9 **Abstract.** We investigated the temporal variability of the surface velocity of thirty glaciers in the Mont Blanc massif  
10 (European Alps). We calculated the monthly velocity between 2016 and 2024 using digital image correlation of Sentinel-2  
11 optical imagery. The main objectives of the study are: (i) to characterise the variability of the velocity fields of such glaciers,  
12 referring both to their temporal (seasonal and interannual) and spatial variations; (ii) to investigate relationships between the  
13 morphology of glaciers and their kinematics. We measured monthly velocities varying from 12.7 m yr<sup>-1</sup> to 487.4 m yr<sup>-1</sup>. We  
14 observed an overall decrease in the velocity between 2016 and 2019 and an unexpected rise in 2020-2022, especially visible  
15 in most glaciers on the southern side of the massif. Considering the whole period, half of the glaciers showed positive  
16 acceleration, which reached values >4 m yr<sup>-2</sup> in three glaciers. In general, the trend absolute value in the cold season is higher  
17 in case of positive acceleration and lower in case of negative acceleration. We found that smaller glaciers have a more  
18 pronounced seasonality, with winter-summer velocity differences of 50-100%. Finally, in 2016, 2018 and 2022, we observed  
19 an exceptionally high winter-summer velocity difference in the 0.3 km<sup>2</sup>-wide Charpoua Glacier, when summer velocities  
20 increased by one order of magnitude.

## 21 1 Introduction

22 Glacier flow was one of the early drivers of glaciological interest and research since it was first studied. Its understanding  
23 and modelling evolved via the observations and findings of Somigliana (1938) in the early 1900s, Glen's laboratory  
24 experiments (Glen, 1952), followed by the interpretations of Nye (Nye, 1952) during the 1950s, to cite just a few, and have  
25 explained that the two main mechanisms of glacier flow rely on ice deformation and basal sliding. However, the motion of  
26 Alpine glaciers is largely related to basal sliding (Willis, 1995). Because continuous monitoring of sliding velocities in the  
27 field is extremely difficult and rarely achieved (Vincent and Moreau, 2016), measuring surface flow velocities can be used as  
28 a strong alternative approach. Nonetheless, the continuous monitoring of surface velocities of Alpine glaciers is complex on  
29 specific study sites, and very rarely has it been performed on a spatially distributed scale.

30 The flow of glaciers generally depends on a variety of physical parameters. The main physical parameter influencing ice  
31 velocity is the ice thickness (Jiskoot, 2011), which is indirectly related to the glacier trend in mass balance as it determines an  
32 evolution towards an increase or decrease in glacier thickness. Other parameters that influence ice flow are glacier surface  
33 slope, ice properties (temperature, density), bedrock conditions (hard, soft, frozen or thawed ice-bed contact), topography, the  
34 glacier's terminal area type (land, sea, ice shelf), but also air temperature and precipitation and their seasonality that influences  
35 subglacial hydrology (Jiskoot, 2011; Humbert et al., 2005; Cuffey and Paterson, 2010; Benn and Evans, 2014; Bindschadler,  
36 1983).

37 The analysis of glacier surface velocity has a wide array of applications: it is a powerful climate change indicator (Beniston  
38 et al., 2018) and also an important input data for ice thickness models (Millan et al., 2022; Samsonov et al., 2021) and mass  
39 balance models that can also approximate sea-level rise contribution by glaciers (Zekollari et al., 2019). In the field of glacial  
40 hazards, it is used as an indicator for the detection of glacier surges with space-borne measurements (Kamb, 1987; Kääh et al.,  
41 2021), and accelerations that can result in glacier-related hazards using ground-based sensors (Pralong and Funk, 2006;  
42 Giordan et al., 2020). Measurements of the surface velocity of glaciers can be achieved by terrestrial techniques (Dematteis et  
43 al., 2021) such as topographic measurements of stakes or fixed points on the glacier (Stocker-Waldhuber et al., 2019), GNSS  
44 repeated or continuous surveys (Einarsson et al., 2016), digital image correlation of oblique photographs (Evans, 2000; Ahn  
45 and Box, 2010) and terrestrial radar interferometry (Luzi et al., 2007; Allstadt et al., 2015). Considering remote sensing  
46 solutions, glacier surface velocities can be measured by different aerial and space-borne sensors. In recent decades, public  
47 access to satellite optical and radar data (especially from Sentinel and Landsat constellation satellites), as well as the  
48 commercial availability of very high resolution (30 cm to 3 m ground resolution) optical imagery (Deilami and Hashim, 2011)  
49 and radar data (Rankl et al., 2014), have given great input to glaciological research. In particular, Sentinel-2 optical imagery  
50 is widely used in glaciological studies and has been tested in the literature on various environments (Paul et al., 2016; Millan  
51 et al., 2019). Nowadays, the automated processing of ice velocity maps with global coverage from satellite imagery is freely  
52 available online from web-based platforms such as the GoLIVE datasets (Fahnestock et al., 2016), the ITS\_LIVE data portal  
53 (<https://its-live.jpl.nasa.gov/>) or the FAU-Glacier portal (RETREAT, 2021 Ice surface velocities derived from Sentinel-1,  
54 Version 1; <http://retreat.geographie.uni-erlangen.de/search>). The availability of such datasets is very relevant globally, but  
55 their application to Alpine glaciers is limited due to their relatively coarse spatial resolution - e.g., 300x300 m (GoLIVE),  
56 120x120 m (ITS\_LIVE) - which can provide data on just a few of the largest Alpine glaciers. Moreover, for the ITS\_LIVE  
57 dataset, the velocity maps are calculated at a resolution of 240 m and statistically downscaled to 120 m, which has major  
58 limitations for small mountain glaciers. The adopted resolution is a trade-off between computational effort and the best  
59 resolution of the output that must cope with the global availability of the analysis. Limiting the processing of images at a  
60 regional scale decreases the computational effort compared to global products and makes it easier to obtain higher resolution  
61 velocity maps that allow Alpine glaciers to be investigated (Berthier et al., 2005), even though very small glaciers (i.e., width  
62 <250 m) are still difficult to analyse (Millan et al., 2019).

63 Recent studies using different techniques have measured spatio-temporal variations of ice velocity on large valley glaciers  
64 in an Alpine environment, like the Argentière (Vincent and Moreau, 2016) and Miage glaciers (Fyffe, 2012) as well as on  
65 steep glacier snouts (e.g., Planpincieux Glacier (Giordan et al., 2020)) but a spatially distributed analysis at a regional scale of  
66 the variations of velocities over glaciers with different morphological characteristics is, as of today, still lacking in the Alpine  
67 environment. Millan et al. (2022) calculated the velocities of world glaciers, but they considered a specific analysis period  
68 (2017-2018) not considering velocity variations in time, while Rabatel et al. (2023a) performed a comparison between yearly  
69 aggregated velocity maps between 2015 and 2021 over three different alpine massifs.

