16 **Abstract.** The taiga ecosystem in northeastern Siberia, a nitrogen-limited ecosystem on permafrost with a dry climate,  
17 changed during the extreme wet event in 2007. We investigated the normalized difference vegetation index (NDVI) as a  
18 satellite-derived proxy of needle production and compared it with ecosystem parameters such as soil moisture water  
19 equivalent (SWE), **larch** foliar C/N ratio,  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ , and ring width index (RWI) at the Spasskaya Pad Experimental  
20 Forest Station in Russia for the period from 1999 to 2019. Historical variations in NDVI showed a large difference between  
21 typical larch forest (unaffected) and the sites affected by the extreme wet event in 2007 because of high tree mortality at  
22 affected sites under extremely high SWE and waterlogging, resulting in a decrease in NDVI, **although there was no**  
23 **difference in the NDVI between typical larch forest and affected sites before the wet event.** Before 2007, the NDVI in a  
24 typical larch forest showed a positive correlation with SWE and a negative correlation with foliar C/N. These results indicate  
25 that not only the water availability (high SWE) in the previous summer and current June but also the soil N availability **likely**  
26 increased needle production. NDVI was also positively correlated with RWI, resulting from similar factors controlling them.  
27 However, after the wet event, NDVI was negatively correlated with SWE, while NDVI showed a negative correlation with  
28 foliar C/N. These results indicate that after the wet event, high soil moisture availability decreased needle production, which  
29 may have resulted from lower N availability. **Foliar**  $\delta^{15}\text{N}$  was positively correlated with NDVI before 2007, but after the wet  
30 event, **foliar**  $\delta^{15}\text{N}$  decreased. This result suggests damage to roots and/or changes in soil N dynamics due to extremely high  
31 soil moisture. **As a dry forest ecosystem, taiga in northeastern Siberia is affected not only by temperature-induced drought but**  
32 **also by high soil moisture, led by extreme wet events, and nitrogen dynamics.**

## 33 1 Introduction

34 Boreal forests in northern regions of North America and Eurasia, including islands, occupy a large area, approximately 27 %  
35 of the world's forest cover (FAO, 2020). Under conditions of increasing atmospheric CO<sub>2</sub> concentrations (e.g. Friedlingstein  
36 et al., 2022), the role of taiga and other terrestrial ecosystems as carbon sinks becomes more important. Among the taiga  
37 areas, Alaska, Canada, and Siberia are distinguished by permafrost, which is one of the main components of the global  
38 carbon cycle. Under warming conditions, northern ecosystems respond differently to environmental changes depending on  
39 the different biomes and regions, as mentioned below from remote sensing satellite observations. The normalized difference  
40 vegetation index (NDVI), the most common remote sensing vegetation data, typically shows increasing trends (greening) in  
41 arctic tundra but decreasing trends (browning) in many boreal forests (Bunn and Goetz, 2006; Verbyla, 2008; Berner and  
42 Goetz, 2022; Miles and Esau, 2016). Observed greening at the tundra and taiga-tundra boundary can be associated with the  
43 expansion of trees and shrubs to the north (Frost and Epstein, 2014; Tape et al., 2006; Shevtsova et al., 2020) and increases in  
44 aboveground plant biomass (Goetz et al., 2005; Berner et al., 2013; Forbes et al., 2010). In turn, the browning of taiga can be  
45 attributed to tree mortality and decreases in forest production because of droughts (Welp et al., 2007; Bunn and Goetz, 2006),  
46 forest fires (Goetz et al., 2005), and extreme wet events (Famiglietti et al., 2021; Nogovitsyn et al., 2022). Nevertheless,  
47 temporal changes in the NDVI of boreal forests are spatially heterogeneous and vary depending on different factors, such as  
48 the plant vegetation types (Myers-Smith et al., 2020; Bunn and Goetz, 2006), stand density (Bunn et al., 2007; Dearborn and  
49 Baltzer, 2021) and topography (Sato and Kobayashi, 2018). One of the most important factors controlling greenness is water  
50 availability (Ruiz-Perez and Vico, 2020; Forkel et al., 2015). Overall, warming condition of boreal forests has positive effects  
51 in wetter regions but negative effects on forest productivity in dry regions (e.g., Ruiz-Perez and Vico, 2020).

52 Siberian taiga is mainly covered with deciduous conifers ~~coniferous trees~~, larches, which grow under severe conditions, such  
53 as continental climate, that is, cold winters, hot summers, low precipitation (Archibold, 1995), and limited nitrogen  
54 availability (Popova et al., 2013; Kajimoto et al., 1999). Permafrost and seasonal ice are important sources of water for  
55 larches during drought (Sugimoto et al., 2003; Sugimoto et al., 2002). These severe conditions make this ecosystem  
56 vulnerable to environmental changes. ~~Under warming, permafrost may decline, which can trigger large amounts of carbon  
57 emissions (Schuur et al., 2015) and change the ecosystem.~~ In northeastern Siberia, the role of the taiga ecosystem and its  
58 responses to climate change have been studied at the Spasskaya Pad Forest Station near Yakutsk over a long-term. ~~This larch  
59 forest is a net CO<sub>2</sub> sink; however, quantitative estimations of the flux from tower measurements and various models differ  
60 (Takata et al., 2017).~~ Over the past few decades, the ring width index (RWI) has decreased in this region as well as in other  
61 continental dry regions, Alaska, Canada, and southern Europe, because of high temperature-induced droughts (Tei et al.,  
62 2017). On the other hand, precipitation extremes, which are predicted to be more intensive and frequent (Douville et al.,  
63 2021; Wang et al., 2021), can also negatively affect the forest. ~~Larch roots, which usually take up water from seasonal ice in~~

64 ~~the active layer (above the permafrost) under dry conditions, can adapt to wet conditions by decreasing vertical distribution~~  
65 ~~(Takenaka et al., 2016).~~ In addition to droughts, extreme wet events occur because of intensive precipitation, such as heavy  
66 rainfall and snowfall. In this forest area, changes in winter precipitation may shift the forest phenology and production of soil  
67 inorganic nitrogen, as demonstrated in snow manipulation experiments (Shakhmatov et al., 2022).

68 In northeastern Siberia, boreal forests have been affected by drought in the past because of the continental climate. However,  
69 ~~the extreme wet event~~ in 2007, ~~when~~ soil moisture was the highest in the past century (Tei et al., 2013); because of large  
70 amounts of rainfall and subsequent winter snowfall, which led to waterlogging in topographic depressions of the forest. This  
71 extreme wet event was fatal for many trees in the forest, especially in the depressions (Iijima et al., 2014; Ohta et al., 2014).  
72 These extremely moist conditions reduced CO<sub>2</sub> uptake by vegetation (gross primary production) and evapotranspiration  
73 (Ohta et al., 2014). Evapotranspiration in this region is mainly controlled by the leaf area index (LAI) (Matsumoto et al.,  
74 2008), suggesting a decrease in LAI in 2007 because of high tree mortality. ~~In addition to high tree mortality, affected sites~~  
75 ~~are distinguished by a secondary succession of the understory and floor vegetation communities to water resistant species~~  
76 ~~(Ohta et al., 2014). It was suggested that such sites in the forest generally emit methane, which makes the ecosystem a net~~  
77 ~~CH<sub>4</sub> source according to estimations of open path eddy covariance measurements (Nakai et al., 2020). The wet event was~~  
78 ~~caused by continuous heavy precipitation, including extremely large snowfall. Snow manipulation experiments in the forest~~  
79 ~~showed the influence of interannual variation in winter precipitation on the phenology and production of soil inorganic~~  
80 ~~nitrogen (Shakhmatov et al., 2022). After the extreme moist conditions formed in 2005–2009~~ However, after the extreme wet  
81 event, eddy-covariance flux measurements showed no significant trends in CO<sub>2</sub> exchange at the ecosystem scale (Kotani et  
82 al., 2019). The affected sites are distinguished not only by high tree mortality but also by a secondary succession of the  
83 understory and floor vegetation communities to water-resistant species, which may have compensated for the reduced water  
84 and CO<sub>2</sub> fluxes (Ohta et al., 2014).

85 Boreal forests in northeastern Siberia have been affected by both drought and extreme wet events, as described above, which  
86 involved complex changes in the forest environment. Tei et al. (2019a) demonstrated that larch trees, which died during the  
87 extreme wet event, were affected by a previous drought. However, at the forest level, the NDVI was not related to gross  
88 primary production in 2004–2014 (Tei et al., 2019b), and the NDVI of the larch forest damaged by waterlogging showed  
89 insignificant trends in 2000–2019 and an insignificant correlation with climate data (Nagano et al., 2022). These phenomena  
90 were attributed to waterlogging-induced changes in the understory and floor vegetation composition (Nagano et al., 2022; Tei  
91 et al., 2019b), but they seem to be also related to changes in the conditions of the larch forest.

92 ~~The high mortality of larches in 2007 could have been caused by two consecutive extreme events—drought and wetness (Tei~~  
93 ~~et al., 2019a). Severe drought and moist conditions in the forest lead to changes in the normalized difference vegetation index~~  
94 ~~(NDVI) (Tei et al., 2019b; Nagano et al., 2022), which is considered a proxy of vegetation productivity. However, gross~~

95 primary production (GPP) was found to be more related to the larch tree RWI in 2004–2014, but not to NDVI, because of  
96 changes in the understory and floor vegetation composition (Tei et al., 2019b). Based on an investigation of spatial variations  
97 in NDVI and foliar parameters in 2018, Nogoviteyn et al. (2022) found that affected sites with lower NDVI due to a smaller  
98 number of living mature trees showed higher nitrogen and light availabilities (higher foliar C/N and  $\delta^{13}\text{C}$ , respectively) due to  
99 low competition for resources. These favorable conditions can contribute to further succession. Although many studies have  
100 been conducted in eastern Siberia, no study has focused on the relationships between historical NDVI and foliar parameters  
101 in this region.

