sum FRP/point values,
292 and its slope and intercept with standard errors were $0.11 (\pm 0.02)$ and $2.5 (\pm 0.22)$, respectively (Figure 6). This positive
293 correlation between the BC/ Δ CO ratio and \sum FRP/point values, represented for the first time to our knowledge, is qualitatively
294 consistent with previous studies that showed that high combustion efficiency (larger than 0.9 in modified combustion
295 efficiency value (MCE)) increased BC/ Δ CO ratios (Selimovic et al., 2019; Kondo et al., 2011b; Pan et al., 2017), which is
296 related to the fact that the BC production process is mostly related to the flaming process (high MCE), while that of CO is
297 related to the smouldering process (low MCE). Although MCE and FRP are different parameters, both parameters indicate
298 combustion conditions and have a strong correlation (Wiggins et al., 2020). Therefore, for the first time, we report a robust
299 correlation between the BC/ Δ CO ratio and FRP as a combustion condition indicator. The wide range of BC/ Δ CO ratios reported
300 from boreal forest wildfires, from $1.7\text{--}3.4 \text{ ng m}^{-3} \text{ ppb}^{-1}$ (Kondo et al., 2011b) to $6.1\text{--}6.3 \text{ ng m}^{-3} \text{ ppb}^{-1}$ (Vasileva et al., 2017),
301 could be better explained when the index introduced here (\sum FRP/point) is considered. This clear relationship should be taken
302 into account when constructing future emission inventories from boreal forest wildfires.

303 A positive correlation was found after optimizing the spatial window size ($\pm 0.5^\circ$ in the longitudinal direction and $\pm 0.25^\circ$ in
304 the latitudinal direction), in which hot spots were taken into account for each hour along the trajectory (from -96 to 0 hours),
305 and the associated time window was used to determine coincident fires that affected the observations (from -24 to 0 hours).
306 The remaining scatter might have arisen from differences in the detection of hot spots in the presence of clouds (Li et al., 2018).
307 To overcome shortcomings in hot spot detection, improvements in the frequency of hot spot scanning should be made, for
308 example, via the use of MODerate Resolution Imaging Spectroradiometer (MODIS) combined with VIIRS observations; it
309 should be noted, however, that there is a significant bias in FRP observations between MODIS and VIIRS, especially for boreal
310 forests (Li et al., 2018). Improvements in the accuracy and consistency of FRP analysis between multiple satellite observations
311 can facilitate a more in-depth understanding of the relationship between FRP and the BC/ Δ CO ratio.

312 The simulated/observed ratios in high BC mass concentration cases were significantly low (0.30, Section 3.3), contrary to the
313 good agreement observed in overall cases (1.0, Section 3.3). The BC/ Δ CO ratios in commonly used emission inventories are
314 $4.4 \text{ ng m}^{-3} \text{ ppb}^{-1}$ for GFED4s (van der Werf et al., 2017) and $4.9 \text{ ng m}^{-3} \text{ ppb}^{-1}$ for Andreae (2019) and are in a range similar to
315 that of our median BC/ Δ CO ratio. However, our observed BC/ Δ CO ratios in high BC concentration cases for forest wildfires
316 had a broad range between 1.7 and $7.3 \text{ ng m}^{-3} \text{ ppb}^{-1}$ at the 10 and 90 percentiles (median was $4.2 \text{ ng m}^{-3} \text{ ppb}^{-1}$), respectively,
317 related to the \sum FRP/point values. This indicates that the BC emission factors from biomass burning could vary depending on

318 the FRP. Our findings suggest the potential for improving BC emission inventories and/or emission factors by using FRP. The
319 frequency of boreal forest fires may increase in the future (Box et al., 2019; Hu et al., 2015); as a result, their impact on climate
320 and air quality might become more severe in Alaska and the Arctic (Kim et al., 2005; Schmale et al., 2018; Stohl et al., 2006).
321 Our long-term observations of BC and CO at an hourly temporal resolution in the interior of Alaska provide unique information
322 to test model simulations and emission inventories relevant to the climate and air quality of the Arctic.
323

