Abstract. We investigated the temporal variability of the surface velocity of thirty glaciers in the Mont Blanc massif (European Alps). We calculated the monthly velocity between 2016 and 2024 using digital image correlation of Sentinel-2 optical imagery. The main objectives of the study are: (i) to characterise the variability of the velocity fields of such glaciers, referring both to their temporal (seasonal and interannual) and spatial variations; (ii) to investigate relationships between the morphology of glaciers and their kinematics. We measured monthly velocities varying from 12.7 m yr^{-1} to 487.4 m yr^{-1}. We observed an overall decrease in the velocity between 2016 and 2019 and an unexpected rise in 2020-2022, especially visible in most glaciers on the southern side of the massif. Considering the whole period, half glaciers showed positive acceleration, which reached values >4 m yr^{-2} in three glaciers. In general, the velocity linear trend is higher in the cold season. We found that smaller glaciers have a more pronounced seasonality, with winter-summer velocity differences of 50-100%. Finally, in 2016, 2018 and 2022, we observed an exceptionally high winter-summer velocity difference in the 0.3 km^2-wide Charpoua Glacier, when summer velocities increased by one order of magnitude.

1 Introduction

Glacier flow was one of the early drivers of glaciological interest and research since it was first studied. Its understanding and modelling evolved via the observations and findings of Somigliana in the early 1900s, Glen's laboratory experiments (Glen, 1952), followed by the interpretations of Nye (Nye, 1952) during the 1950s, to cite just a few, and have explained that the two main mechanisms of glacier flow rely on ice deformation and basal sliding. However, the motion of Alpine glaciers is largely related to basal sliding (Willis, 1995). Because continuous monitoring of sliding velocities in the field is extremely difficult and rarely achieved (Vincent and Moreau, 2016), measuring surface flow velocities can be used as a strong alternative approach. Nonetheless, the continuous monitoring of surface velocities of Alpine glaciers is complex on specific study sites, and very rarely has it been performed on a spatially distributed scale.

The flow of glaciers generally depends on a variety of physical parameters. The main physical parameter influencing ice velocity is the ice thickness (Jiskoot 2011), which is indirectly related to the glacier trend in mass balance as it determines an evolution towards an increase or decrease in glacier thickness. Other parameters that influence ice flow are glacier surface slope, ice properties (temperature, density), bedrock conditions (hard, soft, frozen or thawed ice-bed contact), topography, the glacier's terminal area type (land, sea, ice shelf), but also air temperature and precipitation and their seasonality that influences subglacial hydrology (Jiskoot, 2011; Humbert et al., 2005; Cuffey and Paterson, 2010; Benn and Evans, 2014; Bindschadler, 1983).

The analysis of glacier surface velocity has a wide array of applications: it is a powerful climate change indicator (Beniston et al., 2018) and also an important input data for ice thickness models (Millan et al., 2022; Samsonov et al., 2021) and mass balance models that can also approximate sea-level rise contribution by glaciers (Zekollari et al., 2019). In the field of glacial hazards, it is used as an indicator for the detection of glacier surges with space-borne measurements (Kamb, 1987; Kääb et al., 2021), and accelerations that can result in glacier-related hazards using ground-based sensors (Pralong and Funk, 2006; Giordan et al., 2020). Measurements of the surface velocity of glaciers can be achieved by terrestrial techniques (Dematteis et al., 2021) such as topographic measurements of stakes or fixed points on the glacier (Stocker-Waldhuber et al., 2019), GNSS repeated or continuous surveys (Einarsson et al., 2016), digital image correlation of oblique photographs (Evans, 2000; Ahn and Box, 2010) and terrestrial radar interferometry (Luzi et al., 2007; Allstadt et al., 2015). Considering remote sensing solutions, glacier surface velocities can be measured by different aerial and space-borne sensors. In recent decades, public access to satellite optical and radar data (especially from Sentinel and Landsat constellation satellites), as well as the commercial availability of very high resolution (30 cm to 3 m ground resolution) optical imagery (Deilami and Hashim, 2011) and radar data (Rankl et al., 2014), have given great input to glaciological research. In particular, Sentinel-2 optical imagery is widely used in glaciological studies and has been tested in the literature on various environments (Paul et al., 2016; Millan et al., 2019). Nowadays, the automated processing of ice velocity maps with global coverage from satellite imagery is freely available online from web-based platforms such as the GoLIVE datasets (Fahnestock et al., 2016), the ITS_LIVE data portal (https://its-live.jpl.nasa.gov/) or the FAU-Glacier portal (RETREAT, 2021 Ice surface velocities derived from Sentinel-1, Version 1; http://retreat.geographie.uni-erlangen.de/search). The availability of such datasets is very relevant globally, but their application to Alpine glaciers is limited due to their relatively coarse spatial resolution - e.g., 300x300 m (GoLIVE), 120x120 m (ITS_LIVE) - which can provide data on just a few of the largest Alpine glaciers. Moreover, for the ITS_LIVE dataset, the velocity maps are calculated at a resolution of 240 m and statistically downscaled to 120 m, which has major limitations for small mountain glaciers. The adopted resolution is a trade-off between computational effort and the best resolution of the output that must cope with the global availability of the analysis. Limiting the processing of images at a regional scale decreases the computational effort compared to global products and makes it easier to obtain higher resolution velocity maps that allow Alpine glaciers to be investigated (Berthier et al., 2005), even though very small glaciers (i.e., width <250 m) are still difficult to analyse (Millan et al., 2019).

Recent studies using different techniques have measured spatio-temporal variations of ice velocity on large valley glaciers in an Alpine environment, like the Argentière (Vincent and Moreau, 2016) and Miage glaciers (Fyffe, 2012) as well as on steep glacier snouts (e.g., Planpincieux Glacier by (Giordan et al., 2020) but a spatially distributed analysis at a regional scale of the variations of velocities over glaciers with different morphological characteristics is, as of today, still lacking in the Alpine environment. (Millan et al., 2022) calculated the velocities of world glaciers, but they considered a specific analysis period (2017-2018) not considering velocity variations in time, while (Rabatel et al., 2023a) performed a comparison between yearly aggregated velocity maps between 2015 and 2021 over three different alpine massifs.