102 The taiga ecosystem in eastern Siberia is one of the most important biomes in the world and is vulnerable to climate  
103 change. The purpose of this study was to understand how the larch forest in this region changed, particularly after the  
104 extreme wet event in 2007, and what factors impacted the changes over the past two decades. Therefore, we investigated  
105 historical variations in satellite-derived NDVI to evaluate changes in the forest, as the leaves of deciduous trees reflect the  
106 condition of trees in each year. To understand the factors impacting forest changes, especially related to the extreme wet  
107 event, NDVI data were compared with field-observed parameters in a typical larch forest, such as the RWI, soil moisture,  
108 needle  $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ , C/N, air temperature, and precipitation from 1998 to 2019.

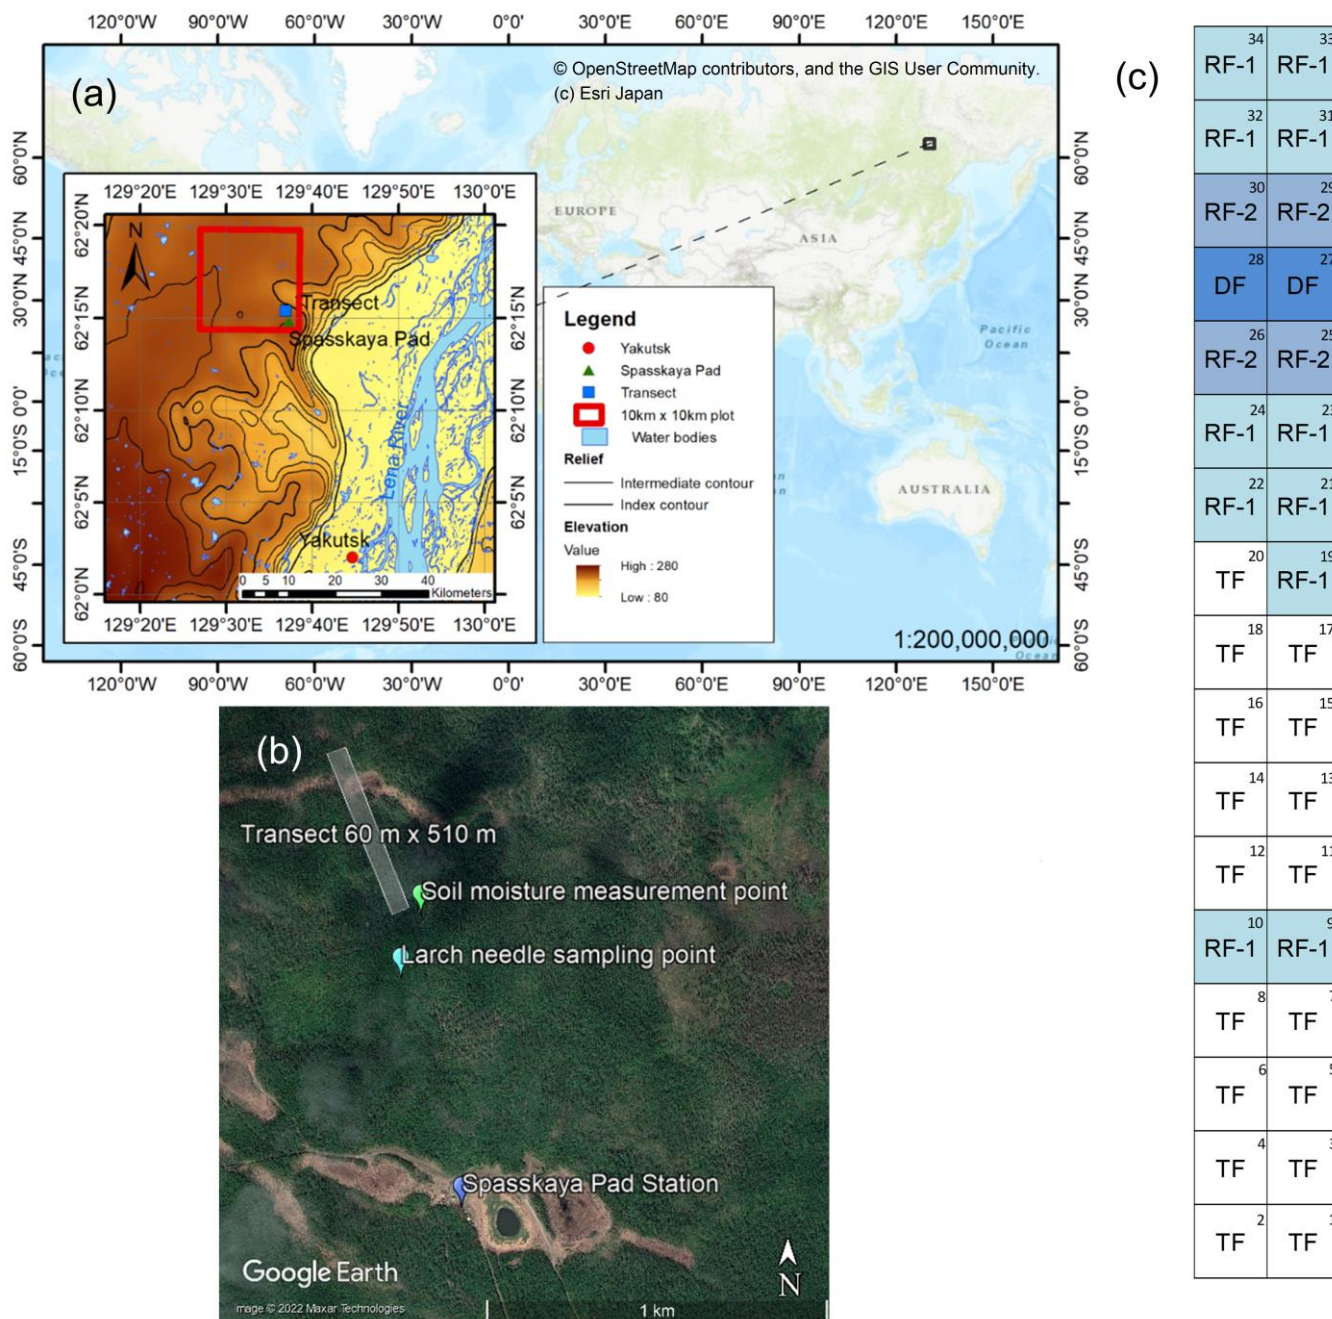

## 109 2 Materials and Methods

### 110 2.1 Study site

111 The study was conducted in the Spasskaya Pad Experimental Forest (62°15'18"N, 129°37'08"E, alt. 220 m a.s.l.), Institute  
112 of Biological Problems of Cryolithozone, Siberian Branch of the Russian Academy of Sciences (IBPC SB RAS), near  
113 Yakutsk, Russia (Fig. 1a). The region in Eastern Siberia is established on continuous permafrost and has a continental climate  
114 (dry climate) with an extremely high annual temperature range. During the observation period from 1991 to 2020 at Yakutsk,  
115 the average annual precipitation was 233 mm, and the average monthly temperature ranged from -37°C to +20 °C in cold  
116 January and warm July, respectively. Dominant species is larch (*Larix cajanderi*) that is deciduous conifer (Abaimov et al.,  
117 1998), mixed with broadleaved birch (*Betula pendula*), and the understory includes small shrubs, such as evergreen cowberry  
118 (*Vaccinium vitis-idaea*) and deciduous bearberry (*Arctous alpina*), and grasses.

119 During the period from 2005 to 2007 (water years, from October to September), there was a large amount of precipitation  
120 ( $307 \pm 29$  mm) continuously, which caused a significant increase in soil moisture (Sugimoto, 2019) and even waterlogging.  
121 Consequently, an extreme wet event occurred in 2007, which damaged larch forests, resulting in high tree mortality and a  
122 change in the composition of understory vegetation to moisture-tolerant grasses and shrubs in some areas, especially in  
123 depressions (Iijima et al., 2014; Iwasaki et al., 2010; Ohta et al., 2014). In the summer of 2018, we set a 60 m × 510 m  
124 transect, which included areas unaffected and affected by the extreme wet event (Fig. 1a, b). The transect was divided into 30

125 × 30 m plots (34 plots in total). Using these plots, we observed spatial variation in NDVI (Nogovitsyn et al., 2022). In this  
126 study, we visually classified the forest conditions based on photographs. Four forest types were identified along the transect  
127 (Fig. 1c): typical mature (TF; number of plots in the transect,  $n = 17$ ), regenerating-1 (RF-1;  $n = 11$ ), regenerating-2 (RF-2;  $n$   
128 = 4), and damaged (DF;  $n = 2$ ) forests. The first TF showed no visible damage from the extreme wet event. The plots  
129 discerned as regenerating forests RF-1, had many dead mature larches and formed forest gaps in the overstory where there  
130 were a large number of young larches (seedlings and saplings with a height of up to 3 m) and shrubs. **Regenerating forests,**  
131 **RF-2, contained more dead mature larches and more young larches compared to those in RF-1.** Damaged forests, DF, where  
132 all mature trees died, was predominantly covered by moisture-tolerant grasses, and had much smaller numbers of young  
133 larches than in RF-1 **and RF-2.** The DF plots were located on a depression in a trough-and-mound topography, and some  
134 patches of the DF plots were flooded. ~~Regenerating forests RF-2 had moderate forest conditions between RF-1 and DF.~~

135

136 **Figure 1.** (a) Location of the Spasskaya Pad Station (62°15'18"N, 129°37'08"E) and the study transect near Yakutsk in the topographic  
 137 map (modified from USGS/NASA Landsat 8 image) zoomed from a global map (Source: © OpenStreetMap contributors, © Esri Japan).