70 Other studies focused on long-term glacier velocity records in the Mont Blanc Massif: at the Argentière Glacier (Vincent  
71 and Moreau, 2016) and Miage Glacier (Smiraglia et al., 2000; Fyffe, 2012). At Argentière Glacier, a unique series of  
72 continuous basal sliding measurements existed from 1997 and was still active as of 2022 (Vincent et al., 2022; Nanni et al.,  
73 2020). The whole series indicates a general decrease in basal sliding velocities (Vincent and Moreau, 2016) since the end of  
74 the 1990s. This general decrease has shown a strong correlation with the negative mass balance of the glacier, which agrees  
75 with the conceptual model from Span and Kuhn (2003), in which the glacier flow variation is primarily driven by the mass  
76 balance of the accumulation area in the previous year (as it determines glacier thickness variations). Seasonal field surveys  
77 conducted at Argentière Glacier from the 1950s document a longer data series than the basal sliding measurements start in  
78 1997, and an increase in surface velocities was measured during a period of positive mass balances in the early 1980s (Vincent

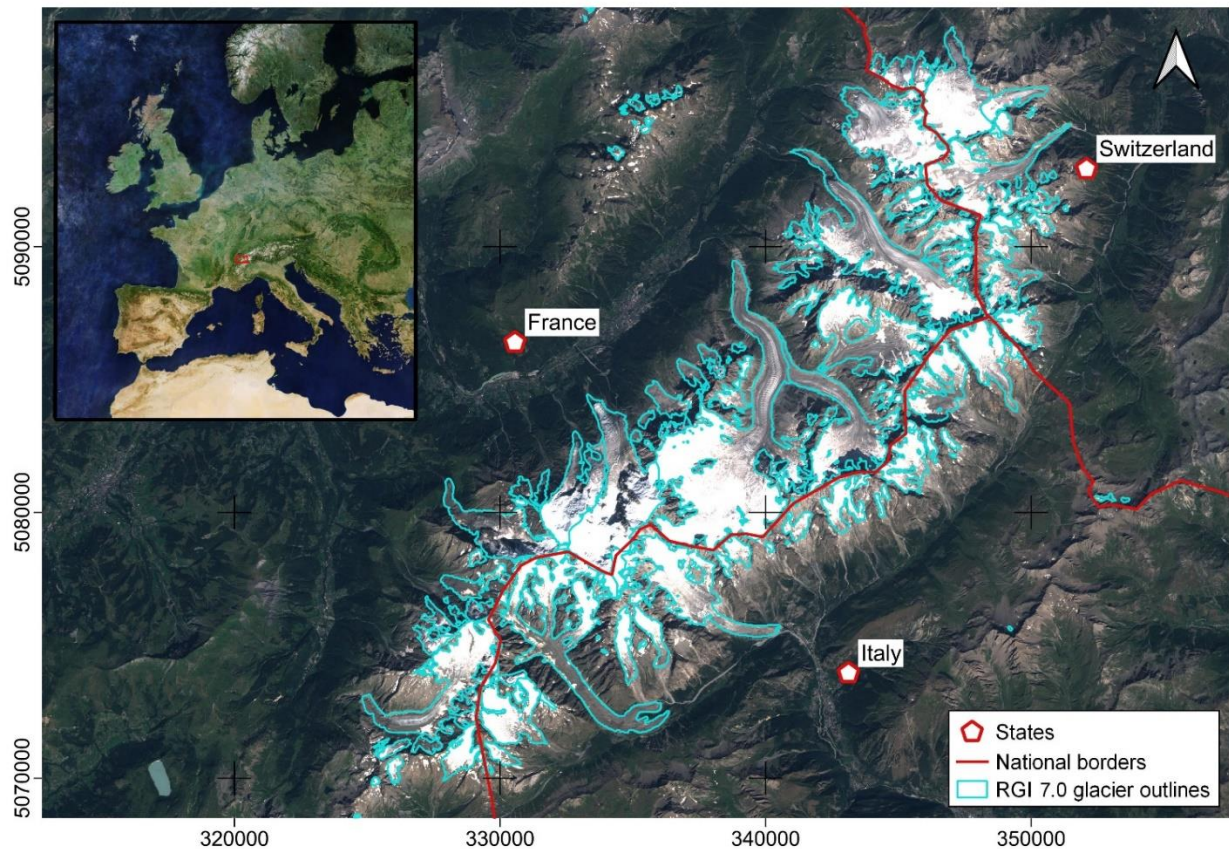

79 and Moreau, 2016). The same trend was highlighted by Span and Kuhn (2003) for at least six other glaciers: Saint Sorlin in  
80 France, Gietro and Corbassiere in Switzerland; Pasterze, Vernagtferner and Odenwinkelkees in Austria. At Miage Glacier,  
81 surface velocities have been measured historically by different authors (Diolaiuti et al., 2005; Smiraglia et al., 2000; Fyffe,  
82 2012; Lesca, 1974; Pelfini et al., 2007; Deline, 2002) and also show a general velocity decrease in recent decades (Smiraglia  
83 et al., 2000; Fyffe, 2012). Glaciers such as Miage and Argentière, reach a low altitude and have flat and little crevassed valley  
84 tongues, for this reason, they have often been historically chosen for glaciological field surveys (Span and Kuhn, 2003).  
85 Therefore, the knowledge of Alpine glacier kinematics is generally mostly related to this type of glacier, which can be  
86 significantly different compared to the other glaciers analysed in this study.

87 Globally, glacier slowdown linked to a negative mass balance trend was also shown for six different regions around the  
88 globe and dates spanning from 1953 to 2009 by Heid and Kääb (2012b) by an analysis of remotely-sensed optical images.  
89 Specific analysis of velocity trends and glacier mass loss showed generalized decreasing velocity trends over different regions  
90 of High Mountain Asia between 2000 and 2017 and a strong correlation with the negative mass balance trend (Dehecq et al.,  
91 2019).

92 The main purposes of this study are the production of eight-year-long velocity time series of the surface velocity of thirty  
93 glaciers at a massif scale, derived from Sentinel-2 optical images, as well as an integrated analysis of morphological and  
94 kinematic features of such glaciers. The identification of possible trends in the velocity time series is a major objective of the  
95 present study. We observed different behaviours of surface velocity and identified a relationship between seasonality and  
96 glacier size.

## 97 **2 Area of study**

98 The study area is the Mont Blanc massif. It is located in the western part of the European Alps bordering France, Italy and  
99 Switzerland (Fig. 1) and culminating at 4809 m a.s.l. with the Mont Blanc summit, the highest peak in Central Europe. Many  
100 other peaks in the Mont Blanc massif reach well above 4000 m a.s.l. and the entire area is very highly frequented with famous  
101 tourist resorts such as Courmayeur and Chamonix attracting thousands of tourists every year.

102 **Fig. 1 Study area of the Mont Blanc massif. Background: true colour image (cloud-free Europe mosaic in the upper**  
 103 **left panel), courtesy of the Copernicus Open Access Hub (<https://scihub.copernicus.eu>, last access: 10 September**  
 104 **2023).**  
 105

106 The total surface of glaciers in the Mont Blanc massif is equal to 169 km<sup>2</sup> and totals 116 glaciers, according to the Randolph  
 107 glacier inventory (RGI 7.0) (RGI Consortium, 2023). The inventory refers to 2003 (Pfeffer et al., 2014; Arendt et al., 2017).  
 108 Forty glaciers are very small, covering an area of less than 0.1 km<sup>2</sup>, forty-seven have surfaces comprised between 0.1 and 1  
 109 km<sup>2</sup>, sixteen glaciers fall in the range between 1 km<sup>2</sup> and 3 km<sup>2</sup>, and thirteen glaciers have surface areas of more than 4 km<sup>2</sup>.

