16 **Abstract**

17 The implementation of agroecological practices often leads to additional soil organic carbon storage,
18 and we have sought to assess the biogeochemical stability of this additional carbon. To achieve this, we
19 implemented a multi-method approach using particle size and density fractionation, Rock-Eval®
20 thermal analyses and long-term incubation (484 days), that we applied to topsoil samples (0-30 cm)
21 from temperate luvisols that had been subjected, in > 20 years long-term experiments in France, to
22 conservation agriculture (CA), organic agriculture (ORG) and conventional agriculture (CON-LC) in
23 La Cage experiment, and to organic wastes products (OWPs) applications in QualiAgro experiment,
24 including biowaste composts (BIOW), residual municipal solid waste composts (MSW), farmyard
25 manure (FYM) and conventional agriculture without organic inputs (CON-QA). The additional carbon
26 resulting from agroecological practices is the difference between the carbon stock of the bulk soil,
27 physical fractions or carbon pools in a soil under the agroecological practices and that of the same soil
28 under a conventional practice as control. The incubations provided information on the additional carbon
29 stability in the short term (i.e., MRT <2 years) and showed that the additional soil organic carbon
30 mineralized faster than the carbon in the conventional control at La Cage but slower at QualiAgro. In
31 OWPs-treated plots at QualiAgro, 60-66% of the additional carbon was stored as mineral-associated

32 organic matter (MAOM-C), and 34-40% as particulate organic matter (POM-C). In CA and ORG
33 systems at La Cage, 77-84% of the additional carbon was stored in MAOM-C, versus 16-23% as POM-
34 C. Management practices hence influenced the distribution of additional carbon in physical fractions.
35 Utilizing the PARTYSOC model with Rock-Eval® thermal analysis parameters, we found that most, if
36 not all, of the additional carbon belonged to the active carbon pool (MRT ~ 30-40 years). In summary,
37 our comprehensive multi-methods evaluation indicates that the additional soil organic carbon is less
38 stable over decadal and pluri-decadal time-scales compared to soil carbon under conventional controls.
39 Our results show that particle size and density fractions can be heterogenous in their biogeochemical
40 stability. On the other hand, although the additional carbon is mainly associated with MAOM, the high
41 proportion of this carbon in the active pool suggests that it has a mean residence time not exceeding ~50
42 years. On the other hand, agroecological practices with equivalent additional carbon stocks (MSW,
43 FYM vs CA) exhibited a higher proportion of additional carbon in POM-C under MSW (40%) and FYM
44 (34%) compared to CA (16%), which suggests a high chemical recalcitrance of POM-C under OWPs
45 management relative to conservation agriculture. Additional soil organic carbon deriving from organic
46 wastes, i.e., biomass that has been partially decomposed and transformed through its processing prior to
47 its incorporation in soil, would be more biogeochemically stable in soil than that deriving directly from
48 plant biomass. The apparent contradictions observed between method can be explained by the fact that
49 they address different kinetic pools of organic carbon. Care must be taken to specify which range of
50 residence times is considered when using any method intending to evaluate the biogeochemical stability
51 of soil organic matter, as well as when using the terms stable or labile. In conclusion, the contrasting
52 biogeochemical stabilities observed in the different management options highlight the need to maintain
53 agroecological practices to keep these carbon stocks at a high level over time, given that the additional
54 carbon is stable on a pluri-decadal scale.

59

1 Introduction

60 Soil organic matter (SOM) plays a crucial role in the functioning of terrestrial ecosystems and
61 can contribute to mitigate climate change. A minor change of soil organic carbon (SOC) content can
62 make a significant difference to global climate because soil contains more carbon than vegetation and
63 atmosphere combined (Lal, 2004). The 4p1000 initiative encourages the implementation of agricultural
64 practices that increase and/or maintain soil carbon stocks (www.4p1000.org, Rumpel et al., 2020). At
65 the field scale, changes in SOC stocks result from an imbalance between C inputs (crop residues, litter,
66 root exudates, exogenous organic matter such as organic wastes products (OWPs)) and C outputs from

67 the system due to crop residue export, SOC mineralization, leaching, or erosion (Lal, 2018). Although
68 some agricultural practices can reduce mineralization rates (e.g., reduced tillage, see review by
69 Haddaway et al., 2017), it is generally accepted that the most effective way to increase SOC stocks is to
70 increase carbon inputs (e.g., Virto et al., 2012; Autret et al., 2016; Fujisaki et al., 2018; Chenu et al.
71 2019). This can be achieved by increasing biomass production in the field and residue return (e.g., cover
72 crops, Poeplau and Don, 2015; Autret et al., 2016), or by mobilizing external carbon resources such as
73 OWPs (Peltre et al., 2012; Paetsch et al., 2016).