138 (b) Detailed view of the study area in the Spasskaya Pad Forest (Source: © Google Earth, © 2022 Maxar Technologies): locations of the  
 139 station, 60 m x 510 m transect, and points of soil moisture measurement and larch needle sampling for  $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ , and C/N. (c) Scheme of  
 140 the transect with a total of 34 plots, which were divided into four forest types based on the level of forest damage (Nogovitsyn et al., 2022):  
 141 typical forests (TF), two types of regenerating forests (RF-1 and RF-2), and damaged forests (DF).

## 142 2.2 NDVI

143 The raster normalized difference vegetation index (NDVI) was computed based on the Landsat Collection-1 Level-2 image  
 144 products (<https://earthexplorer.usgs.gov/>) with a spatial resolution of 30 m using QGIS software (v. 3.2.2-Bonn):

145 
$$\text{NDVI} = (\text{NIR} - \text{R}) / (\text{NIR} + \text{R}),$$

146 where NIR and R are the near-infrared and red surface reflectance bands of the product, respectively. The image products  
147 georeferenced to the WGS-84 UTM 52N coordinate system were selected according to the location of the study transect. The  
148 NDVI value was extracted for each transect plot using the zonal **statistics** function. **The transect plots, which consist of only**  
149 **pixels attributed to quality pixels (clear terrain, low-confidence cloud, and low-confidence cirrus) in the quality assessment**  
150 **bit index band according to Landsat Surface Reflectance product guides, were used in the analysis.**

151 To investigate the historical variation in NDVI, we considered the seasonal maximum of the mean NDVI of the transect for  
152 the long-time period from 1999 to 2019. The longest time-series data available for the study area has been obtained by the  
153 Landsat 7 satellite with the Enhanced Thematic Mapper Plus (ETM+) image sensor since 1999. However, its sparse temporal  
154 resolution (16 days) and scan-line corrector failure in 2003 forced the consideration of additional data from other satellites,  
155 such as Landsat 5 Thematic Mapper (TM) (available until 2011) and Landsat 8 Operational Land Imager (OLI) (available  
156 since 2013). Because the last two have different sensors in contrast to Landsat 7, NDVI values calculated from the TM and  
157 OLI images were converted to ETM+ using the linear equations:

158 
$$\text{NDVI}_{\text{ETM+}} = 1.037 \cdot \text{NDVI}_{\text{TM}},$$

159 
$$\text{NDVI}_{\text{ETM+}} = 0.9589 \cdot \text{NDVI}_{\text{OLI}} + 0.0029$$

160 developed by Ju and Masek (2016) and Roy et al. (2016), respectively, for boreal forests. **Local parametrization of signals**  
161 **from different sensors was not performed for our study site because of the insufficient overlap in the acquired images. We**  
162 **identified that the selected and converted data were close to the 1:1 lines between Landsat 5 and 7 and between Landsat 7 and**  
163 **8.** For each year, a paired sample *t*-test was applied to determine the difference between the mean NDVI of the transect on  
164 the observation days. In the case of statistically insignificant differences among observation days, we selected the day with  
165 the highest number of quality pixels.

166 To verify the historical variation in NDVI of the transect, a larger area, 10 km × 10 km (hereafter, the 10-km plot), including  
167 the Spasskaya Pad Forest, was used for comparison with the transect (the center of the 10-km plot was located at 62°17'4"N,  
168 129°32'44"E; Fig. 1a). For each observation day, the mean NDVI of the 10-km plot was calculated using only quality pixels  
169 using ENVI 5.1 (L3Harris Technologies, USA). For each year, the seasonal maximum NDVI of the 10-km plot was  
170 determined as the highest mean NDVI among observation days, on which the number of quality pixels were more than 50 %  
171 (total, 111,556 pixels). The seasonal maximums of the transect and 10-km plot showed the same day for about three-quarters  
172 of the study period (15 years among 21) and showed a different day in six years (Table S1): 2006 (7 August and 29 July),  
173 2007 (1 and 25 July), 2010 (1 and 15 July), 2011 (5 and 12 August), 2015 (23 and 31 July), and 2019 (1 and 9 July). The  
174 averaged NDVI values of the 10-km plot, transect, and each forest type (TF, RF-1, RF-2, and DF) in the transect are shown  
175 in Fig. 2a and 2b.

176 The NDVI data of larch forest, which is deciduous, quickly increases in early summer, when the NDVI is mostly stable (e.g.,  
177 Huete et al., 2002). This stable NDVI continues for more than 1.5 months (typically from July to mid-August), although the  
178 time period depends on the weather and soil moisture conditions. Seasonal maximum NDVI was identified during this  
179 period. Although the data acquisition days were limited because of the low temporal resolution and cloud coverage, more  
180 than three days of data were acquired by combining three satellite images, and seasonal maximums were determined, except  
181 for in 1999 and 2003. These two years had only one data acquisition day, on 27 August 1999 and 21 July 2003, and both data  
182 points were recognized as the seasonal maximum.

### 183 2.3 Ecosystem and climate parameters

184 Several ecosystem parameters have been observed since 1998 in typical forests. To monitor the physiological response of  
185 larch to environmental changes, the C and N isotopic compositions ( $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ , ‰), and the ratio of C to N content (C/N)  
186 of larch needles have been observed since 1999, except in 2012, at the site 200 m south of the transect (Fig. 1b). The  $\delta^{13}\text{C}$   
187 and  $\delta^{15}\text{N}$  are calculated by:

$$188 \quad \delta^{13}\text{C} \text{ (or } \delta^{15}\text{N)} = (R_{\text{sample}}/R_{\text{std}} - 1) \times 1000 \text{ (‰)},$$

189 where  $R_{\text{sample}}$  and  $R_{\text{std}}$  are isotope ratios ( $^{13}\text{C}/^{12}\text{C}$  or  $^{15}\text{N}/^{14}\text{N}$ ) of the sample and standard, respectively, and standards are  
190 Vienna Peedee Belemnite for C and atmospheric  $\text{N}_2$  for N. The foliar  $\delta^{13}\text{C}$  reflects the physiological condition of  
191 photosynthesis and is widely applied to indicate plant water use efficiency (Farquhar et al., 1989). The  $\delta^{13}\text{C}$  value of plant  
192 tissue (e.g., leaf) is expressed using the following equation:

$$193 \quad \delta^{13}\text{C} = \delta^{13}\text{C}_{\text{atm}} - a - (b - a) (C_i/C_a),$$

194 where  $\delta^{13}\text{C}_{\text{atm}}$  is the C isotopic composition of atmospheric  $\text{CO}_2$ , a (4.4‰) and b (27‰) are isotope fractionations of the  
195 diffusion and photosynthetic reaction, and  $C_i$  and  $C_a$  are intercellular and atmospheric  $\text{CO}_2$  concentrations. The foliar  $\delta^{13}\text{C}$   
196 becomes high when higher irradiance and lower stomatal conductance are observed. At our study site, lower and higher  $\delta^{13}\text{C}$   
197 values of larch needles were typically due to wet and drought conditions. The foliar  $\delta^{15}\text{N}$  is a physiological indicator of the N  
198 source for a plant (Evans, 2001), which can vary depending on numerous physiological and environmental factors. The foliar  
199 C/N represents the N status of a plant (Liu et al., 2005).

200 Larch needles were collected from four to eight young larch trees in August every year. We collected them from the same  
201 trees (sample trees) every August, and these trees are located nearby to each other. Four stems were obtained from each tree,  
202 and the needles from each tree were mixed and analyzed at Kyoto University (samples for 1999–2003) and Hokkaido  
203 University (samples after 2004) using Conflo systems (EA 1108 and Delta S, and Flash EA 1112 and Delta V, Thermo Fisher  
204 Scientific, at Kyoto and Hokkaido Universities, respectively). Analytical precisions (standard deviation) of the C and N  
205 content measurements were better than 0.3% and 0.1%, respectively, and those for the isotopic compositions  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$   
206 were better than 0.2‰. The details of sampling, sample preparation and laboratory analyses of C and N contents and their

207 isotope compositions using the EA-IRMS system are described in Fig. S1. The details of the average calculations are shown  
208 in Fig. S1 and S2. In 2015, there were no data on the  $\delta^{15}\text{N}$  and N content.  
209 For more than 100 years, until 2016, larch ring-width index (RWI) indicating wood growth dynamics was estimated by  
210 detrending and standardizing the raw time-series width data obtained from the collected paired cores (Tei et al., 2019b; Fan et  
211 al., 2021). The RWI data used for analysis are shown in Table S2.  
212 Soil moisture was measured using time-domain reflectometry (TDR), and the soil moisture water equivalent (SWE; the  
213 amount of liquid water contained within the soil layer, mm) in the 0–60 cm soil layer was obtained for 1998–2019 in June,  
214 July, and August using the method described by Sugimoto et al. (2003) (near the transect; Fig. 1b). There were no data for  
215 June of 2002 and 2011 and August of 2003. The details of the intra- and inter-annual variations in SWE are shown in Fig. S3.  
216 Among the climate variables, summer air temperature and precipitation datasets recorded by the meteorological station at  
217 Yakutsk (62.02° N, 129.72° E) were obtained from the All-Russia Research Institute of Hydrometeorological Information -  
218 World Data Centre (RIHMI-WDC) website (<http://aisori-m.meteo.ru/>).