110 The geological setting and the geomorphology of the Mont Blanc massif form a high mountain range with its main ridge  
 111 line oriented in a southwest/northeast direction along the French-Italian border. The valley floors flanking the massif have low  
 112 altitudes - in the range of 1000-1500 m a.s.l. - resulting in steep slopes originating from the highest peaks with large vertical  
 113 altitudinal differences. The meteo-climatic local conditions on the massif are of a continental type, but orographic effects on  
 114 the predominant incoming weather fronts produce larger precipitation compared to nearby regions (Gottardi et al., 2012).

115 The Argentière Glacier is the only glacier with regular mass balance measurements included in the World Glacier  
 116 Monitoring Service (WGMS) 'Reference Glaciers' dataset in the Mont Blanc Massif (Zemp et al., 2009). The Argentière  
 117 Glacier has shown a general negative mass balance trend since the early 1990s (Vincent, 2009), in line with mass balances of  
 118 other Alpine glaciers and glaciers from other mountain ranges across the globe. Geodetic mass balance measurements of the  
 119 Thoula Glacier, a small glacier on the border between France and Italy at altitudes between 2900 and 3300 m a.s.l., represent

120 well the local meteo-climatic conditions that result in slightly less negative mass balance trends compared to other glaciers in  
121 the Alps (Zemp et al., 2021; Zemp et al., 2020; Mondardini et al., 2021).

122 A more spatially distributed analysis of mass balances in the Mont Blanc region has also been outlined in the literature  
123 employing geodetic mass balances of the whole Mont Blanc massif using stereo satellite imagery from the Pléiades and Spot  
124 satellite constellations (Berthier et al., 2014; Beraud et al., 2023). The trend outlined by Berthier et al. (2023) at the massif  
125 scale, reflects data trends comparable to the glaciological mass balances of WGMG reference glaciers in the Alps. Glaciers at  
126 lower altitudes show larger ice volume losses and subsequent substantial glacier front retreats (Paul et al., 2020), while glaciers  
127 at higher altitudes suffer less acute volume loss and shrinkage. Large differences in the glacier frontal position, especially for  
128 the lower altitude terminating glaciers, can be well assessed by the difference of the terminus position in recent satellite imagery  
129 compared to the position outlined on the RGI 7.0.

## 130 **3 Materials and Methods**

### 131 **3.1 General workflow**

132 In this paper, we analysed the Copernicus - ESA Sentinel-2 optical satellite imagery dataset available for the study area. In  
133 addition, we used Pleiades Stereo derived digital elevation models (DEMs) to retrieve morphometric data of glaciers, and  
134 publicly available modelled ice thickness data from Millan et al. (Millan et al., 2022). We used digital image correlation (also  
135 known as feature tracking) to produce monthly-averaged and multi-year averaged velocity maps to investigate variations of  
136 glacier surface velocity in time and space over the selected glaciers. We can hereby summarize the workflow that was used  
137 (Fig. 2).

138 The input data are a DEM of the area of study, the RGI glacier outlines, the modelled glacier thickness and the stack of  
139 Sentinel-2 images in the reference period. The input DEM is used to obtain morphometric data of the glacier while the RGI  
140 glacier outlines are used, together with the selected satellite imagery, to choose suitable glaciers for surface glacier velocity  
141 analysis. After the glacier selection, we updated the RGI glacier outlines according to the current glacier extensions. Selected  
142 imagery is processed with digital image correlation to obtain glacier velocities. The glacier flowlines of the RGI are then used,  
143 together with the updated glacier outlines and the mapped equilibrium line altitudes (ELAs), to identify sampling areas to  
144 extract velocity time series. ELAs are manually digitized each year by the analysis of Sentinel-2 imagery. Subsequently, the  
145 time series are analysed to identify general trends, seasonal patterns or particular kinematic behaviours. Finally, the velocity  
146 dataset is analysed in relation to the morphological characteristics (in particular their size) of the glacier.

**Fig. 2 Workflow of the present study. The input datasets are evidenced in light blue while the processing steps are indicated in white boxes.**

150

### 151 3.2 Sentinel-2 optical satellite imagery

152 We adopted Sentinel-2 optical images acquired between February 2016 and February 2024. We chose to start the analysis  
153 in 2016 because it was the first full year of acquisition by the satellite. Based on different publications (Kääb et al., 2016;  
154 Millan et al., 2019), the geometric misregistration of Sentinel-2 can show up to 1.5 pixel offsets in the horizontal plane even  
155 if it can be usually closer to a value of 0.5 pixels, which corresponds to the absolute geolocation specification by ESA.  
156 Therefore, an image co-registration process or a correction of stable ground shifts is normally needed for multitemporal  
157 analyses.

158 To select the images, we defined the presented approach: (i) to maximize the geometric and geo-referencing precision, we  
159 adopted images acquired from the same orbit and tile (GRANULE T32TLR, relative orbit 108); (ii) to reduce the impact of  
160 clouds, we carried out a visual check of all images with a cloud cover percentage lower than 80% (as detected by the Copernicus  
161 cloud cover estimation algorithm) on the whole tile, which were 323 in total (150 from Sentinel 2B and 173 from Sentinel  
162 2A). From this dataset, we extracted a subset of 123 cloud-free images on the selected glacier areas via the visual inspection  
163 of the individual images. We adopted this manual selection to maximize the quality of the images; in the case of the Mont  
164 Blanc massif (like in most mountainous areas worldwide), the local distribution of clouds can be extremely variable; in many  
165 cases, this can contribute to a considerable cloud percentage, even though high altitude areas may still be cloud-free.

166 The number of suitable images that are available per year varies from 10 to 20 with a yearly mean of 15 images in the  
167 following distribution: 2016: 10; 2017: 18; 2018: 11; 2019: 14; 2020: 13; 2021: 16; 2022: 20, 2023: 19, 2024: 2. The year  
168 2016, and partially 2017, is influenced by the lack of Sentinel 2B images, which was launched on 7 March 2017.

169 To apply image correlation, we used the near-infrared band B08 at the processing level L1C as suggested by previous  
170 studies (Kääb et al., 2016).

### 171 **3.3 Glacier selection**

172 To minimize the presence of noisy and unreliable velocity data, we performed a selection of glaciers from the RGI 7.0  
173 dataset. In particular, we did not include in our study: A) glaciers with an area  $< 0.1 \text{ km}^2$ , as those glaciers would be too small  
174 for the reliable extraction of velocity maps with 10 m resolution optical satellite imagery (Millan et al., 2019); B) glaciers  
175 showing strong variations of cast shadow; C) glaciers that lack surface features to be tracked (e.g., ice caps).

176 Selection of point B) was made by creating a stack of images acquired between October and March, when cast shadows  
177 appear on satellite imagery, especially on north-facing slopes. Subsequently, we manually identified glaciers that are subject  
178 to large variations of shadow on their surface. We used the scene classification map (SCL) class 11 (cast shadows), available  
179 in processing level L2A of the Sentinel-2 images. However, since shadows on glaciers may often be misclassified, we  
180 conducted a manual check to correct potential errors. Selection of point C) is made manually by selecting glaciers that show  
181 very even surfaces on Sentinel-2 images. This is normally noted in ice caps at higher altitudes or flat valley tongues.