74

75 The implementation of selected agroecological practices and systems such as conservation
76 agriculture, agroforestry, OWPs application allows for additional carbon storage in soils (Peltre et al.,
77 2012; Autret et al., 2016; Paetsch et al., 2016; Pellerin et al., 2019; Bohoussou et al., 2022). The
78 additional carbon storage linked to agricultural practice B is the difference between the carbon stock in
79 a soil under practice B and that of the same soil under a reference practice (Pellerin et al., 2019). This
80 additional carbon storage is not necessarily the result of recent carbon inputs, but can also include the
81 legacy carbon. However, knowledge on the biogeochemical stability of this additional carbon is lacking,
82 questioning the reversibility of this storage. The carbon sink effect will indeed be more effective if the
83 additional carbon storage is realized in the form of persistent organic carbon (OC) and not in the form
84 of labile OC. We propose to evaluate and compare the biogeochemical stability of additional organic
85 carbon following implementation of various agroecological practices.

86

87 Several methods have been reported in the literature to assess the organic carbon temporal
88 stability in soils. These methods isolate kinetic pools or carbon fractions with contrasting mean residence
89 times (MRT), e.g., particle size fractionation, Balesdent, 1996; density fractionation, Sollins et al., 2006;
90 sequential extraction, Heckman et al., 2018; thermal analysis, Barré et al., 2016 and incubation, Schädel
91 et al., 2020. Physical fractionation is probably the most used method so far to evaluate SOM stability.
92 Physical fractionation methods isolate fractions based on size, density, or a mixture of both (Chenu et
93 al., 2015). In a study comparing several fractionation methods, Poeplau et al. (2018) found that particle
94 size fractionation was well suited to isolate particulate organic matter (POM) fractions from mineral
95 associated organic matter (MAOM) with contrasting MRT. Fractionation of SOM into POM and
96 MAOM components can reveal insights about the sources and stability of SOC (Kim et al., 2022).
97 However, some studies have shown that SOC fractionation methods fail to accurately separate stable
98 SOC from active SOC, and in particular that the isolated MAOM fractions are mixtures of labile SOC
99 (MRT of months to year) and stable centennial SOC (Balesdent et al. 1987; Jastrow et al., 1996;
100 Sanderman et al., 2013; Torn et al., 2013; Balesdent, 1996; Hsieh, 1992; von Lützow et al., 2007;
101 Sanderman and Grandy, 2020). This may be due to methodological challenges as much as the fact that

102 there are multiple pathways for SOM formation and stabilization (Cotrufo et al., 2013; Sokol et al.,
103 2019).

104

105 Thermal analysis techniques, long used in petroleum exploration and clay mineralogy, offer a
106 promising alternative or complement to physical and chemical fractionation methods, and are
107 increasingly applied to studies of SOC stability (Peltre et al., 2013; Plante et al., 2009). Indeed, several
108 parameters obtained using thermal analysis are strongly related to SOM biogeochemical stability (Barré
109 et al., 2016; Poeplau et al., 2019). However, these parameters do not allow us to separate the kinetic
110 carbon pools (Schiedung et al., 2017). And so, recently, Cécillon et al. (2018, 2021) developed a
111 machine-learning model, called PARTY_{SOC}, showing that Rock-Eval® parameters can be used to
112 predict the fraction of SOC that is stable at a centennial timescale. Kanari et al. (2022) evidenced that
113 SOC fractions calculated using PARTY_{SOC} matched the stable (MRT >100 years) and active (MRT ~
114 30-40 years) OC pools of the AMG model, a model widely validated to simulate SOC stock evolution
115 in French and European croplands (Clivot et al., 2019; Bruni et al., 2022). As a result, one can consider
116 that a Rock-Eval® analysis associated to the PARTY_{SOC} model allows for the quantification of carbon
117 fractions that are stable at a centennial timescale and active *sensu* AMG model.

118

119 The incubation method is, however, the only direct test for the biological stability of SOC, that
120 results from chemical resistance to decomposition and/or organo-mineral associations and/or
121 inaccessibility of organic substrates to microbial decomposition. Long-term incubations (months to
122 years) may diverge from the conditions prevailing in the soil profile but provide insights into the
123 potential decomposability of slower-cycling SOC (e.g., Schädel et al., 2014). In early laboratory
124 incubations, fast-cycling C respiration dominates total respired SOC, but rapidly declines, while slow-
125 cycling SOC accounts for most of the respired SOC after the fast SOC pool is depleted.