## 219 2.4 Statistical analysis

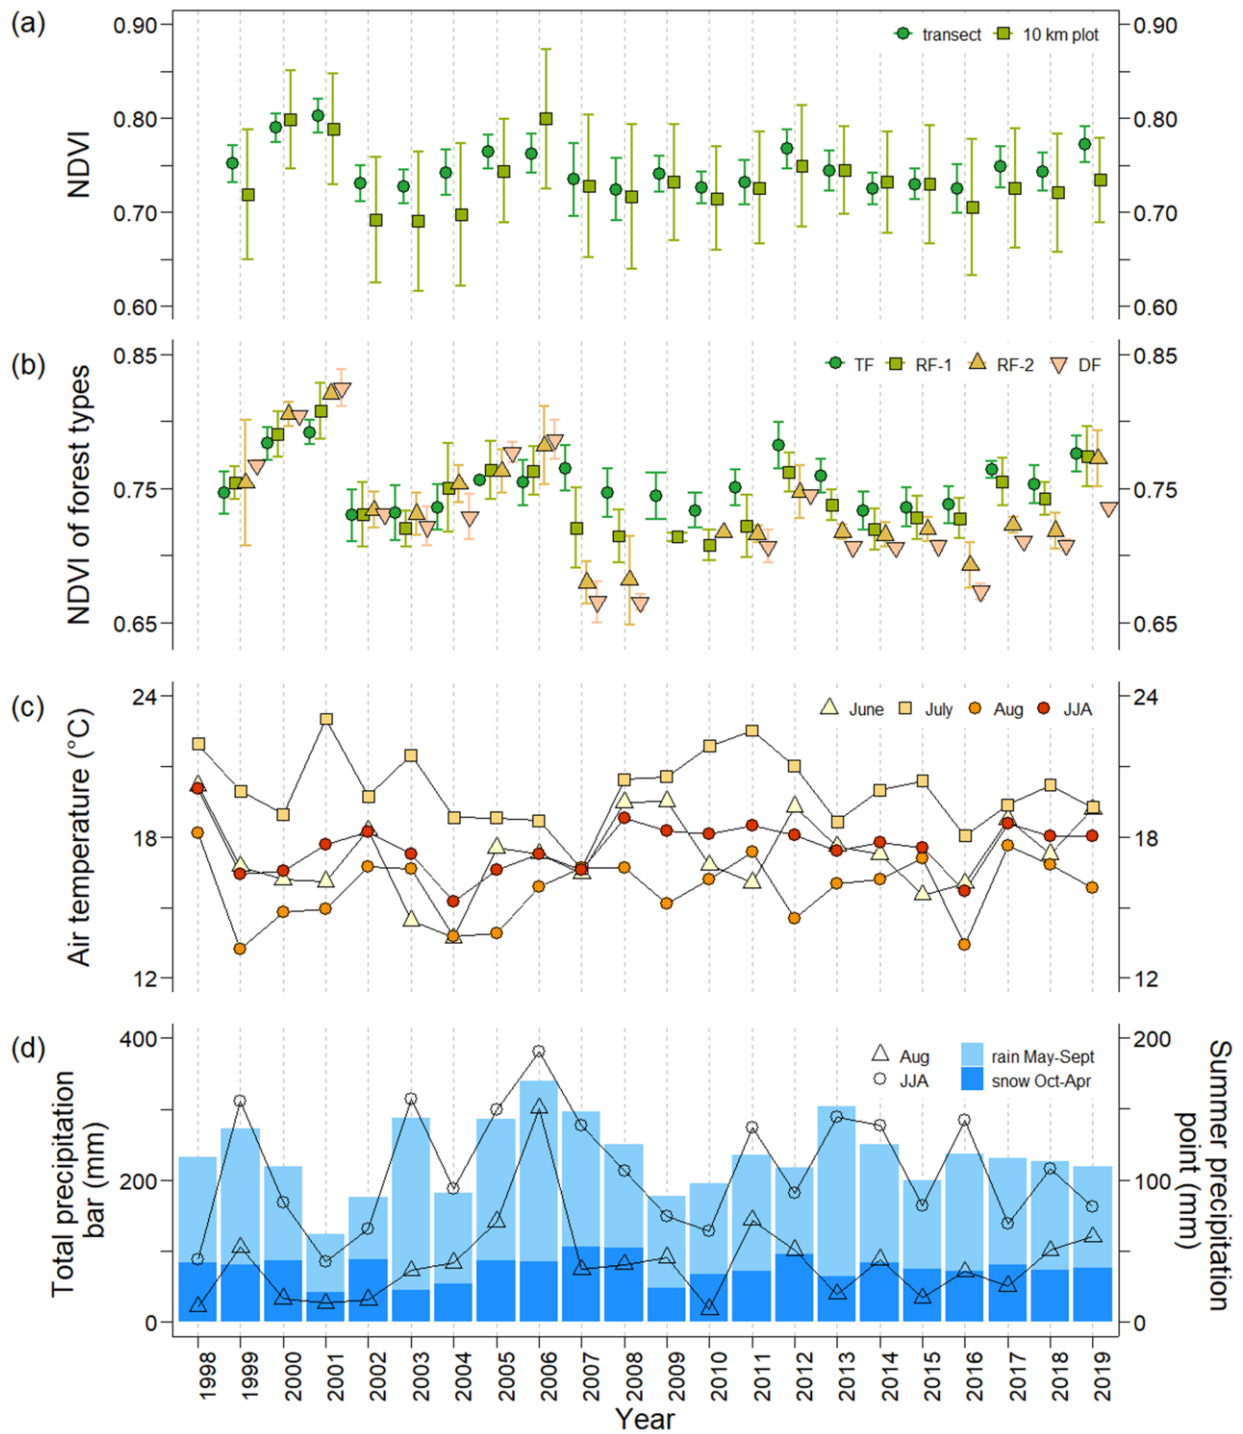

220 All statistical analyses were carried out using R statistics v.4.1.3 (R Core Team). Relationships between datasets were  
221 investigated using a simple linear regression model (function “lm”) and a Pearson correlation test (“cor.test”), the most  
222 common statistical test based on the method of covariance. Trends of NDVI change in 1999–2019 were estimated using the  
223 Mann–Kendall test (package “trend”, function “mk.test”). Differences in NDVI among four forest types (TF, RF-1, RF-2 and  
224 DF) were determined using Kruskal-Wallis test (“kruskal.test”) with pairwise Wilcoxon rank sum test  
225 (“pairwise.wilcox.test”). ~~The criteria for applying a particular test were the data distribution type (normal or non-normal) and  
226 the relation of the data variances to each other (equal or unequal): Student’s *t* test, both datasets have “normal” distributions  
227 and “equal” variances; Welch’s *t* test, “normal”, “unequal”; and Wilcoxon rank sum test, “non normal”, “unequal”. Data  
228 normality and variance equality were checked using the Shapiro–Wilk test and *F* test.~~ The results of the statistical tests are  
229 shown in the Supplemental (Table S3–S9). The models and tests described by levels of statistical significance (*p*-values) less  
230 than 0.05 and 0.1 were considered to be “significant” and “moderately significant”, respectively.

## 231 3 Results

### 232 3.1 Year-to-year variation of seasonal maximum NDVI

233 Fig. 2a shows the historical variation in the seasonal maximum NDVI of the TF and the 10-km plot from 1999 to 2019. Both  
234 NDVI time series varied similarly. The seasonal maximum of each year was observed from 25 June to 13 August, except for  
235 1999 (shown in Table S1). The maximum transect NDVI in 1999 was observed on 27 August ( $0.75 \pm 0.02$ ,  $n = 34$ ) because

236 the Landsat data in 1999 were limited to the latter half of August. The mean seasonal maximum NDVI for the transect varied  
237 between 0.72 and 0.80. During the period from 1999 to 2001, the NDVI of the transect was high from  $0.75 \pm 0.02$  ( $n = 34$ ) to  
238  $0.80 \pm 0.02$  ( $n = 34$ ) (Fig. 2a), but in 2002 and 2003, the NDVI was much lower ( $0.73 \pm 0.02$ ,  $n = 34$ ) than that in 2001. From  
239 2003 to 2006, NDVI again increased from  $0.73 \pm 0.02$  ( $n = 34$ ) to  $0.76 \pm 0.02$  ( $n = 34$ ). During the wet event in 2007–2008,  
240 the NDVI decreased to  $0.73 \pm 0.04$  ( $n = 34$ ). After 2009, NDVI was higher than that in 2008 ( $0.72 \pm 0.03$ ,  $n = 34$ ), except in  
241 2016 ( $0.72 \pm 0.03$ ,  $n = 31$ ).