182 The glacier selection process identified thirty glaciers with a total glacierised surface (at 2018) of  $85.8 \text{ km}^2$ . Compared to  
183 the total glacierised surface of the massif from RGI 7.0, this represents the covering of 50.8% of the total  $169 \text{ km}^2$  and 25.9%  
184 in terms of number of glaciers; this rises to 39.5% if we consider the subset of seventy-six glaciers having a glacierised surface  
185 of more than  $0.1 \text{ km}^2$ . The selected glaciers are highlighted in Fig. 3 and listed in Table 1. Two of the selected glaciers are  
186 located in Switzerland, ten are located in France and eighteen in Italy. This distribution is mainly due to a small portion of the  
187 massif being located in Switzerland and the presence of more fragmented glacierised bodies on the Italian side. Of the thirty  
188 glaciers, seven have been mapped as sub-areas in comparison to RGI 7.0 individual glacier bodies. A brief description of all  
189 the glaciers we analysed is found in section S1.1, to describe the location and geomorphological setting of the glaciers as well  
190 as highlight when a single glacier complex from the RGI 7.0 was divided into independent glacial bodies because of very  
191 distinct kinematic behaviour.

192  
193  
194  
195 **Fig. 3** Surface glacier velocity map averaged in the 2016-2024 period. Selected glaciers for specific analyses are outlined in cyan. Background: Sentinel-2 image (B08 band), courtesy of the Copernicus Open Access Hub (<https://scihub.copernicus.eu>, last access: 10 September 2023).

196 **3.4** Glaciers' outline delineation and morphometric data calculation

197 Since the RGI 7.0 glacier outlines refer to 2003, we updated them to fit with the present glacier extensions and manually  
198 outlined them from Sentinel-2 imagery. We selected a cloud-free scene acquired on 28 August 2018 that represents well the  
199 conditions of the glaciers in the study period; True Color Image was used for this purpose. The main morphometric data that  
200 were determined for each glacier are summarized in Table 1. In some cases, a morphological indication that some parts of the  
201 glaciers could be considered independently from others and divided into individual kinematic domains was considered (Paul  
202 et al., 2022; Zemp et al., 2021). As the velocity maps confirmed distinct behaviours of some glacier parts, those glaciers were  
203 divided and mapped accordingly. The main examples are the tributary glaciers of the larger Miage Glacier complex, which all  
204 have distinct kinematic behaviour, well differentiated from the slow-moving, debris-covered main central valley tongue.  
205 Another example is the Talèfre Glacier, where, over the past twenty years, the western part of the glacier has become  
206 independent from the eastern portion.

207 The determination of morphometric data of sample glaciers was performed using altitudinal data from a 2 m resolution  
208 DEM obtained by the processing of Pleiades stereo pairs acquired in August 2018 (Berthier et al., 2014), while the mean

209 glacier thicknesses were extrapolated from globally modelled ice thickness data (Millan et al., 2022), which has an average  
 210 uncertainty of 30%.

211

### 214 3.5 Glaciers' surface velocity calculation

215 Digital image correlation is a common technique used to measure surface displacements using proximal (Evans, 2000; Ahn  
216 and Box, 2010; Schwalbe and Maas, 2017; Dematteis et al., 2024) and remotely sensed imagery (Scambos et al., 1992; Heid  
217 and Kääb, 2012; Marsy et al., 2021; Dematteis and Giordan, 2021). The processing chain performed in the present study uses  
218 the open-source Glacier Image Velocimetry (GIV) toolbox (Van Wyk De Vries and Wickert, 2021). GIV uses frequency-based  
219 correlation, can efficiently process large datasets and has been shown to perform well on glacier surface velocity measurements  
220 at different test sites (Van Wyk De Vries and Wickert, 2021). GIV calculates stable-ground shifts to correct for georeferencing  
221 errors; therefore, we created a stable ground mask composed of non-glacierized terrain surrounding the massif, and fit a 2D  
222 second-degree polynomial to the residual velocities over stable ground in the x- and y- directions. To measure glacier surface  
223 velocities, we adopted the 'multi-pass' option which updates displacement estimates over multiple iterations, refining initial  
224 coarse chip size displacement calculations using progressively smaller chip sizes. The initial chip size is automatically defined  
225 by GIV and cannot be smaller than 32x32 px. The overlap between matching windows was 0.5. Velocities higher than 1500  
226  $\text{m yr}^{-1}$  were considered unrealistic and discarded. The velocity map resolution was set to 40 m, without resampling. Finally,  
227 we smoothed the velocity maps by applying a 3x3 median filter.

228 To produce the time series, given a specific image, we processed the first and second subsequent images (GIV order 2  
229 time-oversampling). The minimum and maximum temporal repeat cycles were respectively 10 and 120 days. Overall, we  
230 calculated 218 image pairs, with an average temporal baseline of 35 days (Sec. S8).

231 Subsequently, the velocities of image pairs were averaged on a monthly basis. We applied the weighted average included  
232 in GIV, where the weights are proportional to the fraction of time included in a given month over the total time gap between  
233 the image pairs. The presence of clouds or snow on the glacier surface made it impossible to extract reliable data in the  
234 following months: i) January 2017 ii) December 2020, January and February 2021 iii) September 2021. The gaps represent  
235 only five months on which we did not retrieve velocity data out of the eight years considered in the study (i.e., <5%). In Fig.  
236 3, we present a velocity map with a resolution of 40 m. This was obtained by averaging all the single monthly velocity maps  
237 in the study period (2016-2024). In Fig. 4, we present an example of the obtained velocity map and the distribution of sampling  
238 areas over several chosen glaciers. All other parameters of the GIV processing were set at default parameters (Supplementary  
239 Materials section S5).

### 246 3.6 Velocity time series analysis

247 Sampling areas were identified on the velocity maps to analyse the time series of the selected glaciers. Since the surface  
248 velocity of land-terminating glaciers is expected to be the highest in correspondence with the ELA (Nesje, 1992), we cropped  
249 the RGI 7.0 flowlines at the upper and lower altitudinal limits of the ELAs mapped between 2016 and 2023. Around this  
250 section of the ELA, we buffered an area of 40 m (Fig. 4). The velocity values included in the obtained polygons were averaged  
251 to produce the time series (i.e., the velocity was not calculated over the whole glaciers, but only in the region of the ELA).

252 Subsequently, we applied a quadratic locally weighted scatterplot smoothing (LOWESS) (Cappellari et al., 2013) evaluated  
253 on a rolling window of twelve months. Finally, we calculated the linear trend of the smoothed series using the Huber loss  
254 regressor (Huber, 1992). The Huber fit is robust against outliers; thus, sharp velocity fluctuations should not affect the obtained  
255 linear trends. To evaluate the statistical significance level of the fit, we consider the *t-statistics*, i.e., the ratio between the  
256 coefficient values and their standard errors. According to its definition, the *t-statistics* is expected to be low when the slope of  
257 the linear fit is low and/or when the slope is relatively low compared to the data variability.

258 We performed the principal component analysis (PCA) of the time series to investigate the overall behaviour of all the  
259 considered glaciers, and we weighted the time series according to the glacier area. The PCA is a multivariate analysis technique  
260 that allows a reduction in the dimensionality of a given dataset, increasing interpretability but minimising information loss.  
261 This is achieved by creating new, uncorrelated variables that successively maximise the variance of the dataset (Jolliffe and  
262 Cadima, 2016).