126

127 These different methods do not separate similar carbon kinetic pools. Indeed, the incubation
128 method isolates carbon with MRT ranging from days to years (Schädel et al., 2014) while others isolate
129 carbon with longer MRT (decades to centuries) (Cécillon et al., 2018, 2021, Balesdent, 1996). Thus, a
130 multi-method approach will further improve our knowledge of the biogeochemical stability of SOC in
131 the short (<2 years), medium (2-50 years) or long term (>50 years). The objective of this study was to
132 evaluate the biogeochemical stability of additional SOC stored upon the implementation of carbon
133 storing agroecological practices using a multi-method approach. To do so, we characterized SOM using
134 particle size and density fractionation, Rock-Eval® (RE) thermal analysis and incubation in soil from
135 plots managed using various agroecological practices such as addition of OWPs (composts and farmyard

136 manure) and alternative cropping systems including no tillage, permanent cover crop and the
137 introduction of legumes in the rotation. The application of OWPs is likely to provide organic matter
138 (OM) that has been pre-stabilized by the storage (manure) or composting process and is hence less
139 decomposable than the fresh matter provided by plant biomass in alternative cropping systems. Then,
140 we hypothesized (i) that the biogeochemical stability of additional SOC depends on the management
141 practices implemented and (ii) that the additional SOC originating from OWPs would be more stable
142 than that directly originating from plant biomass, but, (iii) overall, that the additional SOC would be less
143 stable than the SOC stored in the conventional controls.

144 2 Materials and methods

145 Field Site and soil sampling

146 This study focuses on two French long-term experiments (LTEs) developed on Luvisols in the
147 same region, where agroecological practices including conservation agriculture, organic agriculture and
148 OWPs application (composts and manure) were implemented.

149 *La Cage experiment* is conducted in Versailles (48°48'N, 2°08'E, alt 120 m). During the 21 years
150 of experimentation, the mean annual temperature and precipitation were 11.6 °C and 633 respectively.
151 The soil is a well-drained deep Luvisol (IUSS Working Group WRB, 2015). The field experiment is
152 arranged in a randomized complete block design, divided into two blocks, themselves divided into four
153 plots for each cropping system. Each plot is divided into two subplots of 0.56 ha, so that two different
154 crops of the crop rotation are present each year, wheat being grown every year in one of the two subplots
155 (Autret et al., 2020). A detailed presentation of crop rotations, soil management and fertilization were
156 given by Autret et al. (2016). The 4 year's crop rotation mainly consisted of rapeseed (*Brassica napus*
157 *L.*), winter wheat (*Triticum aestivum L.*), spring pea (*Pisum sativum L.*) and winter wheat.

- 158 - Conventional agriculture (CON-LC) is characterized by a soil and crop management
159 representative of the Paris Basin cereal production, with annual soil ploughing, the absence of
160 organic amendment, a mineral N fertilization (average rate = 143 kg N ha⁻¹ yr⁻¹) and a
161 systematic use of pesticides.
- 162 - Conservation agriculture (CA) includes a permanent soil cover, initially fescue (*Festuca rubra*)
163 and since 2008 alfalfa, grown under the main crops, except pea. In the rotation, rapeseed is
164 replaced by maize (*Zea mays L.*) in CA and direct seeding is performed.
- 165 - Organic agriculture (ORG) is characterized by alfalfa-alfalfa-wheat-wheat rotation with annual
166 soil ploughing and no synthetic fertilizers nor pesticides.

167 *The QualiAgro experiment* is located at Feucherolles, 20 km west of Versailles (48°52'N, 1°57'E,
168 alt 150 m). During the 21 years of experimentation, the mean annual temperature and precipitation were
169 11.0 °C and 614 respectively. The soil is a Luvisol (IUSS Working Group WRB, 2015). The crop

170 rotation mainly consisted of wheat and maize (Peltre et al., 2012). It is a field experiment conducted in
 171 collaboration with INRAE and Veolia Environment Research and Innovation since 1998, on which
 172 composts of OWPs are applied every 2 years for a dose equivalent to $\sim 4 \text{ t C. ha}^{-1}$ from 1998 to 2013 and
 173 $\sim 2 \text{ t C. ha}^{-1}$ from 2015 to 2020. The unit plots are $10 \times 45 \text{ m}^2$. Each treatment has 4 replicates and OWPs
 174 are applied every two years on wheat stubble. Soils are ploughed every year on this experimental site.
 175 Since 2015, wheat and maize residues are buried in the soil. Four treatments are considered in this study.