**Figure 2.** The temporal variations from 1999 to 2019 in (a) seasonal maximum NDVI averaged for the plots in the transect and the representative 10-km forest plot calculated from available Landsat 5, 7, 8 images; (b) NDVI of four forest types, typical mature forest (TF), regenerating forests (RF-1 and FR-2), and damaged forest (DF); (c) mean air temperature in June, July, August and whole summer period JJA (June-July-August); (d) the amount of precipitation during previous October-current April (snow) and current May-September (rain) shown with blue bars, in August and whole summer period JJA (June-July-August) shown with triangles and circles. Both the mean NDVI of the 10-km plot and the transect decreased from 1999 to 2019 ( $-0.0009$  and  $-0.0010$  year $^{-1}$ , respectively), but not with statistically significant trends. Generally, the mean NDVI in the transect was higher than that in the 10-km plot, except for 2000 and 2014.

## 250 3.2 NDVI of each forest type

251 The NDVI time series for four forest types (typical forest TF, regenerating forests RF-1 and RF-2, and damaged forest DF) in  
252 the transect during 1999–2019 are shown in Fig. 2b. As shown in Fig. 2b and 3a, before 2007, the NDVI of TF during 1999–  
253 2001 ( $0.75 \pm 0.02$  to  $0.79 \pm 0.01$ ,  $n = 17$ ) was higher than that in the subsequent period, 2002–2006 ( $0.73 \pm 0.02$  to  $0.75 \pm$   
254  $0.02$ ,  $n = 17$ ). In 2002, there was a significant decrease in the TF NDVI, which remained low between 2002 and 2004 (Fig.  
255 2b and 3a). During 1999–2006, the NDVI values of the four types were close to each other, but after the wet event, NDVI  
256 values noticeably differed among the forest types (Fig. 2b). In 2007, the NDVI of TF ( $0.76 \pm 0.02$ ,  $n = 17$ ) was the highest,  
257 and those of the other three types decreased in the order of RF-1 ( $0.72 \pm 0.03$ ,  $n = 11$ ), RF-2 ( $0.68 \pm 0.02$ ,  $n = 4$ ), and DF  
258 ( $0.67 \pm 0.02$ ,  $n = 2$ ) (Fig. 2b). In 2008, the NDVI decreased slightly and showed the same order of forest types as that in  
259 2007. After 2009, the difference among the forest types, especially between TF and DF, remained, although it was smaller  
260 than that in 2007.

## 261 3.3 NDVI of the typical forest and ecosystem parameters of the study site

262 To consider the historical variation in the NDVI of typical forests in our study area, the TF NDVI and observed parameters  
263 were compared (Fig. 2 and 3). In Fig. 4, the linear relationships between NDVI and other parameters were investigated for  
264 two different time periods, before (1999–2006) and after (2008–2019), to compare them.

### 265 3.3.1 Climate parameters (temperature and precipitation) at Yakutsk

266 Interannual variations in climatic parameters, such as air temperature and precipitation, from 1999 to 2019 are displayed in  
267 Fig. 2c and 2d. The average air temperature in June–August (summer temperature) was relatively high in 1998, 2001–2002,  
268 and 2008–2012 (Fig. 2c). The TF NDVI showed no correlation with summer temperature. The amount of annual water  
269 precipitation (from October to September) for the period from 1991 to 2020 averaged approximately  $233 \pm 47$  mm. As shown  
270 in Fig. 2d, larger water year precipitation, that is, precipitation higher than 280 mm (one standard deviation above the mean  
271 for 1991–2020), was observed in 2003 (287 mm), 2005–2007 (285, 340, and 296 mm), and 2013 (304 mm). The amount of  
272 water precipitation in 2001 (124 mm) was the lowest during the observation period. The drought year (2001) showed a high  
273 TF NDVI value. Consecutive wet years in 2005–2007 showed slightly higher TF NDVI values, but there was no correlation  
274 between the water year precipitation and NDVI.

**Figure 4.** The relationships between the TF NDVI in transect and (a) larch RWI during 1999–2016, the monthly average of SWE (mm) in (b) June and (c) the previous August, (d) averaged monthly SWE for June–August of the previous year, (e) foliar  $\delta^{13}C$ , (f) C/N, and (g)  $\delta^{15}N$  during 1999–2019. The green circles, red square, and blue triangles show data points during 1999–2006, 2007, and 2008–2019, respectively. Labels nearby the data points are observation years of the TF NDVI. Horizontal and vertical error bars represent standard deviations. Green and blue solid lines show linear regressions for 1999–2006 (before the wet event) and 2008–2019 (after the wet event), respectively, and dark green and purple dotted lines represent other periods.  $p$ -values and  $R^2$  describe the significance and **coefficient of determination of the regression models**, respectively.

### 3.3.2 RWI at the typical forest

The larch RWI showed a trend similar to that of the transect TF NDVI during 1999–2007 (Fig. 3a and b). The RWI and

290 average TF NDVI showed high values in 2000–2001 (0.98–1.08 and 0.78–0.79) followed by low values in 2002–2003 (0.36–  
291 0.61 and 0.73); the RWI in 2003 was the lowest for the whole observation period. Subsequently, both parameters increased  
292 by 2007 (1.25 and 0.76). After 2007, these two parameters exhibited different behaviors. During the period from 2010 to  
293 2013, a one-year time lag was observed in the TF NDVI: there was an increase in RWI from 2009 to 2011, a decrease in  
294 2012, and one year later, from 2010 to 2012, the TF NDVI increased and then decreased in 2013. Statistically, the temporal  
295 correlation between the TF NDVI and RWI was positive at a ~~moderately~~ significant level during 1999–2016 ( $r = 0.47$ ,  $p <$   
296  $0.05$ ; Table S7), with a stronger significant positive correlation before 2007 ( $r = 0.76$ ,  $p < 0.05$ ; Fig. 4a, Table S5) and an  
297 insignificant negative correlation after 2007 (Fig. 4a, Table S6).

### 298 3.3.3 Soil moisture water equivalent at the typical forest

299 The time series of the SWE and TF NDVI showed different correlations in the early and late halves of the observation period  
300 (Fig. 3a and 3c). During 1999–2007, the averaged SWE for June–August (hereafter, summer SWE) and the TF NDVI mostly  
301 showed similar trends. High values of the TF NDVI in 2000 and 2001 corresponded to high values of the SWE in the current  
302 June (239 and 202 mm) and in the last summer (173 and 176 mm in 1999 and 2000). These high values of TF NDVI and  
303 SWE were followed by low values during the drought period in 2002–2003. Subsequently, as summer SWE increased from  
304 2004 (124 mm) to 2007 (218 mm), the TF NDVI also increased. ~~Therefore, before 2007, the TF NDVI showed the lowest~~  
305 ~~values during the dry years, but the highest values were observed in the wet years (Table 1).~~ For the period from 2008 to  
306 2019, the correlation between the TF NDVI and summer SWE was negative, with a one-year time lag in the SWE (Fig. 3a  
307 and 3c). A low summer SWE value was observed in 2011 (91 mm), and a high TF NDVI value was observed in the  
308 subsequent year, 2012. After 2016, the TF NDVI showed an increasing trend, whereas the SWE decreased from 2015 to  
309 2019. Statistically, the TF NDVI showed positive correlations with the SWE in the current June ( $r = 0.83$ ,  $p < 0.05$ ) and the  
310 previous summer ( $r = 0.79$ ,  $p < 0.1$ ), including the previous July ( $r = 0.82$ ,  $p < 0.05$ ) and previous August ( $r = 0.69$ ,  $p < 0.1$ ),  
311 during the period from 1999 to 2006 (Fig. 4b–d and S4d; Table S5). However, after 2008, TF NDVI showed negative  
312 correlations with the SWE in the previous ( $r = -0.65$ ,  $p < 0.05$ ) and current ( $r = -0.73$ ,  $p < 0.01$ ) summer, at a stronger  
313 significance level (Fig. 4b–d and S4a–e; Table S6). During and after 2007, there was no change in the TF NDVI; slightly  
314 damaged RF-1 showed a decrease in NDVI to levels similar to those observed during the 2002 drought (Fig. 2b).

315 **Table 1.** Mean and standard deviation of seasonal maximum NDVI of all plots in the TF and RF 1 in the periods before  
 316 (1999–2006), during (2007), and after (2008–2019) the extreme wet event. Averaged NDVI was also calculated for wet and  
 317 dry periods before the event. Different letters in the superscript (a, b, c, and d) indicate a statistical difference between the  
 318 means, calculated using either the Student's *t* test, Welch *t* test, or Wilcoxon rank sum test. The sample size (*n*) indicates the  
 319 number of plots in an NDVI data group.

Forest type	before the wet event			during the wet event	after the wet event
	wet period (2000, 2001, 2006)	dry period (2002)	1999–2006	(2007)	(2008–2019)

### 320 3.3.4 Larch needle $\delta^{13}\text{C}$ , $\delta^{15}\text{N}$ , C/N at the typical forest

321 As shown in Fig. 3a and 3d, the foliar  $\delta^{13}\text{C}$  and TF NDVI moved in opposite directions in the early half of the observation  
 322 period (from 1999 to 2009) (Fig. 3a and 3d). For example, in 2000 and 2001, the TF NDVI had large values, while the foliar  
 323  $\delta^{13}\text{C}$  values were low ( $-29.5 \pm 0.5$  and  $-28.9 \pm 0.9\text{‰}$ ). During the period from 2002 to 2007, TF NDVI increased, and at the  
 324 same time, foliar  $\delta^{13}\text{C}$  values decreased. Foliar  $\delta^{13}\text{C}$  values higher than  $-28.0\text{‰}$  were observed in 2002, 2003, 2011, and  
 325 2018, when low summer SWE and TF NDVI were observed (Fig. 3a and 3d). The correlation between foliar  $\delta^{13}\text{C}$  and TF  
 326 NDVI was statistically insignificant without a time lag (Fig. 3e, Tables S5–7), but there was a significant correlation between  
 327 foliar  $\delta^{13}\text{C}$  and TF NDVI with a **one-year** time lag of foliar  $\delta^{13}\text{C}$  after the wet event (Table S6). Foliar  $\delta^{13}\text{C}$  was negatively  
 328 correlated with the previous August SWE during 1999–2007 ( $r = -0.79$ ,  $p < 0.05$ ) and 1999–2019 ( $r = -0.62$ ,  $p < 0.01$ ) (Fig.  
 329 5), but also with the SWE in the current year June and July for the period from 1999 to 2007, and June to August for 2008 to  
 330 2019 (Table S8).