Other studies focused on long-term glacier velocity records in the Mont Blanc Massif: at the Argentière Glacier (Vincent and Moreau, 2016) and Miage Glacier (Smiraglia et al., 2000; Fyffe, 2012). At Argentière Glacier, a unique series of continuous basal sliding measurements existed from 1997 and was still active as of 2022 (Vincent et al., 2022; Nanni et al., 2020). The whole series indicates a general decrease in basal sliding velocities (Vincent and Moreau, 2016) since the end of the 1990s. This general decrease has shown a strong correlation with the negative mass balance of the glacier, which agrees with the conceptual model from Span and Kuhn (Span and Kuhn, 2003), in which the glacier flow variation is primarily driven by the mass balance of the accumulation area in the previous year (as it determines glacier thickness variations). Seasonal field surveys conducted at Argentière Glacier from the 1950s document a longer data series than the basal sliding measurements started in 1997, and an increase in surface velocities was measured during a period of positive mass balances in the early 1980s

78 (Vincent and Moreau, 2016). The same trend was highlighted by Span and Kuhn (Span and Kuhn, 2003) for at least six other
79 glaciers: Saint Sorlin in France, Gietro and Corbassiere in Switzerland; Pasterze, Vernagtferner and Odenwinkelkees in
80 Austria. At Miage Glacier, surface velocities have been measured historically by different authors (Diolaiuti et al., 2005;
81 Smiraglia et al., 2000; Fyffe, 2012; Lesca, 1974; Pelfini et al., 2007; Deline, 2002) and also show a general velocity decrease
82 in recent decades (Smiraglia et al., 2000; Fyffe, 2012). Glaciers such as Miage and Argentière, reach a low altitude and have
83 flat and little crevassed valley tongues, for this reason, they have often been historically chosen for glaciological field surveys
84 (Span and Kuhn, 2003). Therefore, the knowledge of Alpine glacier kinematics is generally mostly related to this type of
85 glacier, which can be significantly different compared to the other glaciers analysed in this study.

86   Globally, glacier slowdown linked to a negative mass balance trend was also shown for six different regions around the
87 globe and dates spanning from 1953 to 2009 by Heid and Kääb (2012b) by an analysis of remotely-sensed optical images.
88 Specific analysis of velocity trends and glacier mass loss showed generalized decreasing velocity trends over different regions
89 of High Mountain Asia between 2000 and 2017 and a strong correlation with the negative mass balance trend (Dehecq et al.,
90 2019).

91   The main purposes of this study are the production of eight-year-long velocity time series of the surface velocity of thirty
92 glaciers at a massif scale, as well as an integrated analysis of morphological and kinematic features of such glaciers. The
93 identification of possible trends in the velocity time series is a major objective of the present study. We analysed eight years
94 (2016-2024) of Sentinel-2 optical imagery to retrieve monthly velocity data on thirty glaciers in the Mont Blanc massif. We
95 observed different behaviours of surface velocity and identified a relationship between kinematic seasonality and glacier size.

96 **2 Area of study**

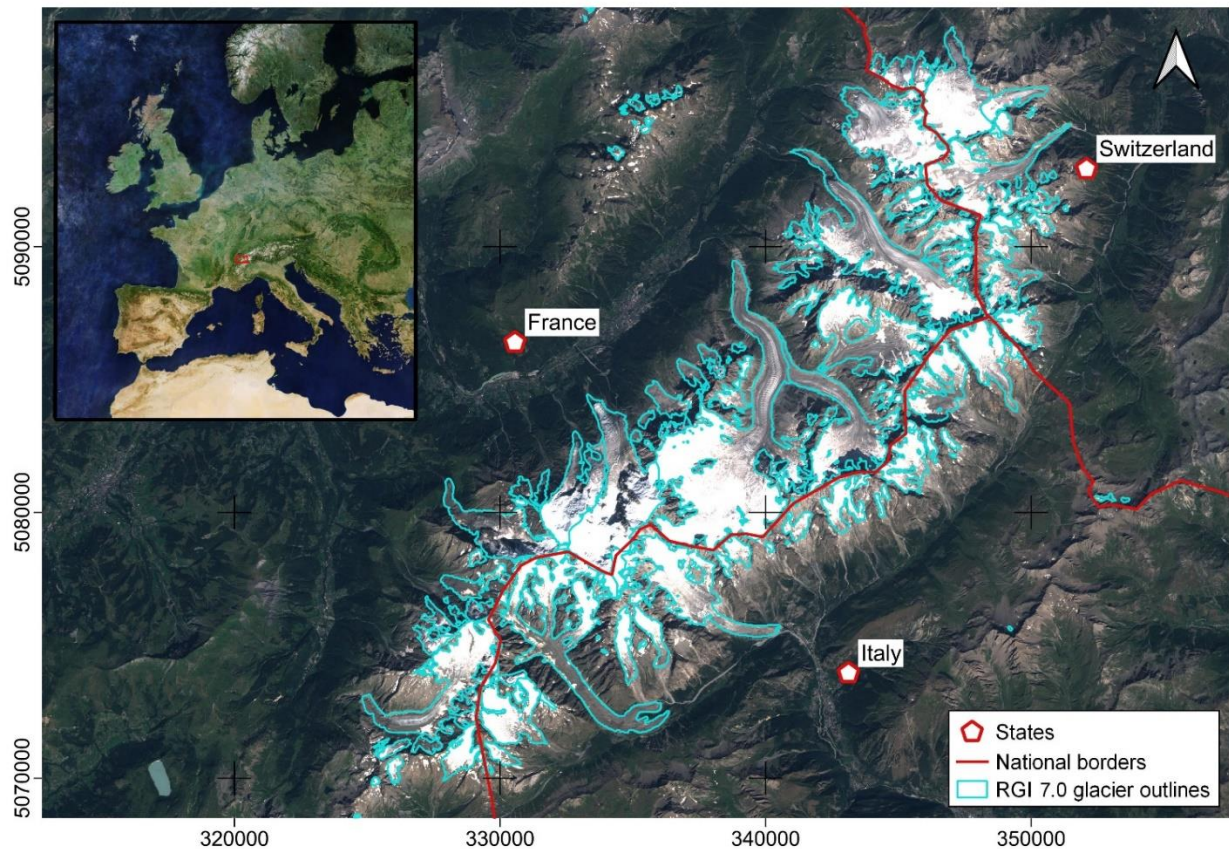
97   The study area is the Mont Blanc massif. It is located in the western part of the European Alps bordering France, Italy and
98 Switzerland (Fig. 1) and culminating at 4809 m with the Mont Blanc summit, the highest peak in Central Europe. Many other
99 peaks in the Mont Blanc massif reach well above 4000 m and the entire area is very highly frequented with famous tourist
100 resorts such as Courmayeur and Chamonix attracting thousands of tourists every year.