- 176 – Conventional agriculture (CON-QA): is characterized by a soil and crop management
 177 representative of the Paris Basin cereal, the absence of organic amendment, a mineral N
 178 fertilization (average rate = $167 \text{ kg N ha}^{-1} \text{ yr}^{-1}$).
- 179 – Biowaste compost (BIOW): composting of the fermentable fraction of selectively collected
 180 household waste, mixed with green waste;
- 181 – Municipal solid waste compost (MSW): composting of the residual fraction of household waste
 182 after selective collection of packaging;
- 183 – Farmyard manure (FYM) which represents a reference amendment.

184 At both sites, four replicate plots were available per treatment. From each plot, 3 sub-samples were
 185 taken from the topsoil $30 \pm 1 \text{ cm}$ (in September 2019 at QualiAgro and in November 2020 at La Cage),
 186 thoroughly mixed and combined into one sample. The samples were sieved to 4 mm, homogenized, the
 187 plant material was removed and the soil was oven dried at 35°C for 72h before particle size and density
 188 fractionation and RE thermal analysis.

189

190 **Table 1** Soil organic carbon (SOC), soil organic nitrogen (SON) and C/N measured in topsoil. Values
 191 in brackets are standard deviations. CON-QA: conventional agriculture without organic inputs, MSW:
 192 municipal solid waste compost, FYM: farmyard manure, BIOW: biowaste compost, CON-LC:
 193 conventional agriculture, ORG: organic agriculture and CA: conservation agriculture.

194

195 **Calculation of SOC stocks and additional carbon stocks**

196 SOC stocks were calculated at equivalent soil mass in both long-term experiments. Thus, at
 197 QualiAgro the SOC stock was calculated by multiplying the SOC content by bulk density (data provided
 198 by QualiAgro) and was normalized to a depth of 10 cm (factor 10^{-3}) (reference soil mass of 3963 kg. ha⁻¹
 199 ¹). Bulk densities between 1998 and 2019 increased significantly in all plots. We calculated the
 200 additional soil thickness required to achieve this equivalent soil mass in treatments with lighter tilled
 201 layers as described by Ellert and Bettany (1995):

$$202 \quad T_{\text{add}} = \frac{(M_{\text{soil equiv}} - M_{\text{soil topsoil}}) * 10^{-4}}{\rho_{\text{b subsoil}}}, \quad (1)$$

203 where T_{add} is the additional thickness of the sub-soil layer expressed in cm needed to reach the equivalent
 204 soil mass, $M_{\text{soil equiv}}$ is the equivalent soil mass of the denser horizon in kg. ha⁻¹. In our study, the dense
 205 0-29 cm layer was the reference treatment in 2019 with a bulk density of 1.37 g.cm⁻³ giving an equivalent
 206 soil mass ($M_{\text{soil equiv}}$) of 3963 kg. ha⁻¹. $M_{\text{soil topsoil}}$ is the soil mass in the surface (tilled) layer and $\rho_{\text{b sub-}}$
 207 soil is the bulk density of the underlying 29-35 cm layer (in g.cm⁻³). Carbon stocks per hectare in
 208 equivalent soil masses ($\text{Stock}_{\text{C equiv}}$) were calculated by adding the carbon stock in the surface layers
 209 ($\text{Stock}_{\text{C topsoil}}$) and in the additional underlying layers ($\text{Stock}_{\text{C, Tadd}}$) with the following formula:

$$210 \quad \text{Stock}_{\text{C equiv}} = \text{Stock}_{\text{C topsoil}} + \text{Stock}_{\text{C Tadd}}, \quad (2)$$

211 At La Cage experiment, the soil sampling strategy was designed to calculate SOC stocks on an
 212 equivalent soil mass (ESM) basis Ellert and Bettany (1995) over a depth at least equal to the deepest
 213 tillage event. The ploughing depth was *ca.* 30 cm before 1998 and shallower afterwards, about 25 cm

214 (Autret et al., 2016). The sample was taken at the depth equivalent to a soil mass of 4300 kg. ha⁻¹. The
215 carbon stocks were calculated by multiplying the SOC contents with this equivalent soil mass.