331 Similar to  $\delta^{13}\text{C}$ , foliar C/N and TF NDVI moved in opposite directions (Fig. 3a and 3f). In 2000 and 2001, the foliar C/N had  
 332 low values ( $25.6 \pm 1.1$  and  $28.8 \pm 3.4$ , respectively), while the TF NDVI was high. There was also a distinct negative  
 333 correlation between trends in C/N and TF NDVI before and after 2007, excluding 2019 (Fig. 4f).

334 Foliar  $\delta^{15}\text{N}$  values decreased after 2005 (Figure 3e). A positive correlation was observed between foliar  $\delta^{15}\text{N}$  and TF NDVI  
 335 before 2007 (Fig. 3a, 3f, and 4g).

336

337 **Figure 5.** The relationship between the foliar  $\delta^{13}\text{C}$  and monthly mean SWE in the previous August (mm) during 1999–2019. The green  
 338 circles, red square, and blue triangles show data points during 1999–2006, 2007, and 2008–2019, respectively. Labels nearby the data  
 339 points are observation years of the foliar  $\delta^{13}\text{C}$ . Vertical error bars represent standard deviations. The linear regressions for 1999–2007,  
 340 2008–2019, and 1999–2019 are presented by green, blue, and black solid lines.  $p$ -values and  $R^2$  describe the significance and **coefficient of**  
 341 **ion of the regression models**, respectively.

## 342 4 Discussion

### 343 4.1 NDVI variation among forest conditions

344 Before 2007, there was a small difference in the NDVI among the four forest types (Fig. 2b and Table S3 and S4). In **most**  
 345 **some** years before 2007, the NDVI values in RF and DF were higher than those in TF. **The difference in elevation between**  
 346 **the south and north ends of the transect (approximately 5 m according to Google Earth) may lead to differences in soil**  
 347 **moisture; therefore, the RF and DF plots showed higher soil moisture contents and a lower possibility of drought compared**  
 348 **with TF before 2007.** During 2007–2008, there was a large difference in NDVI among the forest types, especially between  
 349 the TF and DF (Fig. 2a). During this period, the SWE reached extremely high values (Fig. 3c), caused by a large precipitation  
 350 amount during 2005–2008 (Fig. 2d). Consequently, the forest floor was partially waterlogged, resulting in damage to the  
 351 larch forest, especially in the DF and RF **plots**. These data indicate that during the drought years (before 2007), wet sites such  
 352 as DF and RF showed higher NDVI values than dry TF sites because of higher water availability. However, after 2007, the  
 353 TF, which was visually unaffected by the wet event, showed a higher NDVI than the DF and RF. The presence of surface  
 354 water in DF and soil saturated with water in DF and RF could also reduce the NDVI values. **Water predominantly absorbs**  
 355 **NIR radiation and therefore has a low NIR reflectance, resulting in a lower NDVI than that of vegetation (Holben, 1986).**

356 After 2009, as the soil became dry, the difference in NDVI among the forest types decreased (Fig. 2b). This may have been  
357 caused by the change in the vegetation in RF and DF, that is, the change from mature larch trees to understory and floor  
358 vegetation, such as water-tolerant species and seedlings of birch and larch trees via secondary succession. In 2016, the  
359 difference in NDVI between TF and DF increased again (Fig. 2b). This may have been caused by the high SWE observed in  
360 2015 (Fig. 3c), which lowered the NDVI in RF and DF.

361 However, the difference in NDVI between TF and DF remained at the end of the observation period. Previously, the spatial  
362 variation in NDVI along the transect was investigated a decade after the wet event in 2018 (Nogovitsyn et al., 2022).  
363 Nogovitsyn et al. (2022) concluded that NDVI was higher in TF than in DF because of a difference in the stand density of  
364 mature trees, as NDVI indicates a leaf area index (LAI), which corresponds to the number of mature trees in this forest.

365 As described in the Methods 2.2, we combined images from three Landsat satellites with different sensors. Although  
366 combining data from different sensors can lead to uncertainty in the signals (Shin et al., 2023), our result or historical  
367 variation in the NDVI reflected the change in the forest condition observed *in situ*.

#### 368 4.2 Trends in NDVI of the transect and 10-km plot

369 The NDVI of the 10-km plot showed a trend similar to that of the transect NDVI during the observation period ( $r = 0.78$ ,  $p <$   
370  $0.001$ ), as shown in Fig. 2a, and the mean NDVI value of the 10-km plot was lower than that of the transect in most years.  
371 We found year-to-year variations in both NDVI datasets, but no significant increasing or decreasing trends were observed,  
372 which is consistent with the observations during previous studies at this site (Nagano et al., 2022; Tei et al., 2019b; Lloyd et  
373 al., 2011). Therefore, our observational data can be used for the analyses of ecosystem changes not only at the plot scale but  
374 also at the regional scale.

#### 375 4.3 Historical variation in NDVI of typical forest

376 We studied historical variations in NDVI and field-observed ecosystem and climatic parameters of a typical forest to  
377 understand forest conditions.

##### 378 4.3.1 Water availability

379 As described in the Sect. 3.3.3, SWE controls forest NDVI because the observation site (northeastern taiga) is established in  
380 a continental dry area. We found positive and negative correlations between the NDVI and SWE. Before 2007, the TF NDVI  
381 was positively correlated with the June SWE in the current year (Fig. 4b) and positively correlated with the SWE in the  
382 previous year June, July, August, and the previous year summer (JJA: June–July–August) (Fig. 4c, 4d, S4c, and S4d, Table  
383 S5). This indicates the influence of hydrological conditions in the previous year and early summer of the current year on the  
384 leaf productivity of larch trees in the current year.

385 Larches, as deciduous trees, assimilate carbon through photosynthesis (photoassimilate) during the summer to prepare  
386 needles in the next year, and the elongation of needles may be affected by hydrological conditions in the early summer. In the  
387 Spasskaya Pad Forest, pulse-labeling experiments with  $^{13}\text{CO}_2$  showed that stored carbon from the previous year contributed  
388 approximately 50 % to formation of new needles in *Larix gmelini* saplings (Kagawa et al., 2006). The high level of water  
389 availability in the summers of 1999 and 2000 likely contributed to increased carbon storage and, as a result, the high  
390 formation of needles in 2000 and 2001. The significant NDVI decrease in 2002 was probably caused by a low level of soil  
391 moisture (i.e., dry conditions). The high summer air temperature (Fig. 2c) and the small amount of precipitation (Fig. 2d) in  
392 2001 and 2002 caused droughts in 2002 and 2003. Subsequently, the soil moisture increased due to a large amount of water  
393 year precipitation (Fig. 2d), which likely contributed to an increase in NDVI until 2007.

394 It is known that the NDVI depends on the previous-year precipitation in arid and semi-arid regions (e.g., Burry et al., 2018;  
395 Camberlin et al., 2007). In addition, historical time series of climate indices, based on both precipitation and temperature,  
396 were related to one-year lagged NDVI (e.g., Verbyla, 2015; Liu et al., 2017). In boreal interior Alaska, the summer moisture  
397 index showed a correlation with maximum summer NDVI not only at a one-year time lag in two 10-km climate station  
398 buffers but also at a two-year time lag in many other ones (Verbyla, 2015). Possible reasons for the multi-year NDVI lag  
399 could be the long-term negative vegetation responses to drought events, such as a decrease in carbon allocation by plants  
400 (e.g., Kannenberg et al., 2019) and plant mortality (e.g., Anderegg et al., 2012). Negative effects of drought events also  
401 occurred in our study.

402 ~~The effect of the preceding hydrological conditions on NDVI is also evidenced by the significant negative correlation~~  
403 ~~between foliar  $\delta^{13}\text{C}$  and the previous August SWE during 1999–2007 ( $r = 0.79, p < 0.05$ ; Fig. 5). The mechanism by which~~  
404 ~~plant  $\delta^{13}\text{C}$  responds to changes in light and water availability has been well explained in previous studies (e.g., Farquhar et~~  
405 ~~al., 1989). Under drought stress during 2001–2002, there was a decrease in needle stomatal conductance, resulting in a~~  
406 ~~decrease in carbon assimilation. In the subsequent years, 2002–2003, larches produced fewer needles (lower NDVI) from the~~  
407 ~~previously photosynthesized carbon, and as a result, had high  $\delta^{13}\text{C}$  values. Comparing the decrease in TF NDVI for drought~~  
408 ~~events, the decrease in TF NDVI for the extreme wet event was not as large (Fig. 2b and 3a), although the extreme wet event~~  
409 ~~caused a significant decrease in the NDVI of RF-1 and RF-2. However~~ As described above, the positive correlations between  
410 the TF NDVI and soil moisture were observed during 1999–2006; however, the correlations were shifted to negative values  
411 during 2008–2019 (Fig. 4b–d and S4a–e). After 2007, the TF NDVI was negatively correlated with the SWE of all months in  
412 the previous (with a one-year time lag) and current years (without a lag) (Table S6). This may indicate that after the extreme  
413 wet event, the soil moisture in the previous and current years seemed to negatively affect the current TF NDVI. Therefore, a  
414 high level of soil moisture may affect needle production (i.e., carbon assimilation, needle formation, and/or needle  
415 elongation).