Fig. 1 Study area of the Mont Blanc massif. Background: true colour image (cloud-free Europe mosaic in the upper left panel), courtesy of the Copernicus Open Access Hub (https://scihub.copernicus.eu, last access: 10 September 2023).

The total surface of glaciers in the Mont Blanc massif is equal to 169 km^2 and totals 116 glaciers, according to the Randolph glacier inventory (RGI 7.0) (RGI Consortium, 2023). The inventory refers to 2003 (Pfeffer et al., 2014; Arendt et al., 2017). Forty glaciers are very small, covering an area of less than 0.1 km^2, forty-seven have surfaces comprised between 0,1 and 1 km^2, sixteen glaciers fall in the range between 1 km^2 and 3 km^2, and thirteen glaciers have surface areas of more than 4 km^2.

The geological setting and the geomorphology of the Mont Blanc massif form a high mountain range with its main ridge line oriented in a southwest/northeast direction along the French-Italian border. The valley floors flanking the massif have low altitudes - in the range of 1000-1500 m - resulting in steep slopes originating from the highest peaks with large vertical altitudinal differences. The meteo-climatic local conditions on the massif are of a continental type, but orographic effects on the predominant incoming weather fronts produce larger precipitation compared to nearby regions (Gottardi et al., 2012).

The Argentière Glacier is the only glacier with regular mass balance measurements included in the World Glacier Monitoring Service (WGMS) 'Reference Glaciers' dataset in the Mont Blanc Massif (Zemp et al., 2009). The Argentière Glacier has shown a general negative mass balance trend since the early 1990s, in line with mass balances of other Alpine glaciers and glaciers from other mountain ranges across the globe. Geodetic mass balance measurements of the Thoula Glacier, a small glacier on the border between France and Italy at altitudes between 2900 and 3300 m, represent well the local meteo-

119 climatic conditions that result in slightly less negative mass balance trends compared to other glaciers in the Alps (Zemp et al.,
120 2021; Zemp et al., 2020; Mondardini et al., 2021).
121   A more spatially distributed analysis of mass balances in the Mont Blanc region has also been outlined in the literature
122 employing geodetic mass balances of the whole Mont Blanc massif using stereo satellite imagery from the Pléiades and Spot
123 satellite constellations (Berthier et al., 2014; Beraud et al., 2023). The trend outlined by Berthier et al. (2014) at the massif
124 scale, reflects data trends comparable to the glaciological mass balances of WGMG reference glaciers in the Alps. Glaciers at
125 lower altitudes show larger ice volume losses and subsequent substantial glacier front retreats (Paul et al., 2020), while glaciers
126 at higher altitudes suffer less acute volume loss and shrinkage. Large differences in the glacier frontal position, especially for
127 the lower altitude terminating glaciers, can be well assessed by the difference of the terminus position in recent satellite imagery
128 compared to the position outlined on the RGI 7.0.

129 **3 Materials and Methods**

130 **3.1 General workflow**

131 In this paper, we analysed the Copernicus - ESA Sentinel-2 optical satellite imagery dataset available for the study area. In
132 addition, we used Airbus Pleiades Stereo derived digital elevation models (DEMs) to retrieve morphometric data of glaciers,
133 and publicly available modelled ice thickness data from Millan et al. (Millan et al., 2022). We used digital image correlation
134 (also known as feature tracking) to produce monthly-averaged and multi-year averaged velocity maps to investigate variations
135 of glacier surface velocity in time and space over the selected glaciers. We can hereby summarize the workflow that was used
136 (Fig. 2).
137   The input data are a DEM of the area of study, the RGI glacier outlines, the modelled glacier thickness and the stack of
138 Sentinel-2 images in the reference period. The input DEM is used to obtain morphometric data of the glacier while the RGI
139 glacier outlines are used, together with the selected satellite imagery, to choose suitable glaciers for surface glacier velocity
140 analysis. After the glacier selection, we updated the RGI glacier outlines according to the current glacier extensions. Selected
141 imagery is processed with digital image correlation to obtain glacier velocities. The glacier flowlines of the RGI are then used,
142 together with the updated glacier outlines and the mapped equilibrium line altitudes (ELAs), to identify sampling areas to
143 extract velocity time series. ELAs are manually digitized each year by the analysis of Sentinel-2 imagery. Subsequently, the
144 time series are analysed to identify general trends, seasonal patterns or particular kinematic behaviours. Finally, the velocity
145 dataset is analysed in relation to the morphological characteristics (in particular their size) of the glacier.
146
147
148   **Fig. 2 Workflow of the present study. The input datasets are evidenced in light blue while the processing steps are**
149   **indicated in white boxes.**