216 We then calculated the additional carbon storage (Δ SOC stock) considering each time the conventional
217 control at La Cage (CON-LC) and the conventional control at QualiAgro (CON-QA). The following
218 formula was used:

$$219 \quad \Delta\text{SOC stock} = \text{Stock}_{\text{C Practice}} - \text{Stock}_{\text{C conventional}} \cdot (3)$$

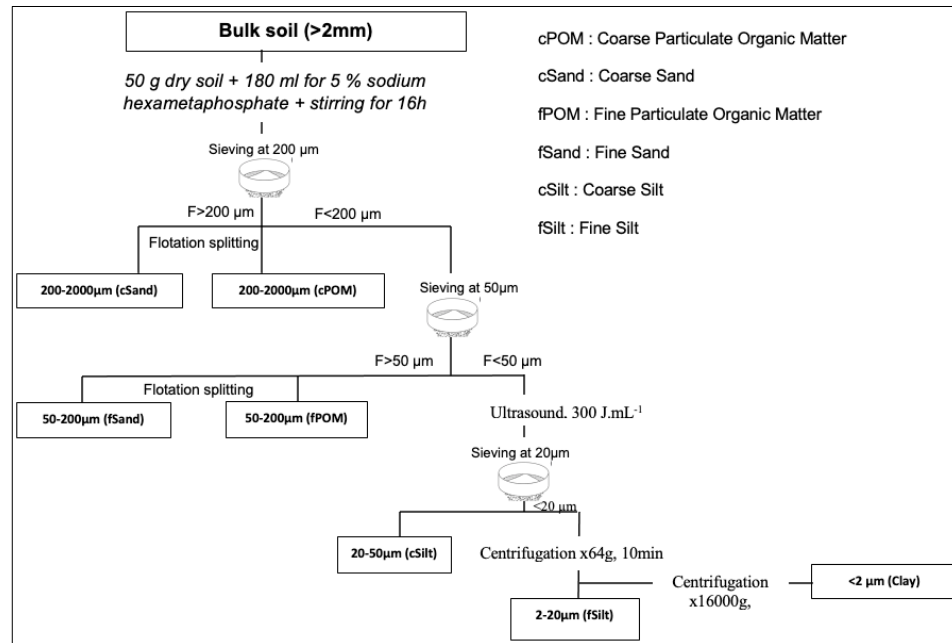

220 With $\text{Stock}_{\text{C Practice}}$: the carbon stock of the agroecological practice and $\text{Stock}_{\text{C conventional}}$: the carbon stock
221 of the conventional control. The standard deviation used for the additional carbon stock was calculated
222 based on the equation described by Kuzyakov and Bol, (2004) as follows:

$$223 \quad SD_{\Delta\text{SOC stock}} = \sqrt{(SD_{\text{stock C Practice}})^2 + (SD_{\text{stock C conventional}})^2}, (4)$$

224 **Particle size and density fractionation**

225 The method uses a preliminary disaggregation aiming at the best compromise between maximum
226 destruction of micro-aggregates of size < 50 μm , and respect of the integrity of organic debris (Balesdent
227 et al., 1991) and combines fractionation by particle size to separate POM from OM associated with clays
228 and silts minerals with water flotation to separate POM from sands. For this purpose, approximately 50
229 g of soil was suspended in 180 mL of 0.5% sodium hexametaphosphate (SHMP) saline solution in a 250
230 mL polyethylene bottle; 10 glass beads were added and the whole set to agitation by inversion (REAX
231 2 type inversion mixers) for 16 hours, at a speed of approximately 50 rpm to destroy the aggregates. The
232 SHMP solution and the glass beads allows to completely disperse soil aggregates > 50 μm diameter in
233 these soils (Balesdent et al., 1991). After agitation, the suspension was first sieved on a 200 μm sieve
234 from which the refusal, the coarse fraction, was recovered in a 250mL glass beaker. We separated the
235 coarse POM (cPOM) from the coarse sands (cSand) by flotation in water. The suspension <200 μm in
236 a second time was submitted to a second sieving at 50 μm and the same operations were performed to
237 separate the fine POM (fPOM) from the fine sands (fSand) using water flotation. The suspension <50
238 μm is submitted to ultrasounds by imposing an energy of 300 J.mL⁻¹ necessary to disperse the micro-
239 aggregates (Balesdent et al., 1998). After this step, we sieved the suspension <50 μm to 20 μm to recover
240 the coarse silts of size between 20 and 50 μm (cSilt) remaining on the sieve. The suspensions containing
241 particles <20 μm were pooled in a 2L beaker. The separation of the fine silts between 2 and 20 μm (fSilt)
242 from the clays was performed by centrifugation of the <20 μm filtrate at 64 g (circa 500 rpm) for 10min.
243 The supernatant containing the clays was collected in a 5L beaker. The same process was repeated 4 to
244 5 times by resuspending the pellet for an optimal recovery of fine silts by decantation. The supernatant
245 collected in the 5L beaker constitutes the clay fraction (<2 μm) and the pellet after repeated
246 centrifugation constitutes the fine silt fraction. To reduce the volume of the clay suspension to be freeze-
247 dried, we added CaCl₂ to flocculate the clay particles and by centrifugation for 20 min at 16000 g (circa

248 8000 rpm) we recovered the pellet which constitutes the clay fraction. An aliquot of the supernatant was
 249 taken to determine the dissolved organic carbon (DOC). The particle-size and density fractionation
 250 resulted in recovery rates of $95 \pm 2\%$ of the initial sample mass and $98 \pm 6\%$ recovery of carbon.