## 263 4 Results and discussion

### 264 4.1 Distributions of monthly velocities

265 Overall, the velocities of the thirty glaciers we investigated in this study, the monthly velocity values range from 30-40 m  
266  $\text{yr}^{-1}$ , typically reached during winter months by smaller glaciers, to  $> 400 \text{ m yr}^{-1}$ , typically reached in summer/late summer by  
267 faster glaciers. The highest velocities are attained by the Brenva and the Bossons glaciers. In particular, monthly extreme  
268 values vary from  $11.8 \pm 9.8 \text{ m yr}^{-1}$ , reached on January 2022 by the Des Glaciers Glacier, to  $487.4 \pm 10.8 \text{ m yr}^{-1}$ , reached  
269 by the Brenva Glacier in July 2016. The mean surface velocities averaged over the whole period range from  $29.9 \pm 10.9 \text{ m}$   
270  $\text{yr}^{-1}$  at the Pierre-Joseph Glacier to  $375.9 \pm 10.9 \text{ m yr}^{-1}$  at the Brenva Glacier. The standard deviation of the velocity time  
271 series of single glaciers varies from  $10.3 \text{ m yr}^{-1}$  at the Pierre Joseph Glacier to  $70.7 \text{ m yr}^{-1}$  at the Charpoua Glacier. Fig. 5  
272 presents the distributions of the raw monthly velocity of the considered glaciers.

**Fig. 5. Boxplot showing the distributions of the glaciers' raw monthly velocity. Glaciers are sorted by their median velocity. The background colours of the glacier names indicate their size: white < 1 km<sup>2</sup>; green 1-4 km<sup>2</sup>; blue >4 km<sup>2</sup>. The boxes's limits and central line represent the first, second (i.e., the median) and third quartiles, respectively; the whiskers indicate the first/third quartiles minus/plus 1.5 IQR (interquartile range). The white circles are outliers.**

## 4.2 Velocity time series

Large and thick glaciers have in general high velocities, and two of them (Brenva and Bossons) show the highest values. The velocity values remain high throughout the whole year (Fig. 6). Brenva displays irregular seasonality variations, while Bossons has an almost absent seasonal cycle. Their morphology is complex - e.g., the slope varies considerably along their extent. In the present study, we concentrated the analyses on the middle sectors (near the ELA) of the glaciers, which are the fastest (Nesje, 1992). In the time series, the biggest glacier (Mer de Glace) appears slower because we extracted the monthly velocity over an area which does not entirely include the most active sector of the Mer de Glace Glacier (i.e., the Géant Ice Fall), where the velocity reached values >400 m yr<sup>-1</sup>.

Medium-sized glaciers' morphology is less homogeneous, even though most are generally gentler and thicker than average. We can divide the group into two sets based on the elongation ratio. Medium-sized glaciers which are more elongated generally feature strong kinematic activity, their velocity is higher than average with marked variability and they often show a pronounced regular annual cycle, as in the cases of the Bionassay (IT), Brouillard, Mont Blanc and Freney glaciers. The second set of more "compact" glaciers, show lower mean velocities and have a minor amplitude of the seasonal variability. In particular, even though some display a regular seasonal cycle (e.g., Planpincieux, Dome, Rochefort), their velocity variability is much lower (Fig. 6).

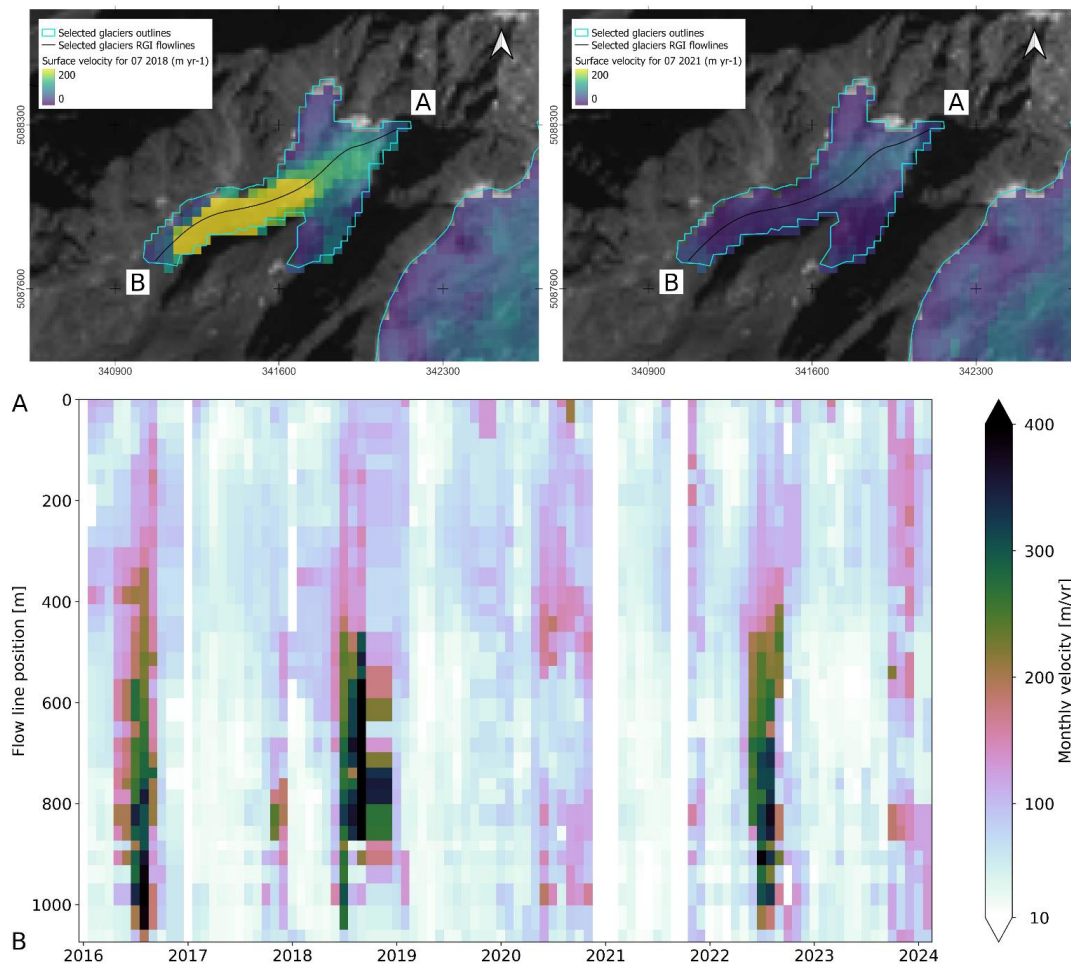

293 Small glaciers show lower average velocities, but most show marked and regular seasonality. In this group, some very  
294 small glaciers (e.g., Greuvettaz W, Greuvettaz E, A Neuve N, Pierre Joseph) show a modest, irregular or even non-detectable  
295 seasonal cycle since the velocity in winter is close to the measurement uncertainty (Fig. 6). It is worth highlighting that signals  
296 of potential velocity fluctuations could exist but remotely-sensed data are not currently suited for analysing such small glaciers.  
297 On the other hand, Pra Sec and Charpoua, small steep elongated glaciers, feature very low minimum velocities (between  
298  $25 \text{ m yr}^{-1}$  and  $50 \text{ m yr}^{-1}$ ) and very marked peaks during which the velocity increased by one order of magnitude. These high  
299 velocity periods appear in summer/late summer and extreme velocity changes from winter to summer velocities can be noticed.  
300 In 2016, 2018 and 2022, the summer velocity of Charpoua Glacier was exceptionally high compared to the usual. Moreover,  
301 in these years, the spatial distribution of velocities varied, and the highest velocities were registered towards the frontal part of  
302 the glacier, while normally it was higher in the upper sector (Fig. 7). Pra Sec Glacier displays more regular annual speedups  
303 in the period analysed, every summer it had a clear velocity peak (except in 2018), particularly pronounced in 2016, 2020 and  
304 2022. In both glaciers, possible glacier advances are prevented by the steep bedrock cliff at the snout, which causes the  
305 disintegration of the glacier by repeated ice falls from the terminus (Giordan et al., 2020; Pralong and Funk, 2006).