3.2 Sentinel-2 optical satellite imagery

151   We adopted Sentinel-2 optical images acquired between 2016 and 2024. We chose to start the analysis in 2016 because it
152 was the first full year of acquisition by the satellite. Based on different publications (Kääb et al., 2016; Millan et al., 2019), the
153 geometric misregistration of Sentinel-2 can show up to 1.5 pixel offsets in the horizontal plane even if it can be usually closer
154 to a value of 0.5 pixels, which corresponds to the absolute geolocation specification by ESA. Therefore, an image co-
155 registration process or a correction of stable ground shifts is normally needed for multitemporal analyses.
156   To select the images, we defined the presented approach: (i) to maximize the geometric and geo-referencing precision, we
157 adopted images acquired from the same orbit and tile (GRANULE T32TLR, relative orbit 108); (ii) to reduce the impact of
158 clouds, we carried out a visual check of all images with a cloud cover percentage lower than 80% (as detected by the Copernicus
159 cloud cover estimation algorithm) on the whole tile, which were 323 in total (150 from Sentinel 2B and 173 from Sentinel
160 2A). From this dataset, we extracted a subset of 123 cloud-free images on the selected glacier areas via the visual inspection
161 of the individual images. We adopted this manual selection to maximize the quality of the images; in the case of the Mont
162 Blanc massif (like in most mountainous areas worldwide), the local distribution of clouds can be extremely variable; in many
163 cases, this can contribute to a considerable cloud percentage, even though high altitude areas may still be cloud-free.
164   The number of suitable images that are available per year varies from 10 to 20 with a yearly mean of 15 images in the
165 following distribution: 2016: 10; 2017: 18; 2018: 11; 2019: 14; 2020: 13; 2021: 16; 2022: 20, 2023: 19, 2024: 2. The year
166 2016, and partially 2017, is influenced by the lack of Sentinel 2B images, which was launched on 7 March 2017.
167   To apply image correlation, we used the near-infrared band B08 at the processing level L1C as suggested by previous
168 studies (Kääb et al., 2016).

3.3 Glacier selection

To minimize the presence of noisy and unreliable velocity data, we performed a selection of glaciers from the RGI 7.0 dataset. In particular, we did not include in our study: A) glaciers with an area < 0.1 km^2, as those glaciers would be too small for the reliable extraction of velocity maps with 10 m resolution optical satellite imagery (Millan et al., 2019); B) glaciers showing strong variations of cast shadow; C) glaciers that lack surface features to be tracked (e.g., ice caps).

Selection of point B) was made by creating a stack of images acquired between October and March, when cast shadows appear on satellite imagery, especially on north-facing slopes. Subsequently, we manually individuated glaciers that are subject to large variations of shadow on their surface. We used the scene classification map (SCL) class 11 (cast shadows), available in processing level L2A of the Sentinel-2 images. However, since shadows on glaciers may often be misclassified, we conducted a manual check to correct potential errors. Selection of point C) is made manually by selecting glaciers that show very even surfaces on Sentinel-2 images. This is normally noted in ice caps at higher altitudes or flat valley tongues.

The glacier selection process identified thirty glaciers with a total glacierised surface (at 2018) of 85.8 km^2. Compared to the total glacierised surface of the massif from RGI 7.0, this represents the covering of 50.8% of the total 169 km^2 and 25.9% in terms of number of glaciers; this rises to 39.5% if we consider the subset of seventy-six glaciers having a glacierised surface of more than 0.1 km^2. The selected glaciers are highlighted in Fig. 3 and listed in Table 1. Two of the selected glaciers are located in Switzerland, ten are located in France and eighteen in Italy. This distribution is mainly due to a small portion of the massif being located in Switzerland and the presence of more fragmented glacierised bodies on the Italian side. Of the thirty glaciers, seven have been mapped as sub-areas in comparison to RGI 7.0 individual glacier bodies. A brief description of all the glaciers we analysed is found in section S1.1, to describe the location and geomorphological setting of the glaciers as well as highlight when a single glacier complex from the RGI 7.0 was divided into independent glacial bodies because of very distinct kinematic behaviour.
190
191 **Fig. 3 Surface glacier velocity map averaged in the 2016-2024 period. Selected glaciers for specific analyses are**
192 **outlined in cyan. Background: Sentinel-2 image (B08 band), courtesy of the Copernicus Open Access Hub**
193 **(https://scihub.copernicus.eu, last access: 10 September 2023).**

194 **3.4 Glaciers' outline delineation and morphometric data calculation**

195   Since the RGI 7.0 glacier outlines refer to 2003, we updated them to fit with the present glacier extensions and manually
196 outlined them from Sentinel-2 imagery. We selected a cloud-free scene acquired on 28 August 2018 that represents well the
197 conditions of the glaciers in the study period; True Color Image was used for this purpose. The main morphometric data that
198 were determined for each glacier are summarized in Table 1. In some cases, a morphological indication that some parts of the
199 glaciers could be considered independently from others and divided into individual kinematic domains was considered (Paul
200 et al., 2022; Zemp et al., 2021). As the production of velocity maps confirmed distinct behaviours of some glacier parts, those
201 glaciers were divided and mapped accordingly. The main examples are the tributary glaciers of the larger Miage Glacier
202 complex, which all have distinct kinematic behaviour, well differentiated from the slow-moving, debris-covered main central
203 valley tongue. Another example is the Talèfre Glacier, where, over the past twenty years, the western part of the glacier has
204 become independent from the eastern portion.
205   The determination of morphometric data of sample glaciers was performed using altitudinal data from a 1 m resolution
206 DEM obtained by the processing of Pleiades stereo pairs acquired in August 2018 (Berthier et al., 2014), while the mean

207 glacier thicknesses were extrapolated from globally modelled ice thickness data (Millan et al., 2022), which has an average
208 uncertainty of 30%.

209

3.5 Glaciers' surface velocity calculation

Digital image correlation is a common technique used to measure surface displacements using proximal (Evans, 2000; Ahn and Box, 2010; Schwalbe and Maas, 2017; Dematteis et al., 2024) and remotely sensed imagery (Scambos et al., 1992; Heid and Kääb, 2012; Marsy et al., 2021; Dematteis and Giordan, 2021). The processing chain performed in the present study uses the open-source Glacier Image Velocimetry (GIV) toolbox (Van Wyk De Vries and Wickert, 2021). GIV uses frequency-based correlation, can efficiently process large datasets and has been shown to perform well on glacier surface velocity measurements at different test sites (Van Wyk De Vries and Wickert, 2021). GIV calculates stable-ground shifts to correct for georeferencing errors; therefore, we created a stable ground mask composed of non-glacierized terrain surrounding the massif, and fit a 2D second-degree polynomial to the residual velocities over stable ground in the x- and y- directions. To measure glacier surface velocities, we adopted the 'multi-pass' option which updates displacement estimates over multiple iterations, refining initial coarse chip size displacement calculations using progressively smaller chip sizes. The initial chip size is automatically defined by GIV and cannot be smaller than 32x32 px. The overlap between matching windows was 0.5. Velocities higher than 1500 m yr^{-1} were considered unrealistic and discarded. The velocity map resolution was set to 40 m, without resampling. Finally, we smoothed the velocity maps by applying a 3x3 median filter.