251
 252 **Fig. 1** Particles size and density fractionation protocol (adapted from Balesdent et al., 1998).
 253 The POM fraction is the sum of the cPOM, fPOM, cSand and fSand fractions, while the
 254 MAOM fraction is the sum of the cSilt, fSilt and Clay fractions.

255 2.1.1 Fractions preparation and elemental analysis (C, N)

256 The fractions obtained during this fractionation were dried or freeze-dried. The organic (cPOM,
 257 fPOM) and mineral (cSand, fSand, cSilt) fractions were oven dried at 50°C for 3 days, while the fine
 258 silt (fSilt) and clay (Clay) fractions were freeze dried. Each fraction was weighed and C, N were
 259 determined using dry combustion (elemental analyzer, Elemantar Vario ISOTOP).

260

261 Rock-Eval® (RE) thermal analysis

262 We analyzed 28 samples of bulk soil, using a RE6 Turbo apparatus (Vinci Technologies). A small
 263 amount of soil (about 60 mg) was required for the analysis, which was performed in two consecutive
 264 steps, during which carbon-containing effluents were directly detected. First, the sample underwent
 265 pyrolysis in an inert atmosphere (N₂), followed by oxidation in the presence of O₂ (ambient air). The
 266 heating routine applied during pyrolysis was that proposed by Disnar et al. (2003) and Baudin et al.
 267 (2015), including a three-minute isotherm at 200 °C, followed by a 30 °C·min⁻¹ heating ramp to 650 °C.
 268 Oxidation began with a one-minute isotherm at 300 °C, followed by a 20 °C·min⁻¹ heating ramp to 850
 269 °C and a final five-minute isotherm at 850 °C (oxidation routine presented in Baudin et al. (2015) as the

270 "bulk rock/basic" method). Simultaneous detection of effluents during both analytical steps generated a
271 total of five thermograms per sample describing the evolution of hydrocarbons during pyrolysis
272 (HC_PYR), and CO and CO₂ during both pyrolysis and oxidation steps (CO_PYR, CO₂_PYR, CO_OX,
273 CO₂_OX).

274 **2.1.2 Rock-Eval® parameters**

275 The classical Rock-Eval® parameters were acquired using the RockSix software (Vinci
276 Technologies) with a good reproducibility (Pacini et al., 2023). They include: six automatically
277 generated "peaks" defined as specific areas of the three pyrolysis thermograms (S1, S2, S3, S3', S3CO
278 and S3'CO; Lafargue et al. (2018)), the amount of pyrolyzed carbon (PC corresponding to the sum of
279 organic C released as HC, CO, and CO₂ during pyrolysis), total organic carbon (TOC corresponding to
280 the amount of organic C released during analysis), inorganic carbon (MinC corresponding to the amount
281 of C released from carbonate cracking), hydrogen index (HI corresponding to the ratio of hydrocarbons
282 released to TOC), and oxygen index (OI_{RE6} corresponding to the ratio of organic oxygen released to
283 TOC). In addition, other parameters used as predictors by the PARTYSOCv2.0EU model were
284 calculated based on thermograms obtained using R scripts available on Zenodo
285 (<https://zenodo.org/record/4446138#.YDe84Xlw2SQ>) (Cécillon et al., 2021, Kanari et al., 2021). These
286 include: PseudoS1 (the sum of carbon released during the first 200 s of isothermal 200°C pyrolysis as
287 HC, CO, and CO₂), the S2/PC ratio (the ratio of the amount of hydrocarbons released excluding the first
288 200 s of pyrolysis to the pyrolyzed carbon), the PC/TOC ratio, the HI/OIRE6 ratio, and ten temperature
289 parameters (e.g., T30, T50, T70, T90) that describe the evolutionary steps, i.e., at what temperature 30,
290 50, 70, and 90% of a given gas was released. A detailed description of the definition, units, and equations
291 used to calculate all parameters can be found in the study of Kanari et al. (2021). The HI and OIRE6 are
292 commonly reported indices that represent proxies of the SOM H/C and O/C ratios respectively.