324
325 Figure 6. Correlation between the BC/ΔCO ratio in the high BC mass concentration cases observed at the PFRR and
326 ΣFRP/point values. The linear regression curve is shown by a red line.
327

328 4 Conclusion

329 We showed key features of the BC and CO concentrations observed at the PFRR in interior Alaska since 2016 in this paper.
330 The annual medians of the BC mass concentration and CO mixing ratio were 11–15 ng m⁻³ and 109.7–131.3 ppb, respectively.
331 Large and short-term increases in BC mass concentrations were sometimes observed between June and September. A clear
332 seasonal variation was observed in the CO mixing ratio, which was high in spring (between February and April, 143.5 ppb in
333 the median) and low in summer (July and August, 103.3 ppb in the median). The CO mixing ratio coincided with the high BC
334 mass concentration peaks, suggesting a strong contribution from forest wildfires to BC and CO concentrations.

335 The BC mass concentrations observed at other sites in Alaska, i.e., DENA, TRCR, and TOOL, were compared with our results.
336 The annual median BC mass concentrations at the PFRR were lower than those at TRCR, DENA, and TOOL, but coinciding
337 BC mass concentration peaks were found at these observation sites. In these high BC mass concentration cases, BC mass
338 concentrations at the PFRR were larger than those at TRCR and TOOL but similar at DENA, indicating that significant BC
339 emissions from forest wildfires occurred in interior Alaska and affected broad areas in Alaska.

340 The dominance of forest wildfires in Alaska as a major cause of high BC mass concentration was also supported by the model
341 simulations. We simulated BC mass concentration using the FLEXPART-WRF model and compared the simulations with the
342 observation results. The model simulation could capture observational results ($r = 0.70$) in which the median
343 simulated/observed ratio was 1.0. The estimated BC source sectors and regions were biomass burning from Russia and Alaska
344 between June and September, while those for other periods were domestic sources and transport and were mainly from Alaska.
345 When we focused on high BC mass concentration cases (greater than 98 percentile values), we found that forest wildfires
346 occurring in Alaska were the dominant source of BC in those cases from the model simulation results. The mean ages of BC
347 and biomass burning contributions in these high BC mass concentration cases estimated by FLEXPART-WRF were 2.6 days
348 and 95.5%, respectively, relatively shorter and higher than those in other cases (6.9 days and 7.6%, respectively). The peaks
349 of the calculated biomass burning contributions from Alaska to BC mass concentrations at the PFRR coincided well with
350 observed and simulated peaks in high BC mass concentration cases, suggesting that the forest wildfires that occurred around
351 the PFRR are significant.

352 The median observed BC/ Δ CO ratio in high BC mass concentration cases related to forest wildfires was 4.2 ng m⁻³ ppb⁻¹ and
353 was in the same range as that in previous studies reporting the BC/ Δ CO ratio of boreal forest wildfire emissions. Finally, we
354 tracked air mass origin for 4 days using the HYSPLIT model in these cases and investigated the relationship between the
355 observed BC/ Δ CO ratio and FRP, which was normalized by the number of hot spots (points) observed by VIIRS. A positive
356 correlation was found between these parameters ($r = 0.44$), with a slope and intercept of 0.11 (± 0.02) and 2.5 (± 0.22),
357 respectively. For the first time, the properties of the BC/ Δ CO ratio from boreal forest wildfires were systematically
358 characterized in terms of FRP, suggesting the potential to improve emission inventories and/or emission factors by using FRP.

359

360 **Data availability**

361 The BC and CO observation results at the PFRR site are available from the corresponding author upon request. We used public
362 data for BC observation results at Denali, Trapper Creek, and Toolik Lake Field Station
363 (<http://views.cira.colostate.edu/fed/QueryWizard/>).

364

365 **Supplement**

366 The supplement related to this article is available online at <https://doi.org/xxxxxxx>.

367

368 **Author contributions**

369 TK, FT, CZ, YK, and YK conducted and recorded observations for BC and CO at the PFRR site. MT conducted the
370 FLEXPART-WRF model simulations. YK assisted in the fieldwork at the PFRR site. TK, FT, MP, and YK summarized the
371 observation results, and TK wrote the first draft with MT. All authors contributed to the discussion and writing of the
372 manuscript.