To produce the time series, given a specific image, we processed the first and second subsequent images (GIV order 2 time-oversampling). The minimum and maximum temporal repeat cycles were respectively 10 and 120 days. Overall, we calculated 218 image pairs, with an average temporal baseline of 35 days (Sec. S8).

Subsequently, the velocities of image pairs were averaged on a monthly basis. We applied the weighted average included in GIV, where the weights are proportional to the fraction of time included in a given month over the total time gap between the image pairs. The presence of clouds or snow on the glacier surface made it impossible to extract reliable data in the following months: i) January 2017 ii) December 2020, January and February 2021 iii) September 2021. The gaps represent only five months on which we did not retrieve velocity data out of the eight years considered in the study (i.e., <5%). In Fig. 3, we present a velocity map with a resolution of 40 m. This was obtained by averaging all the single monthly velocity maps in the study period (2016-2024). In Fig. 4, we present an example of the obtained velocity map and the distribution of sampling areas over several chosen glaciers. All other parameters of the GIV processing were set at default parameters (Supplementary Materials section S5).
Fig. 4 a) Details of glacier surface velocity map averaged in the 2016-2024 period and sampling areas of selected sample glaciers. b, c) show monthly velocity maps of July and February 2018 respectively. 3.6 Velocity time series analysis

Sampling areas were identified on the velocity maps to analyse the time series of the selected glaciers. Since the surface velocity of land-terminating glaciers is expected to be the highest in correspondence with the ELA (Nesje, 1992), we cropped the RGI 7.0 flowlines at the upper and lower altitudinal limits of the ELAs mapped between 2016 and 2023. Around this section of the ELA, we buffered an area of 40 m (Fig. 4). The velocity values included in the obtained polygons were averaged to produce the time series.

Subsequently, we applied a quadratic locally weighted scatterplot smoothing (LOWESS) (Cappellari et al., 2013) evaluated on a rolling window of twelve months. Finally, we calculated the linear trend of the smoothed series using the Huber loss regressor (Huber, 1992). The Huber fit is robust against outliers; thus, sharp velocity fluctuations should not affect the obtained linear trends. To evaluate the statistical significance level of the fit, we consider the *t-statistics*, i.e., the ratio between the coefficient values and their standard errors. According to its definition, the t-statistics is expected to be low when the slope of the linear fit is low and/or when the slope is relatively low compared to the data variability.

We performed the principal component analysis (PCA) of the time series to investigate the overall behaviour of all the considered glaciers, and we weighted the time series according to the glacier area. The PCA is a multivariate analysis technique that allows a reduction in the dimensionality of a given dataset, increasing interpretability but minimising information loss. This is achieved by creating new, uncorrelated variables that successively maximise the variance of the dataset (Jolliffe and Cadima, 2016).

4 Results and discussion

4.1 Distributions of monthly velocities

On the thirty glacial bodies we investigated in this study, the monthly velocity values range from 30-40 m yr^{-1}, typically reached during winter months, to 350 and 400 m yr^{-1}, typically reached in summer/late summer. The highest velocities are attained by the Brenva and the Bossons glaciers. In particular, monthly extreme values vary from 11.8 +/- 9.8 m yr^{-1}, reached on January 2022 by the Des Glaciers Glacier, to 487.4 +/- 10.8 m yr^{-1}, reached by the Brenva Glacier in July 2016. The mean surface velocities averaged over the whole period range from 29.9 +/- 10.9 m yr^{-1} at the Pierre-Joseph Glacier to 375.9 +/- 10.9 m yr^{-1} at the Brenva Glacier. The standard deviation of the velocity time series of single glaciers varies from 10.3 m yr^{-1} at the Pierre Joseph Glacier to 70.7 m yr^{-1} at the Charpoua Glacier. Fig. 5 presents the distributions of the raw monthly velocity of the considered glaciers.
271
Fig. 5. Distributions of the glaciers' raw monthly velocity. Glaciers are sorted by their median velocity. The background colours of the glacier names indicate their size: white < 1 km^2; green 1-4 km^2; blue >4 km^2.

4.2 Velocity time series

Large and thick glaciers have in general high velocities, and two of them (Brenva and Bossons) show the highest values. The velocity values remain high throughout the whole year (Fig. 6). Brenva displays irregular seasonality variations, while Bossons has an almost absent seasonal cycle. Their morphology is complex - e.g., the slope varies considerably along their extent. In the present study, we concentrated the analyses on the middle sectors (near the ELA) of the glaciers, which are the fastest (Nesje, 1992). In the time series, the biggest glacier (Mer de Glace) appears slower because we extracted the monthly velocity over an area which does not entirely include the most active sector of the Mer de Glace glacier, where the velocity reached values >400 m yr^{-1}.

Medium-sized glaciers' morphology is less homogeneous, even though most are generally gentler and thicker than average. We can divide the group into two sets based on the elongation ratio. Medium-sized glaciers which are more elongated generally feature strong kinematic activity, their velocity is higher than average with marked variability and they often show a pronounced regular annual cycle, as in the cases of the Bionassay (IT), Brouillard, Mont Blanc and Freney glaciers. The second set of more "compact" glaciers, show lower mean velocities and have a minor amplitude of the seasonal variability. In particular, even though some display a regular seasonal cycle (e.g., Planpincieux, Dome, Rochefort), their velocity variability is much lower (Fig. 6).