293 **2.1.3 PARTYSOC model based on Rock-Eval® (RE)**

294 In this study, we used the random forest model based on RE results PARTYSOCv2.0EU
295 (<https://zenodo.org/record/4446138#.YDe84Xlw2SQ>) proposed by Cécillon et al. (2021). This model
296 was calibrated on data from 6 long-term agricultural experiments including a bare fallow treatment in
297 northwestern Europe and can predict the proportion of persistent SOC at a centennial timescale in topsoil
298 samples (0-30 cm). The model requires a set of 18 RE parameters (e.g., Kanari et al., 2021) characteristic
299 of a sample and provides a prediction of the proportion of stable SOC for soils from the La Cage and
300 the QualiAgro long-term experiments. The 18 RE parameters retained were the RE temperature
301 parameters T70HC_PYR, T90HC_PYR, T30CO₂_PYR, T50CO₂_PYR, T70CO₂_PYR, T90CO₂_PYR,
302 T70CO_OX, T50CO₂_OX, T70CO₂_OX, and T90CO₂_OX and the RE parameters PseudoS1, S2, S2 /
303 PC, HI, HI / OI_{RE6}, PC, PC / TOC_{RE6}, and TOC_{RE6} (Cécillon et al., 2021).

304 **Long-term incubation**

305 Polyvinyl chloride (PVC) cylinders 5.7 cm in diameter and 4 cm in height with 2 mm perforations
306 were used to build soil microcosms. A 50 μm mesh fabric at the bottom of the cylinder supported the
307 soil while promoting gas exchange. Each cylinder was weighed empty and then with fresh soil
308 equivalent to 100 g of dry soil. The soil samples were then brought to a bulk density of $1.3 \text{ g}\cdot\text{cm}^{-3}$ with
309 a hand press and mold. Knowing the initial water content, the samples were gradually brought to pF 2.5
310 by adding water with a Pasteur pipette. Then, the microcosms were mounted in 0.5 L jars. The soil
311 cylinders were placed on PVC racks and 15 mL of water was added to the bottom of the jars to stabilize
312 the humidity. The jars were sealed and the whole set was placed in the incubator at 20°C for one week
313 pre-incubation. Four replicates per agricultural practice were prepared.

314 After the pre-incubation period, we readjusted the water content of the soil cylinders to pF 2.5
315 when necessary. A total of 28 soil cylinders were incubated for 484 days under the same temperature
316 (20°C) and moisture (pF2.5) conditions.

317 **▪ Mineralization measurement**

318 Soil organic carbon (SOC) mineralization in samples from both long-term experiments (LTEs)
319 was measured nondestructively using a micro gas chromatograph (μGC 490; Agilent Technologie;
320 USA). Measurements were performed 1, 3, 7, 14, 28, 35 days, then one measurement every 2 weeks
321 until the sixth month and finally, one measurement every month until the end of incubation. The CO_2
322 emitted is measured in parts per million (ppm). It is then converted to $\mu\text{g C-CO}_2 \text{ g}^{-1}$ of dry soil using the
323 following formula: $\mu\text{g C} - \text{CO}_2 \cdot \text{g}^{-1} \text{ dry soil} = \frac{\text{CO}_2(\text{ppm}) * M_c * V_b}{V_M * M_{\text{soil}}} (5)$, (Védère et al., 2020).

324 With CO_2 (ppm): amount of CO_2 emitted measured by gas phase microchromatograph; M_c : molar mass
325 of carbon in $\text{g}\cdot\text{mol}^{-1}$; V_b : volume of the jar in L; V_M : molar volume of the gas in $\text{L}\cdot\text{mol}^{-1}$ and M_{soil} : mass
326 of the incubated dry soil in g. The absolute amount of carbon mineralized was expressed per unit of
327 SOC to obtain the specific SOC mineralization in $\mu\text{g C-CO}_2/100 \mu\text{g SOC}$, i.e., % SOC mineralized
328 (Kpemoua et al., 2023). To calculate the amount of additional carbon mineralized over the 484 days, we
329 first calculated the difference in absolute carbon mineralization between the agroecological practice and
330 the conventional control. We assume that the extra absolute carbon mineralized in the agroecological
331 practice relative to the conventional control comes from the additional carbon. Given the amount of
332 additional carbon (ΔSOC), we then expressed this extra absolute carbon mineralization in terms of
333 additional carbon (% ΔSOC).