416 Additionally, the  $\delta^{13}\text{C}$  values of needles at our study site often depend on water availability (Kagawa et al., 2003; Tei et al.,  
417 2019a). As shown in Fig. 5, there was the significant negative correlation between foliar  $\delta^{13}\text{C}$  and the previous August SWE  
418 in 1999–2007 ( $r = -0.79$ ,  $p < 0.05$ ). Interestingly, not only before the wet event but also for the whole observation period  
419 (1999–2019), a negative correlation was found between foliar  $\delta^{13}\text{C}$  and the previous August SWE (Fig. 5). These results  
420 differed from the correlations between the NDVI and SWE, which changed from positive to negative values. Before the wet  
421 event, under drought stress during 2001–2002, needle stomatal conductance was decreased, resulting in decreased carbon  
422 assimilation. In the subsequent years, 2002–2003, larches probably produced fewer needles (lower NDVI) with higher  $\delta^{13}\text{C}$   
423 from the previously photosynthesized C (Fig. 3a and 3d).

424 ~~However, based on the foliar  $\delta^{13}\text{C}$  data, there was no evidence that the needle stomatal conductance, which is an indicator of~~  
425 ~~the rates of transpiration and carbon assimilation, was disturbed by the event because the correlation between~~ After the wet  
426 event, the foliar  $\delta^{13}\text{C}$  and SWE remained negative, indicating high stomatal conductance (low foliar  $\delta^{13}\text{C}$ ). ~~During 2008–~~  
427 ~~2019, foliar  $\delta^{13}\text{C}$  was mainly controlled by hydrological conditions in the current year rather than those in the previous year.~~  
428 ~~In years with a high SWE, such as 2009 and 2015, stomatal conductance increased (low foliar  $\delta^{13}\text{C}$ ), which usually indicates~~  
429 High stomatal conductance typically contributes to the higher potential of a plant to assimilate  $\text{CO}_2$ , store C, and produce  
430 needles (high TF NDVI); however, after the wet period, larch produced fewer needles (low TF NDVI).  
431 Compared with the decrease in the TF NDVI for drought events, that for the extreme wet event was smaller (Fig. 2b and 3a),  
432 although the extreme wet event caused a significant decrease in the NDVI of RF-1 and RF-2. The decrease in the TF NDVI  
433 in wet years may be due to different factors, such as nitrogen availability for larches, which can control needle formation.  
434 This factor will be discussed in the next chapter.

#### 435 4.3.2 Nitrogen availability

436 Before 2007, the TF NDVI showed a significant negative correlation with foliar C/N (Fig. 4f), indicating a positive  
437 correlation with foliar N content. In this ecosystem, there have been no previous studies on the temporal correlation between  
438 NDVI and plant N content (or  $\delta^{15}\text{N}$ ). Changes in leaf nitrogen, which is an important element of chlorophyll (green pigment),  
439 were detected using NDVI (Gamon et al., 1995). Previously, the relationship between NDVI and leaf N content was  
440 predominantly investigated in crops for agricultural purposes but not in natural ecosystems. In coniferous forests, the  
441 estimation of foliar nitrogen using remote-sensing methods showed the highest uncertainty due to the complex structure of  
442 needleleaf canopies (reviewed by Homolova et al., 2013).

443 As leaf N content is considered to be an indicator of nitrogen availability for a plant in some boreal regions, where the  
444 ecosystem is usually poor in N (Matsushima et al., 2012; Liang et al., 2014), we concluded that forest greenness (NDVI) was  
445 strongly controlled by nitrogen uptake by larch trees. Therefore, soil moisture is suggested to play a crucial role in  
446 maintaining forest nitrogen status. During 2000–2001, soil water was available for plants and induced favorable conditions

447 for soil nitrogen uptake by trees. Under suitable soil moisture conditions, the production of soil inorganic N may increase.  
448 This may lead to a high production of larch needles (high NDVI). During 2002–2003—the drought years—dry conditions  
449 caused less productivity of soil inorganic N and less N uptake by trees. In the post-drought period of 2004–2007, an increase  
450 in soil moisture gradually recovered the forest conditions in terms of nitrogen uptake and needle production.  
451 After 2007, the foliar C/N still showed a negative correlation with the TF NDVI during 2008–2018, but this correlation was  
452 statistically weaker compared to that during 1999–2006 (Fig. 4f). At the same time, the positive correlations between the TF  
453 NDVI and SWE changed to negative ones during 2008–2019. According to these results, high soil moisture could lead to low  
454 needle production under low nitrogen availability. When extremely high soil moisture, resulting in the saturation of soil with  
455 water, caused less production of soil inorganic nitrogen, low TF NDVI and high C/N values may be observed; thus, TF NDVI  
456 and SWE were negatively correlated.

457 While N content reflects the plant's nitrogen status, plant  $\delta^{15}\text{N}$  is widely accepted to depend on the isotopic composition of  
458 nitrogen sources (e.g., Evans, 2001). Therefore, the  $\delta^{15}\text{N}$  of soil inorganic ammonium  $\text{NH}_4^+$ , which is the main nitrogen  
459 source in the Spasskaya Pad forest (Popova et al., 2013), presumably determined the foliar  $\delta^{15}\text{N}$  in larches. As shown in Fig.  
460 3e, foliar  $\delta^{15}\text{N}$  gradually decreased after 2005. These data suggest that larch trees used less soil inorganic N, especially from  
461 the deeper soil layers, which usually have higher soil  $\delta^{15}\text{N}$  (Amundson et al., 2003; Fujiyoshi et al., 2017). This may be  
462 related to either a change in soil N dynamics, a decrease in the vertical distribution of roots (Takenaka et al., 2016), or  
463 damage to the lower roots due to extremely high soil moisture. Under root oxygen stress due to soil flooding, plant  
464 metabolism changes from aerobic respiration to anaerobic fermentation, characterized by energy deficiency and ethanol  
465 production, both of which induce decreased nutrient uptake and plant growth (reviewed by Pezeshki and Delaune, 2012).  
466 Reduced soil conditions can also induce soil phytotoxin production, damaging the root system (Pezeshki, 2001).

467 It should be noted that not only the extreme wet event in 2007, but also the extreme drought in 2001 may have caused a  
468 change in N availability. Many studies have shown that foliar  $\delta^{15}\text{N}$  increases during drought (Penuelas et al., 2000; Handley  
469 et al., 1999; Lopes and Araus, 2006; Ogaya and Penuelas, 2008). However, in the present study, the drought in 2001 and  
470 2002 decreased foliar  $\delta^{15}\text{N}$ . We could not identify the exact reason, but drought in 2001 and 2002 might have affected the N  
471 availability for larch trees.

### 472 4.3.3 NDVI and RWI of larch trees

473 Two parameters of aboveground biomass, the RWI and TF NDVI, were positively correlated at a significant level ( $r = 0.76, p$   
474  $< 0.05$ ; Fig. 4a) during 1999–2006. Similarly, in other northern regions, temporal patterns of the NDVI and  
475 dendrochronological data were similar for larch (Erasmi et al., 2021; Berner et al., 2011; Berner et al., 2013), pine (Berner et  
476 al., 2011), and spruce (Andreu-Hayles et al., 2011; Beck et al., 2013; Berner et al., 2011; Lopatin et al., 2006). This means  
477 that tree growth (RWI) and needle production (NDVI as an indicator of LAI) showed synchronous responses to

478 environmental changes before 2007. However, there was no significant correlation between the TF NDVI and RWI after  
479 2007. Thus, the extreme wet event in 2007 could have changed the physiological response of larch trees to the environment  
480 in terms of needle and wood production.

481 The correlation between NDVI and RWI at our observation site was previously reported by Tei et al. (2019b). They used  
482 GIMMS-NDVI3g and found its positive correlation with the RWI in the subsequent year during 2004–2014 at the study site.  
483 These two parameters, the NDVI and RWI, reflect the carry-over of carbon, which is fixed via needles in the previous year  
484 and used in the current year, as experimentally demonstrated by Kagawa et al. (2006). ~~In our study, we could not find a  
485 significant correlation between the TF NDVI and RWI at the one year lag of RWI (Fig. S4g).~~ In previous studies,  
486 dendrochronological data showed that tree growth responded to climate with a time lag (e.g., Tei and Sugimoto, 2018). **In our  
487 study, we did not observe a significant correlation between the TF NDVI and RWI at the one-year lag of RWI (Fig. S4g).** ~~In  
488 our study, soil moisture and nitrogen availability for trees seemed to be the key factors of the environment affecting not only  
489 the NDVI, as mentioned above, but also the RWI. However, the TF NDVI and RWI were not significantly correlated after  
490 2007, whereas there was a significant positive correlation before 2007. Thus, the extreme wet event in 2007 could have  
491 changed the physiological response of larch trees to the environment in terms of needle and wood production.~~

#### 492 **4.4 Changes in larch forest NDVI due to drought and the extreme wet event**

493 As shown in Fig. 2b, the NDVI in TF showed a significant decrease in 2002. Such a decrease in NDVI has been repeated in  
494 the past because the climate is continental (dry) in this region. Compared to this decrease in NDVI due to drought, the  
495 extreme wet event in 2007 showed only a slight decrease in the NDVI in TF, although the NDVI in DF and RF-2 decreased  
496 considerably.