289   Small glaciers show lower average velocities, but most show marked and regular seasonality. In this group, some very
290 small glaciers (e.g., Greuvettaz W, Greuvettaz E, A Neuve N, Pierre Joseph) show a modest, irregular or even non-detectable
291 seasonal cycle since the velocity in winter is close to the measurement uncertainty (Fig. 6). It is worth highlighting that signals
292 of potential velocity fluctuations could exist but remotely-sensed data are not currently suited for analysing such small glaciers.
293   On the other hand, Pra Sec and Charpoua, small steep elongated glaciers, feature very low minimum velocities (between
294 25 m yr^{-1} and 50 m yr^{-1}) and very marked peaks during which the velocity increased by one order of magnitude. These high
295 velocity periods appear in summer/late summer and extreme velocity changes from winter to summer velocities can be noticed.
296 In 2016, 2018 and 2022, the summer velocity of Charpoua Glacier was exceptionally high compared to the usual. Moreover,
297 in these years, the spatial distribution of velocities varied, and the highest velocities were registered towards the frontal part of
298 the glacier, while normally it was higher in the upper sector (Fig. 7). Pra Sec Glacier displays more regular annual speedups
299 in the period analysed, every summer it had a clear velocity peak (except in 2018), particularly pronounced in 2016, 2020 and
300 2022. In both glaciers, possible glacier advances are prevented by the steep bedrock cliff at the snout, which causes the
301 disintegration of the glacier by repeated ice falls from the terminus (Giordan et al., 2020; Pralong and Funk, 2006).

Fig. 6. Time series of monthly glacier surface velocities over the 2016–2024 period. Robust linear trends are represented in dashed black lines. The background colour of the glaciers' names denotes their size: white, green and blue are for small, medium and large glaciers, respectively. The velocity seasonality is indicated with markers: brown diamonds (low seasonality), orange circles (average seasonality) and pink rectangles (high seasonality).

308 **band), courtesy of the Copernicus Open Access Hub (https://scihub.copernicus.eu, last access: 10 September 2023)**

309 **4.3 Interannual velocity variability and trend**

310   The overall behaviour of the glacier velocity can be well represented by the PCA of the time series, weighted by the glacier
311 area. Fig. 8 shows the 1st PC, which explained >50% of the variance. In general, this analysis reflects a common trend of many
312 time series: a first period between 2016 and 2019 showing decreasing velocities, an anomaly of higher velocities between 2020
313 and 2022 followed by a new velocity decrease in 2023 (Fig. 6). According to historical observations at the Argentière and
314 Miage glaciers, the velocity decrease from the early 2000s can be linked to continuous negative mass balances (Vincent and
315 Moreau, 2016) of most Alpine glacier since the 2000s (Zemp et al., 2021). The results of our study agree with this negative
316 trend in the first part of the considered period (i.e., 2016–2019), but we detected a rupture in the trend and a velocity rise from
317 2020 to 2022 occurring in a large number of glaciers under study. An interesting remark about the geographical distribution
318 of the trends is that the glaciers showing a clear velocity anomaly during 2020-2022 are located on the southeast side of the

319 massif ridgeline along the Italian and Swiss part of the Massif (e.g., A Neuve Central, Bionassay (IT), Brenva, Planpincieux
320 and Lex Blanche glaciers). This might be linked to different dominant meteorological conditions distributions on the two sides
321 of the massif. A specific analysis of seasonal meteorologic data in the different areas could give more insights into this
322 hypothesis, even though whether stations are located far from the glacier accumulation areas and could not get a specific signal
323 present in the higher altitude sectors.
324
325 **Fig. 8. 1st PC of the LOWESS velocity values of all the time series of glacier monthly velocity.**

326   The glacier velocities shown in Fig. 6 have different linear trends over the full period of the study (Fig. 9). In general, the
327 linear trends of each glacier calculated using winter, summer months or the whole year have similar behaviour (i.e., they are
328 always negative or positive), with winter trends having higher values than summer ones (~30% higher on average). As
329 expected, lower absolute linear trends (i.e., ≲1 m yr^{-1}) have t-statistics<2. Besides, even though Brenva's trend is high (2.8 m
330 yr^{-2}), its velocity is very large, thus lowering the t-statistics. Most trends lie in a relatively thigh cluster which crosses the
331 domain diagonally, except for Charpoua and Planpincieux which have dissimilar seasonal values. In the Charpoua case, this
332 is probably related to the strong velocity fluctuations occurring only in some years in summer, while the Planpincieux positive
333 summer trend is likely led by the anomaly 2020-2022, which is particularly strong in this glacier. Notably, the three glaciers
334 with the highest linear trends (i.e., Freney, Bionassay (IT) and Aiguille de Tré-la-Tete) are all located in Val Veny, on the
335 southern side of the massif. Bionassay (IT) and Freney have a very similar morphology (Tab. 1), they are both medium-size
336 (1.3 km^2 and 1.02 km^2), relatively elongated (2.2 m^{-1} and 2.5 m^{-1}) glaciers, with slopes of ~25° and elevations between 2400
337 m and 3800 m. Differently, Aiguille de Tré-la-Tete is a small (0.3 km^2), much-elongated (4.34 m^{-1}) and low-altitude glacier
338 (2408-3010 m). Aiguille de Tré-la-Tete and Bionassay (IT) are both tributaries of the Miage Glacier.
339   An accelerating trend (+5 m yr^{-2} between 2015-2021) has recently been shown for the Brenva Glacier by an analysis of
340 remotely-sensed optical images (Rabatel et al., 2023b) while detecting decelerating trends on many other glaciers of the Massif.
341 Our study showed Brenva Glacier an accelerating trend of +3 m yr^{-2} between 2016-2024, which is in good agreement
342 considering the velocity decrease shown in 2022 and 2023. Besides, (Rabatel et al., 2023b) observed a slight ice thickening
343 (~1 m between 2000 and 2019) in an upper sector of the Brenva Glacier. They proposed three hypotheses to explain the

344 acceleration of the Brenva: a) a glacier thickening; b) a change in thermal regime; and c) a change in subglacial hydrology,
345 possibly related to an increased ablation in the upper reaches of the glacier.

346 Even though the hypothesis of glacier thickening could explain the specific case of Brenva, the glacier surface elevation
347 change across the Mont Blanc massif has been generally negative in the last years, as evidenced by the negative mass balance
348 of the reference glaciers in the area (Zemp et al., 2021; Zemp et al., 2009). Local anomalies of positive mass balance could
349 explain an increase of velocity but the lack of measurements at higher altitudes does not allow us to confirm this behaviour at
350 present. However, the meteorological conditions in recent years have remained approximately constant, which makes unlikely
351 a general glacier thickening in the region (see S6 "Meteorological conditions"). Localized high rates of accumulation due to
352 increased avalanche activity and wind accumulation could also contribute to the ice thickening (thus yielding an acceleration),
353 but cannot be investigated at this stage. It is worth highlighting that the three glaciers highlighting a high winter accelerating
354 trend in Fig. 9 (Bionassay (IT), Aig Tré la Tete and Freney) are near to each other and located in a small part of the massif on
355 its southeast side.