### 318 4.3 Interannual velocity variability and trend

319 The overall behaviour of the glacier velocity can be well represented by the PCA of the time series, weighted by the glacier  
320 area. Fig. 8 shows the 1<sup>st</sup> PC, which explained >50% of the variance. In general, this analysis reflects a common trend of many  
321 time series: a first period between 2016 and 2019 showing decreasing velocities, an anomaly of higher velocities between 2020  
322 and 2022 followed by a new velocity decrease in 2023 (Fig. 6). According to historical observations at the Argentière and  
323 Miage glaciers, the velocity decrease from the early 2000s can be linked to continuous negative mass balances (Vincent and  
324 Moreau, 2016) of most Alpine glacier since the 2000s (Zemp et al., 2021). The results of our study agree with this negative  
325 trend in the first part of the considered period (i.e., 2016–2019), but we detected a rupture in the trend and a velocity rise from  
326 2020 to 2022 occurring in a large number of glaciers under study. An interesting remark about the geographical distribution  
327 of the trends is that the glaciers showing a clear velocity anomaly during 2020-2022 are located on the southeast side of the

328 massif ridgeline along the Italian and Swiss part of the Massif (e.g., A Neuve Central, Bionassay (IT), Brenva, Planpincieux  
 329 and Lex Blanche glaciers). This might be linked to different dominant meteorological conditions distributions on the two sides  
 330 of the massif. A specific analysis of seasonal meteorologic data in the different areas could give more insights into this  
 331 hypothesis, even though whether stations are located far from the glacier accumulation areas and could not get a specific signal  
 332 present in the higher altitude sectors.

333  
 334

**Fig. 8. 1<sup>st</sup> PC of the LOWESS velocity values of all the time series of glacier monthly velocity.**

335 The glacier velocities shown in Fig. 6 have different linear trends over the full period of the study (Fig. 9). In general, the  
 336 linear trends of each glacier calculated using winter, summer months or the whole year have similar behaviour (i.e., they are  
 337 always negative or positive), with winter trends having higher absolute values than summer ones in case of positive acceleration  
 338 and lower in case of negative acceleration (~30% difference on average). As expected, lower absolute linear trends (i.e.,  $\leq 1$   
 339  $\text{m yr}^{-2}$ ) have  $t$ -statistics  $< 2$ . Besides, even though Brenva's trend is high ( $2.8 \text{ m yr}^{-2}$ ), its velocity is very large, thus lowering  
 340 the  $t$ -statistics. Most trends lie in a relatively tight cluster which crosses the domain diagonally, except for Charpoua and  
 341 Planpincieux which have dissimilar seasonal values. In the Charpoua case, this is probably related to the strong velocity  
 342 fluctuations occurring only in some years in summer, while the Planpincieux positive summer trend is likely led by the anomaly  
 343 2020-2022, which is particularly strong in this glacier. Notably, the three glaciers with the highest linear trends (i.e., Freney,  
 344 Bionassay (IT) and Aiguille de Tré-la-Tete) are all located in Val Veny, on the southern side of the massif. Bionassay (IT) and  
 345 Freney have a very similar morphology (Tab. 1), they are both medium-size ( $1.3 \text{ km}^2$  and  $1.02 \text{ km}^2$ ), relatively elongated ( $2.2$   
 346  $\text{m}^{-1}$  and  $2.5 \text{ m}^{-1}$ ) glaciers, with slopes of  $\sim 25^\circ$  and elevations between 2400 m a.s.l. and 3800 m a.s.l.. Differently, Aiguille de  
 347 Tré-la-Tete is a small ( $0.3 \text{ km}^2$ ), much-elongated ( $4.34 \text{ m}^{-1}$ ) and low-altitude glacier (2408-3010 m a.s.l.). Aiguille de Tré-la-  
 348 Tete and Bionassay (IT) are both tributaries of the Miage Glacier.

349 An accelerating trend ( $+5 \text{ m yr}^{-2}$  between 2015-2021) has recently been shown for the Brenva Glacier by an analysis of  
 350 remotely-sensed optical images (Rabatel et al., 2023b) while detecting decelerating trends on many other glaciers of the Massif.  
 351 Our study showed Brenva Glacier an accelerating trend of  $+3 \text{ m yr}^{-2}$  between 2016-2024, which is in good agreement  
 352 considering the velocity decrease shown in 2022 and 2023 (the linear trends of annual velocity over the overlapping period of  
 353 this study and Rabatel et al (2023b) – from February 2016 to December 2021 – are respectively  $0.85 \text{ m yr}^{-2}$  and  $0.68 \text{ m yr}^{-2}$

354 (Tab. S1)). Besides, Rabatel et al. (2023b) observed a slight ice thickening (~1 m between 2000 and 2019) in an upper sector  
355 of the Brenva Glacier, which agrees with the findings of Bertier et al (2023) between 2012 and 2021, obtained with high-  
356 resolution satellite images. They proposed three hypotheses to explain the acceleration of the Brenva: a) a glacier thickening;  
357 b) a change in thermal regime; and c) a change in subglacial hydrology, possibly related to an increased ablation in the upper  
358 reaches of the glacier.

359 Even though the hypothesis of glacier thickening could explain the specific case of Brenva, the glacier surface elevation  
360 change across the Mont Blanc massif has been generally negative in the last years, as evidenced by the negative mass balance  
361 of the reference glaciers in the area (Zemp et al., 2021; Zemp et al., 2009) as well as massif scale studies (Berthier et al., 2023).  
362 Local anomalies of positive mass balance could explain an increase of velocity but the lack of measurements at higher altitudes  
363 does not allow us to confirm this behaviour at present. However, the meteorological conditions in recent years have remained  
364 approximately constant, which makes unlikely a general glacier thickening in the region (see S6 “Meteorological conditions”).  
365 Localized higher than usual rates of accumulation due to increased avalanche activity and wind accumulation could also  
366 contribute to the ice thickening (thus yielding an acceleration), but cannot be investigated at this stage. It is worth highlighting  
367 that the three glaciers highlighting a high winter accelerating trend in Fig. 9 (Bionassay (IT), Aig Tré la Tete and Freney) are  
368 near to each other and located in a small part of the massif on its southeast side.

369 A change in the thermal regime of the glaciers could explain accelerating trends, but it would explain long-term trends and  
370 not short-period variations such as the one highlighted in 2020-2022, as basal temperature measurements show a warming at  
371 the ice bedrock interface on a decadal to multi-decadal timescale on the Mont Blanc massif (Vincent et al., 2007).

372 A variation of the hydrology of groups of glaciers is a plausible hypothesis for the explanation of accelerating trends, but  
373 it would result in stronger trends in summer rather than in winter, as basal sliding is enhanced over deformation during summer.  
374 Such a combination of trends is not shown by most glaciers as highlighted in Fig. 9. Only the trends of Planpincieux and Mer  
375 de Glace glaciers could relate well with this hypothesis, showing almost no trend in winter and an accelerating trend during  
376 the summer months.