497 Tree mortality in the DF and RF during the extreme wet event is controlled by soil properties and topographic features, that  
498 is, depressions (Iwasaki et al., 2010). However, the effects of the event may not only include tree mortality but also invisible  
499 damage to living trees. In this study, NDVI, a potential indicator of needle production in a typical forest, was negatively  
500 related to the summer SWE in the previous and current years during 2008–2019 and with the current-year needle C/N during  
501 2008–2018 (Table S6). This may indicate that needle production in the current and subsequent years during the summer was  
502 disturbed by increased soil moisture and decreased soil N uptake by trees. We suggest that N uptake by larches might be  
503 reduced in wet soils due to damaged lower roots, decreased vertical distribution of roots (Takenaka et al., 2016), or altered  
504 soil N production.

505 Changes in the process of needle production may affect tree growth in the current and subsequent years in the forest (Kagawa  
506 et al., 2006; Tei et al., 2019b). However, we found no evidence that tree radial growth was disturbed after 2007, and the RWI  
507 responded well to changes in the SWE (Fig. 3b and 3c). Additionally, at the ecosystem scale, there was no significant change  
508 in the CO<sub>2</sub> exchange measured by the 32-m flux tower in this larch forest (Kotani et al., 2019). However, the observed

509 increase in understory biomass was suggested to compensate for negative changes in fluxes at the overstory level (Kotani et  
510 al., 2019) and in the NDVI of the forest (Nagano et al., 2022). This means that the negative effects of the extreme wet event  
511 on living larch trees were not excluded in the previous studies. Our study showed that limitation in N uptake at high soil  
512 moisture levels is one of the factors that may potentially reduce tree growth in the future.

513 In our previous study (Nogovitsyn et al., 2022), spatial variations in NDVI and foliar traits identified favorable conditions in  
514 the sites affected by the extreme wet event (RF). The larch forest in RF with lower NDVI (lower stand density) had higher  
515 light (higher  $\delta^{13}\text{C}$ ) and nitrogen (lower foliar C/N) availability for one mature larch tree than that in unaffected areas (TF)  
516 because of reduced competition for light and soil nitrogen among trees. Such favorable conditions and the presence of a large  
517 number of young larch trees may lead to further RF succession after an extremely wet event. However, because weather  
518 extremes are expected to be more frequent and intensive (Douville et al., 2021), the period between extremes may exceed the  
519 period of recovery after the extremes. Therefore, in the future, forests may be damaged rather than recovered.

520 We showed that NDVI values in affected areas were lower than those in typical larch forests for more than 10 years after the  
521 extreme wet event. In other boreal regions, the NDVI was higher in damaged forests because of the strong contribution of  
522 understory to surface greenness (Bunn et al., 2007; Dearborn and Baltzer, 2021), suggesting the need to combine field and  
523 remote sensing observations. Regarding the prediction of tree growth in this dry region, there is a discrepancy between the  
524 different vegetation models. The dynamic global vegetation model (DGVM) simulated increased forest production  
525 throughout the circumboreal region in the nearest century, whereas the RWI-based model showed the opposite result in the  
526 regions of Alaska, Canada, Europe and our study site (Tei et al., 2017). In these regions with a continentally dry climate, tree  
527 growths suffers because of the effects of temperature-induced drought stress and are predicted to decrease under warming  
528 conditions (Tei et al., 2017). In addition, extreme wet events are also likely to have a negative impact on forest production  
529 because of changes in nitrogen availability, as demonstrated in this study. Some models may overestimate production  
530 because they do not include important parameters such as soil moisture, soil N production, and N uptake by trees. To better  
531 understand changes in the forest, long-term observation of variations in soil N availability depending on soil moisture and  
532 other factors is necessary.

## 533 5 Conclusions

534 In this study, historical variations in satellite-derived NDVI (seasonal maximum) and field-observed parameters of larch  
535 forests were investigated to understand the effects of the extreme wet event on the larch forests of northeastern Siberia. The  
536 NDVI values of the plots visually unaffected (typical mature larch forest, TF) and affected by the event were similar before  
537 2007, and the NDVI values at both plots were similarly decreased by drought. However, both NDVI values but differed after  
538 2007 because of the high tree mortality in affected plots caused by waterlogging and the presence of water in the depression.

539 Although the TF was visually unaffected by the event, it also changed. Before the wet event, the positive relationship  
540 between the TF NDVI and SWE in the previous summer and the current June showed that needle production increased with  
541 water availability, as previously observed in this dry region. However, after the wet event, the relationship between the TF  
542 NDVI and soil moisture in the previous and current years unexpectedly shifted from positive to negative, which may have  
543 been related to N availability. ~~Temporal correlations revealed that before the wet event, needle production (TF NDVI) was~~  
544 ~~positively related to the SWE in the previous summer and current June and tree ring growth (RWI). In this dry region,~~  
545 ~~larches used the previous year soil water to make photosynthates (carbon assimilated by photosynthesis) to prepare needles~~  
546 ~~and wood in the current year and used the early summer soil water for the elongation of needles in the current year.~~  
547 N is considered an important factor controlling needle production before and after the wet event, as the negative correlations  
548 between TF NDVI and needle C/N ratio were observed until 2018 (except for in 2007). In addition, the needle  $\delta^{15}\text{N}$   
549 continuously decreased after the wet event, suggesting that the larch trees used a different N source when the lower roots  
550 were damaged by anaerobic conditions. Before the wet event, the high (but suitable) soil moisture level presumably produced  
551 more soil inorganic N, and consequently produced more larch needles, whereas the extreme wetness after 2007 likely had a  
552 long-term negative effect on needle production because of the lower soil N production. As shown in this study, extreme wet  
553 events in continental dry regions may alter the interaction between water availability and tree performance (for example,  
554 NDVI) over a long time because of shifts in N availability for trees.

555 ~~In addition, the TF NDVI showed significant negative correlations with needle C/N ratio (or positive correlation with needle~~  
556 ~~N content) before the wet event, and this correlation continued until 2018 (except for 2007). This indicates that nitrogen is an~~  
557 ~~important parameter for this ecosystem before and after a wet event. The  $\delta^{15}\text{N}$  in 1999–2006 showed a positive correlation~~  
558 ~~with TF NDVI. Under suitable soil moisture conditions, the production of soil inorganic N, and consequently, the production~~  
559 ~~of larch needles, may be increased. However, after the wet event in 2008–2019, the temporal correlations between the TF~~  
560 ~~NDVI and SWE in the previous summer and current June surprisingly shifted from positive to negative. Needle N content~~  
561 ~~was positively correlated with the TF NDVI and negatively correlated with the SWE in June. In addition, needle  $\delta^{15}\text{N}$~~   
562 ~~generally decreased, indicating that larches used less inorganic nitrogen from deeper soils, which usually have higher  $\delta^{15}\text{N}$ .~~  
563 ~~During this period, extremely high soil moisture may have caused inactive soil inorganic N, anaerobic stress-induced root~~  
564 ~~damage, and/or production of soil phytotoxins, which decreased nitrogen uptake and plant growth.~~

565 **Data availability.** Yakutsk air temperature and precipitation data are available from the RIHMI-WDC website ([http://aisori-](http://aisori-m.meteo.ru/)  
566 [m.meteo.ru/](http://aisori-m.meteo.ru/)). NDVI data was calculated from Landsat 5, 7, 8 images, which are available from the USGS website  
567 (<https://earthexplorer.usgs.gov/>). The seasonal maximum NDVI data and larch RWI data are described in the Supplement  
568 (Table S1 and S2). All other data presented in this work have been deposited in the Arctic Data Archive System (ADS): soil

569 moisture data at Spasskaya Pad (<https://ads.nipr.ac.jp/dataset/A20230217-001>) and larch needle C/N and carbon and nitrogen  
570 isotopes at Spasskaya Pad (<https://ads.nipr.ac.jp/dataset/A20230217-002>).

571 **Author contributions.** AS designed the research and AN calculated the NDVI and performed the analyses. TM, ST, and NS  
572 helped with the analyses, and TCM managed all the field observations. RS and YM helped with field observations. AN and  
573 AS prepared the paper with contributions from all co-authors.

574 **Competing interests.** The authors declare that they have no conflict of interest.

575 **Acknowledgements.** The authors are grateful to Dr. A. Kononov, R. Petrov, and other colleagues from the IBPC for  
576 supporting our fieldwork at the Spasskaya Pad Forest Station and M. Grigorev for his assistance in the fieldwork. The  
577 authors also appreciate Y. Hoshino, S. Nunohashi, A. Alekseeva, and E. Starostin for their support in laboratory work and  
578 logistics.

579 **Financial support.** This work was supported by the Belmont Forum Arctic program COPERA (C budget of ecosystems,  
580 cities, and villages on permafrost in the eastern Russian Arctic) project, the International Priority Graduate Programs (IPGP),  
581 funded by the Ministry of Education, Culture, Sports, Science, and Technology-Japan (MEXT), and the Hokkaido University  
582 DX Doctoral Fellowship (Grant No. JPMJSP2119), funded by the Japan Science and Technology Agency.