356 A change in the thermal regime of the glaciers could explain accelerating trends, but it would explain long-term trends and
357 not short-period variations such as the one highlighted in 2020-2022, as basal temperature measurements show a warming at
358 the ice bedrock interface on a decadal to multi-decadal timescale on the Mont Blanc massif (Vincent et al., 2007).

359 A variation of the hydrology of groups of glaciers is a plausible hypothesis for the explanation of accelerating trends, but
360 it should highlight stronger trends in summer rather than in winter, as basal sliding is enhanced over deformation during
361 summer. Such a combination of trends is not shown by most glaciers as highlighted in Fig. 9. Only the trends highlighted by
362 Planpincieux and Mer de Glace glaciers could relate well with this hypothesis, showing almost no trend in winter and an
363 accelerating trend during the summer months.

364 The distribution of the acceleration trend over different areas of the massif and regarding different types of glaciers suggest
365 the existence of a long-term meteo-climatic driver of the phenomenon, even though it is not evident limiting the analysis to
366 the period 2015-2023 (Section S6). In the end, a definitive answer cannot be formulated so far and further research is necessary
367 to understand the processes involved in this trend.
368

370   **(from November to April) and summer (from June to September) months, respectively. The colours indicate the**
371   **global trend. The glaciers with linear trends with *t*-statictis<2 have markers with dashed edge lines.**

4.4 Relationship between glacier size, velocity and seasonal behaviour

We examined the relationship between the glacier size, the seasonal velocity behaviour and velocity distribution. To this end, we divided the glaciers into three classes for each feature. Concerning the size, we considered very small glaciers with an area of < 1 km², according to (Bahr and Radić, 2012), while medium and large glaciers have areas between 1 km² and 4 km², and >4 km², respectively. Concerning the velocity distribution, we observed that, besides Brenva and Bossons, which have much higher velocity compared to the rest of the glaciers, a group of sixteen glaciers have the 75th percentile of monthly velocity <100 m yr⁻¹ (from Pierre Joseph to Charpoua in Fig. 5). Finally, twelve glaciers have their 25th and 75th percentiles between ~100 m yr⁻¹ and ~200 m yr⁻¹ (from Des Rognons to Freney in Fig. 5).

Concerning the seasonal velocity behaviour, we analysed the raw time series (Fig. 6) and the LOWESS smoothed time series normalised by their median value (Fig. S6). Glaciers such as Freney, Brouillard, and Bionassay (IT) show evident and regular seasonal behaviour and large winter/summer differences; in these cases, summer velocities (occurring between July and October) are 50% to 100% higher than winter ones (occurring between January and April). Another group of glaciers has smaller winter/summer differences or pronounced but irregular variability (e.g., Planpincieux, Pre de Bard, Talefre). A third group does not display evident or regular seasonal behaviour (e.g., Taconnaz, Mer de Glace, Pierre Joseph), with

386 winter/summer differences below 10%. Overall, the maximum velocity occurs in August-September, while the annual
387 minimum is reached in March (Fig. 8).

388   The double-entry heatmaps are presented in Fig. 10, which show a tendency for the smaller glaciers to have more
389 pronounced seasonality, while larger glaciers show a more homogeneous velocity throughout the year. Since the glacier area
390 is strongly correlated with its thickness (Cuffey and Paterson, 2010), a possible cause of this phenomenon could be related to
391 enhanced basal sliding during the accelerating period. In fact, a thicker glacier could be less prone to exhibit enhanced sliding
392 because of the larger mass to be uplifted by basal positive water pressures, while shallower glaciers could more easily benefit
393 from enhanced sliding by pressure build-up at the ice-bedrock interface by increasing inputs in the hydrological subglacial
394 drainage network. Moreover, in winter, the base of thin glaciers could freeze, thus preventing the sliding and determining
395 lower winter velocities causing even larger summer-winter velocity differences.

396   On the other hand, as expected, larger (and thicker) glaciers tend to be faster than smaller ones.
Fig. 10 Glacier classification according to their size (SMALL: <1 km², MED: 1-4 km², LARGE: >4 km²) and a) seasonal velocity behaviour (qualitatively estimated) and b) median velocity (SLOW: <100 m yr⁻¹; AVG: 100-300 m yr⁻¹; FAST: >300 m yr⁻¹). The digits within the grid tiles indicate the number of glaciers belonging to each group.

401 **4.5 Uncertainty analysis**

402   To estimate the quality of our data, we performed two investigations. First, following the method proposed by (Millan et
403 al., 2019), we calculated the median absolute deviation of the velocity obtained on stable terrain for each monthly data. In
404 these areas, we applied an outlier spatial filter to the velocity maps according to Rabatel et al. (2023a). The median value of
405 the monthly uncertainty was 10.9 m yr⁻¹. In their study, Millan et al. (2019) estimated the nominal precision according to the
406 temporal baseline between the correlated images, which they found to be between 6–16 m yr⁻¹ for baselines respectively of 40
407 and 20 days, which is the typical range of temporal gaps between images used in our study. Moreover, the value of 10.9 m yr⁻¹
408 is in close agreement with the uncertainty found by Mouginot et al. (2023), which obtained a root mean squared error of 10.5
409 m yr⁻¹ between glacier velocities measured over the Mer de Glace and Argèntiere glaciers using image correlation of Sentinel-
410 2 images and GNSS in situ data (https://glacioclim.osug.fr/). A comparison with the data from Rabatel et al. (2023) is proposed
411 in the supplementary materials (section S4, figure S3) for the glaciers of Brenva, Bionassay (FR), Bossons and Brouillard over
412 the timespan that overlaps the two studies (2016-2021).