377 The distribution of the acceleration trend over different areas of the massif and regarding different types of glaciers could  
378 suggest the existence of a meteo-climatic driver of the phenomenon, even though it is not evident limiting the analysis to the  
379 period 2015-2023 (Section S6). In the end, a definitive answer cannot be formulated so far and further research is necessary  
380 to understand the processes involved in this trend.

**Fig 9. Linear trends of the glacier monthly velocity. The x- and y-axes refer to the trends calculated using winter (from November to April) and summer (from June to September) months, respectively. The colours indicate the global trend. The glaciers with linear trends with  $t$ -statistic < 2 have markers with dashed edge lines.**

#### 4.4 Relationship between glacier size, velocity and seasonal behaviour

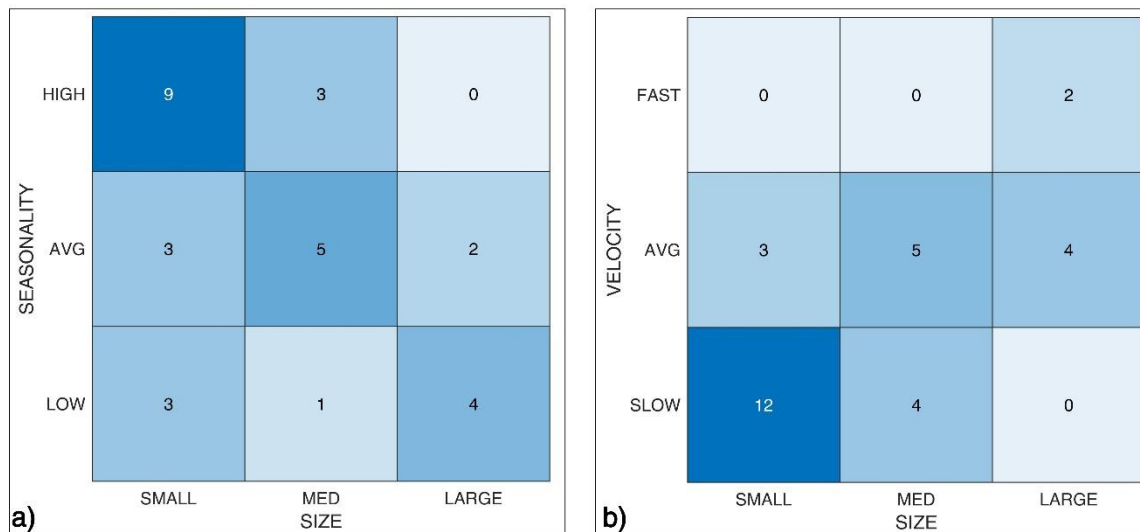

We examined the relationship between the glacier size, the seasonal velocity behaviour and velocity distribution. To this end, we divided the glaciers into three classes for each feature. Concerning the size, we considered very small glaciers with an area of < 1 km<sup>2</sup>, according to (Bahr and Radić, 2012), while medium and large glaciers have areas between 1 km<sup>2</sup> and 4 km<sup>2</sup>, and >4 km<sup>2</sup>, respectively. Concerning the velocity distribution, we observed that, besides Brenva and Bossons, which have much higher velocity compared to the rest of the glaciers, a group of sixteen glaciers have the 75<sup>th</sup> percentile of monthly velocity < 100 m yr<sup>-1</sup> (from Pierre Joseph to Charpoua in Fig. 5). Finally, twelve glaciers have their 25<sup>th</sup> and 75<sup>th</sup> percentiles between ~100 m yr<sup>-1</sup> and ~200 m yr<sup>-1</sup> (from Des Rognons to Freney in Fig. 5).

Concerning the seasonal velocity behaviour, we analysed the raw time series (Fig. 6) and the LOWESS smoothed time series normalised by their median value (Fig. S6). Glaciers such as Freney, Brouillard, and Bionassay (IT) show evident and regular seasonal behaviour and large winter/summer differences; in these cases, summer velocities (occurring between July and October) are 50% to 100% higher than winter ones (occurring between January and April). Another group of glaciers has smaller winter/summer differences or pronounced but irregular variability (e.g., Planpincieux, Pre de Bard, Talefre). A third group does not display evident or regular seasonal behaviour (e.g., Taconnaz, Mer de Glace, Pierre Joseph), with

399 winter/summer differences below 10%. Overall, the maximum velocity occurs in August-September, while the annual  
 400 minimum is reached in March (Fig. 8).

401 The double-entry heatmaps are presented in Fig. 10, which show a tendency for the smaller glaciers to have more  
 402 pronounced seasonality, while larger glaciers show a more homogeneous velocity throughout the year. Since the glacier area  
 403 is strongly correlated with its thickness (Cuffey and Paterson, 2010), a possible cause of this phenomenon could be related to  
 404 enhanced basal sliding during the accelerating period. In fact, a thicker glacier could be less prone to exhibit enhanced sliding  
 405 because of the larger mass to be uplifted by basal positive water pressures, while shallower glaciers could more easily benefit  
 406 from enhanced sliding by pressure build-up at the ice-bedrock interface by increasing inputs in the hydrological subglacial  
 407 drainage network. Moreover, in winter, the base of thin glaciers could freeze, thus preventing the sliding and determining  
 408 lower winter velocities causing even larger summer-winter velocity differences.

409 On the other hand, as expected, larger (and thicker) glaciers tend to be faster than smaller ones.

410

411 **Fig. 10 Glacier classification according to their size (SMALL: <1 km<sup>2</sup>; MED: 1-4 km<sup>2</sup>; LARGE: >4 km<sup>2</sup>) and a)**  
 412 **seasonal velocity behaviour (qualitatively estimated) and b) median velocity (SLOW: <100 m yr<sup>-1</sup>; AVG: 100-300 m**  
 413 **yr<sup>-1</sup>; FAST: >300 m yr<sup>-1</sup>). The digits within the grid tiles indicate the number of glaciers belonging to each group.**

#### 414 4.5 Uncertainty analysis

415 To estimate the quality of our data, we performed two investigations. First, following the method proposed by (Millan et  
 416 al., 2019), we calculated the median absolute deviation of the velocity obtained on stable terrain for each monthly data. In  
 417 these areas, we applied an outlier spatial filter to the velocity maps according to Rabatel et al. (2023a). The median value of  
 418 the monthly uncertainty was 10.9 m yr<sup>-1</sup>. In their study, Millan et al. (2019) estimated the nominal precision according to the  
 419 temporal baseline between the correlated images, which they found to be between 6–16 m yr<sup>-1</sup> for baselines respectively of 40  
 420 and 20 days, which is the typical range of temporal gaps between images used in our study. Moreover, the value of 10.9 m yr<sup>-1</sup>  
 421 is in close agreement with the uncertainty found by Mouginit et al. (2023), which obtained a root mean squared error of 10.5  
 422 m yr<sup>-1</sup> between glacier velocities measured over the Mer de Glace and Argéntiere glaciers using image correlation of Sentinel-  
 423 2 images and GNSS in situ data (<https://glacioclim.osug.fr/>). A comparison with the data from Rabatel et al. (2023a) is  
 424 proposed in the supplementary materials (Sec. S4, Fig. S3 and Tab. S1) for the glaciers of Brenva, Bionassay (FR), Bossons

425 and Brouillard over the timespan that overlaps the two studies (from February 2016 to December 2021), which evidences high  
426 agreement between the two studies.

427 Second, we considered the glacier velocity from Millan et al. (2019), who published mean annual velocity in the period  
428 2017–2018 on a 50x50 m regular grid. They adopted normalised cross-correlation and chip size refinement (initial size of  
429 16x16 px). They estimated an overall uncertainty of glacier surface velocity time series of  $\sim 12 \text{ m yr}^{-1}$  over the Mont Blanc  
430 glaciers, and, specifically at Brenva and Bosson glaciers, an uncertainty of 15–20  $\text{m yr}^{-1}$ . We compared these data and ours  
431 along four glacier longitudinal central lines (i.e., in Bossons, Brenva, Freney and Taconnaz), obtaining good agreement (Fig.  
432 11). The largest differences ( $>50 \text{ m yr}^{-1}$ ) were found in a specific sector of the Taconnaz Glacier (Fig. 11d), where the ice flux  
433 is highly channelized in a narrow passage. There, the data of Millan et al. (2019) show a large velocity decrease that seems  
434 unlikely considering the geometry of the site. Our data show a similar but less pronounced velocity decrease. However, the  
435 velocity profiles are similar elsewhere. On average, the surface velocities that we obtained are slightly higher, with a mean  
436 difference of  $0.03 \text{ m yr}^{-1}$  and root mean squared deviation (RMSD) of  $24.0 \text{ m yr}^{-1}$  (Table 2). The slightly higher RMSD  
437 compared to the expected uncertainty can be due to the fact that the error over glacierized areas is probably larger than in ice-  
438 free zones because the surface texture is different and changes (e.g., snow precipitation, surface melt, glacier movement) occur  
439 more rapidly, therefore causing more decorrelation (Millan et al., 2019).

440

447 **Table 2. Mean difference and root mean squared deviation (RMSD) between this study and Millan et al. (2022) along velocity**  
 448 **longitudinal profiles.**

	Bossons	Brenva	Freney	Taconnaz	Mean all profiles
Mean difference [m yr <sup>-1</sup> ]	-13.1	-8.8	13.7	8.3	0.03
RMSD [m yr <sup>-1</sup> ]	22.3	25.2	29.6	19.0	24.0

#### 454 4.6 Uses and limits of the proposed methodology

455 The methodology presented in this study allows the detection of monthly changes in glacier velocity, which can be  
 456 precursors of ice avalanches (Pralong et al., 2005; Faillettaz et al., 2008; Giordan et al., 2020). For example, ice avalanches  
 457 from the Pra Sec Glacier occurred in 2020 (Forestry Service of Aosta Valley). In our study, we observed high velocities in  
 458 2020, which could have led to the break-off. At the Charpoua Glacier, an ice avalanche of 45000 +/- 15000 m<sup>3</sup> occurred in  
 459 2018 (Lehmann, 2018 - <https://news.unil.ch/display/1536777918113>, accessed online 11 October 2023), when we measured  
 460 velocities >200 m yr<sup>-1</sup>, much higher than usual.

461 In this frame, it would be very relevant to measure and know the typical velocity fluctuations of specific glaciers in stable  
 462 conditions. This could allow an assessment and to what extent a suspect acceleration may be anomalous and potentially  
 463 destabilising, bearing in mind that high-rate monitoring is essential to detect glacial instabilities since the expected sharp  
 464 increase in velocity in the weeks before the failure (Pralong and Funk, 2006) could be hardly detectable from remote sensing  
 465 (e.g., due to scarce visibility, image decorrelation, low resolution).

466 Limits of the methodology presented in this study should also be considered: glaciers moving at slow rates can be surveyed  
 467 using temporal baselines of one year (Millan et al., 2019; Mouginot et al., 2023), but this implies losing the ability to catch  
 468 short-term velocity fluctuations, like those observed at Charpoua and Pra Sec glaciers. Another known issue pertains to the  
 469 lack of features of the glacier surface that make it impossible to track movements using optical imagery. Satellite optical  
 470 imagery is limited and can be strongly influenced by the presence of clouds that could yield extensive periods without data  
 471 acquisition, even though, in the present study, we had only four of 96 months with no data. Anomalies due to image  
 472 decorrelation for the presence of shadows, snow or morphological surface modifications can occur and an expert-based visual  
 473 check may be required to discriminate anomalous velocities.

#### 474 6 Conclusions

475 We produced ice velocity maps and time series of thirty glaciers of the Mont Blanc massif during the period 2016–2024.  
 476 The proposed results are different compared to the existing publicly available automatically processed velocity datasets that  
 477 have a coarse resolution (i.e., >100 m) and cannot correctly detect the kinematics of most Alpine glaciers, due to their small  
 478 size. Therefore, specific processing and studies are needed to characterize the surface kinematics of Alpine glaciers. In our  
 479 study, we used Sentinel-2 imagery due to its free availability, good ground resolution and high revisit time in the study area to  
 480 obtain monthly surface velocity time series. In addition, we proposed a classification of different groups of glaciers based on  
 481 their morpho-kinematic features. Plus, we observed a significant acceleration trend in many of the studied glaciers in the last  
 482 years (2020–2022), but the causes are still not well understood.

483 From a methodological point of view, the use of the proposed approach can be very useful to process and analyse available  
484 satellite images of other massifs in the Alps and other parts of the World. This approach could stimulate innovative research  
485 on high-resolution spatiotemporal variations of velocities on alpine glaciers and, especially, on understanding the variations in  
486 the motion of mountain glaciers. A large research question remains open and deals with understanding and measuring the  
487 drivers of change in the motion of alpine glaciers. This implies the complex acquisition of data related to the possible drivers  
488 of the variations such as mass balances, water inputs and temporal variations in the subglacial hydrology of single glaciers.  
489 However, in order to delve further into these investigations, velocity databases at higher spatial and temporal resolutions, such  
490 as that presented in this study, are needed to build future research on the topic.

## 491 **Acknowledgements**

492 The authors would like to thank Jean Pierre Fosson, Raffaele Rocco, Valerio Segor, and Guido Giardini for their support  
493 and their will to stimulate cryospheric research activities in the Aosta Valley region and on the Italian side of Mont Blanc  
494 massif. We thank all the staff at Fondazione Montagna Sicura for supporting all the research activities of the research team.  
495 Dr Etienne Berthier supplied a processed 2018 Pleiades stereo DEM on which retrieving altitudinal data that was presented in  
496 this paper. Dr. Antoine Rabatel supplied velocity data for the comparison with their 2023 dataset. We thank Dr. Christian  
497 Vincent for his advice on research activity and for supplying useful additional information, especially on the French glaciers  
498 of Mont Blanc.

## 499 **Data availability**

500 The following data are available for download on Zenodo <http://dx.doi.org/10.5281/zenodo.11349445>: i) monthly velocity  
501 maps, ii) updated outlines (from RGI7) of the analysed glaciers, iii) sampling areas of extraction of the velocity time series,  
502 iv) time series of monthly velocity. The data description and format are reported in Sec S9. Sentinel-2 imagery is available  
503 from the Copernicus Open Access Hub (<https://scihub.copernicus.eu>, Copernicus, 2022). The GIV toolbox is freely available  
504 online (<https://github.com/MaxVWDV/glacier-image-velocimetry>).

505 **Competing interests.** The authors declare that they have no conflict of interest.