413   Second, we considered the glacier velocity from Millan et al. (2019), who published mean annual velocity in the period
414   2017–2018 on a 50x50 m regular grid. They adopted normalised cross-correlation and chip size refinement (initial size of
415   16x16 px). They estimated an overall uncertainty of glacier surface velocity time series of ~12 m yr^{-1} over the Mont Blanc
416   glaciers, and, specifically at Brenva and Bosson glaciers, an uncertainty of 15–20 m yr^{-1}. We compared these data and ours
417   along four glacier longitudinal central lines (i.e., in Bossons, Brenva, Freney and Taconnaz), obtaining good agreement (Fig.
418   11). The largest differences (>50 m yr^{-1}) were found in a specific sector of the Taconnaz Glacier (Fig. 11d), where the ice flux
419   is highly channelized in a narrow passage. There, the data of Millan et al. (2019) show a large velocity decrease that seems
420   unlikely considering the geometry of the site. Our data show a similar but less pronounced velocity decrease. However, the
421   velocity profiles are similar elsewhere. On average, the surface velocities that we obtained are slightly higher, with a mean
422   difference of 0.03 m yr^{-1} and root mean squared deviation (RMSD) of 24.0 m yr^{-1} (Table 2). The slightly higher RMSD
423   compared to the expected uncertainty can be due to the fact that the precision in glacierized areas is probably larger (less
424   precise) than in ice-free zones because the surface texture is different and changes (e.g., snow precipitation, surface melt,
425   glacier movement) occur more rapidly, therefore causing more decorrelation (Millan et al., 2019).

426
Fig 11. Comparison of velocity profiles from Millan et al. (2022) (red) and from this study (black) at (a) Bossons Glacier, (b) Brenva Glacier, (c) Freney Glacier and (d) Taconnaz Glacier. The velocity profiles are represented in yellow in the maps on the left, and the velocity profiles start from the upper to the lower altitudes. RMSD [m yr^{-1}]	22.3	25.2	29.6	19.0	24.0

4.6 Uses and limits of the proposed methodology

The methodology presented in this study allows the detection of monthly changes in glacier velocity, which can be precursors of ice avalanches (Pralong et al., 2005; Faillettaz et al., 2008; Giordan et al., 2020). For example, ice avalanches from the Pra Sec Glacier occurred in 2020 (Forestry Service of Aosta Valley). In our study, we observed high velocities in 2020, which could have led to the break-off. At the Charpoua Glacier, an ice avalanche of 45000 +/- 15000m3 occurred in 2018 (Lehmann, 2018 - https://news.unil.ch/display/1536777918113, accessed online 11 October 2023), when we measured velocities >200 m yr^{-1}, much higher than usual.

In this frame, it would be very relevant to measure and know the typical velocity fluctuations of specific glaciers in stable conditions. This could allow an assessment and to what extent a suspect acceleration may be anomalous and potentially destabilising, bearing in mind that high-rate monitoring is essential to detect glacial instabilities since the expected sharp increase in velocity in the weeks before the failure (Pralong and Funk, 2006) could be hardly detectable from remote sensing (e.g., due to scarce visibility, image decorrelation, low resolution).

Limits of the methodology presented in this study should also be considered: glaciers moving at slow rates can be surveyed using temporal baselines of one year (Millan et al., 2019; Mouginot et al., 2023), but this implies reducing the ability to catch short-term velocity fluctuations, like those observed at Charpoua and Pra Sec glaciers. Another known issue pertains to the lack of features of the glacier surface that make it impossible to track movements using optical imagery. Satellite optical imagery is limited and can be strongly influenced by the presence of clouds that could yield extensive periods without data acquisition, even though, in the present study, we had only four of 96 months with no data. Anomalies due to image decorrelation for the presence of shadows, snow or morphological surface modifications can occur and an expert-based visual check may be required to discriminate anomalous velocities.

6 Conclusions

We produced ice velocity maps and time series of thirty glaciers of the Mont Blanc massif during the period 2016–2024. The proposed results are different compared to the existing publicly available automatically processed velocity datasets that have a coarse resolution (i.e., >100 m) and cannot correctly detect the kinematics of most Alpine glaciers, due to their small size. Therefore, specific processing and studies are needed to characterize the surface kinematics of Alpine glaciers. In our study, we used Sentinel-2 imagery due to its free availability, good ground resolution and high revisit time in the study area to obtain monthly surface velocity time series. In addition, we proposed a classification of different groups of glaciers based on their morpho-kinematic features. Plus, we observed a significant acceleration trend in many of the studied glaciers in the last years (2020–2022), but the causes are still not well understood.

From a methodological point of view, the use of the proposed approach can be very useful to process and analyse available satellite images of other massifs in the Alps and other parts of the World. This approach could stimulate innovative research on high-resolution spatiotemporal variations of velocities on alpine glaciers and, especially, on understanding the variations in the motion of mountain glaciers. A large research question remains open and deals with understanding and measuring the drivers of change in the motion of alpine glaciers. This implicates the complex acquisition of data related to the possible drivers of the variations such as mass balances, water inputs and temporal variations in the subglacial hydrology of single glaciers. However, in order to delve further into these investigations, velocity databases at higher spatial and temporal resolutions, such as that presented in this study, are needed to build future research on the topic.

Acknowledgements

The authors would like to thank Jean Pierre Fosson, Raffaele Rocco, Valerio Segor, and Guido Giardini for their support and their will to stimulate cryospheric research activities in the Aosta Valley region and on the Italian side of Mont Blanc massif. We thank all the staff at Fondazione Montagna Sicura for supporting all the research activities of the research team. Dr Etienne Berthier supplied a processed 2018 Pleiades stereo DEM on which retrieving altitudinal data that was presented in this paper. Dr. Antoine Rabatel supplied velocity data for the comparison with their 2023 dataset. We thank Prof. Christian Vincent for his advice on research activity and for supplying useful additional information, especially on the French glaciers of Mont Blanc.

Data availability

The following data are available for download on Zenodo http://dx.doi.org/10.5281/zenodo.11349445: i) monthly velocity maps, ii) updated outlines (from RGI7) of the analysed glaciers, iii) sampling areas of extraction of the velocity time series, iv) time series of monthly velocity. The data description and format are reported in Sec S9. Sentinel-2 imagery is available from the Copernicus Open Access Hub (https://scihub.copernicus.eu, Copernicus, 2022). The GIV toolbox is freely available online (https://github.com/MaxVWDV/glacier-image-velocimetry).

Competing interests. The authors declare that they have no conflict of interest.