334

335 **Statistical analysis**

336 All data were tested for normality and homogeneity of variance. Log-transformation was applied
337 to the data for the cSand and fSand fractions, as the transformation improved the normality and variance
338 substantially. A one-way ANOVA was used to detect significant differences at the 5% threshold in bulk
339 soil carbon stocks, fractions, carbon pools and amount of carbon mineralized (C_{min}). Once a significant
340 difference was detected, Tukey's multiple comparison test was used to compare carbon stocks, additional
341 carbon stocks, percentage of total carbon storage and percentage of additional carbon storage in either
342 bulk soil, fractions and carbon pools according to agricultural practices. All statistical analyses were
343 completed in R (version 4.0.2).

344

345 **3 Results**

346 **SOC stocks**

347 The application of organic wastes products (OWPs), increased soil organic carbon (SOC) contents
348 in soils by 64% in biowaste composts treatment (BIOW), 40% in farmyard manure treatment (FYM)
349 and 39% in residual solid waste compost treatment (MSW) compared to the conventional control (CON-
350 QA); while, at La Cage, the implementation of organic agriculture (ORG) and conservation agriculture
351 (CA) increased SOC contents by 6% and 35% respectively, relative to conventional control (CON-LC)
352 (Table 1). The OWPs application significantly increased carbon stocks at QualiAgro. The SOC stocks
353 were in the order: BIOW > FYM ≥ MSW > CON-QA (Table. 1). At La Cage, SOC stocks were in this
354 order: CA > ORG ≥ CON-LC (Table 1).

355

356 **SOC distribution in fractions**

357 The mass proportion, carbon content and % carbon distribution of the physical fractions after
358 particle size and density fractionation are presented in the supplementary data Table. S1 and Table. S2.
359 The distribution of SOC stocks over the fractions obtained, expressed in t C. ha⁻¹, is given in Figs. 2a
360 and 2b. Carbon distribution in conventional controls (CON-LC and CON-QA) showed that 19-22% of
361 carbon was found in POM fractions, versus 78-81% in MAOM fractions (Figs. 4a and 4b). Overall, most
362 of the organic carbon was located in the clay fraction (64 -72% SOC, see Table. S1 and S2) regardless
363 of site and the agricultural practice implemented. The carbon distribution in QualiAgro indicated a
364 significant increase of SOC stocks in the cSand, fPOM, cSilt and Clay fractions after OWPs application
365 (p<0.05), while no significant difference was observed in the cPOM, fSand and fSilt fractions (p>0.05).
366 In La Cage, the implementation of conservation agriculture significantly increased SOC stocks as fPOM
367 and Clay fractions compared to organic and conventional agriculture which remained statistically equal.

387

We calculated the distribution of additional carbon (Δ SOC) in the fractions by difference of the carbon stock of the bulk soil or physical fractions under agroecological practices with the carbon stock of the bulk soil or physical fractions under conventional control (CON-QA or CON-LC respectively for the QualiAgro and the La Cage experiments). The additional carbon stock at QualiAgro was 23.86 ± 1.79 t C. ha⁻¹ in BIOW compared to 15.46 ± 1.43 t C. ha⁻¹ in FYM and 14.72 ± 1.28 t C. ha⁻¹ in MSW (Fig. 2c). At La Cage, the additional SOC stock was 14.95 ± 2.49 t C. ha⁻¹ in CA compared to 2.44 ± 1.38 t C. ha⁻¹ in ORG (Fig. 2d). In terms of percentage, we observed that the coarse mineral fractions (cSand and fsand) have a negligible proportion of additional carbon at La Cage, representing 1% in CA and 0% in ORG, while this proportion was raised to 2% in FYM, 5% in MSW and 7% in BIOW at QualiAgro. This non-negligible proportion of carbon in the sand at QualiAgro suggests that not all particulate organic matter (POM-C) has probably been isolated from the sand. Hence, in the following, to define the POM-C fraction class, we combine the fractions of cPOM, fPOM, cSand and fSand together. Thus, we observed in the QualiAgro experiment that, 60-66% of the additional carbon was localized in mineral-associated organic matter fractions (MAOM-C), which included the cSilt, fSilt, and Clay fractions, versus 34-40% in POM-C; whereas, in La Cage experiment, 77-84% of the additional SOC stock was located in the MAOM-C versus 16-23% in the POM-C. Furthermore, among practices with equivalent additional carbon stocks (MSW, FYM, CA), OWPs application resulted in a higher proportion of additional carbon in POM-C (MSW: 34%; FYM: 40%) compared to CA (16%).

388

389 **Fig. 2** Soil organic carbon stock and additional carbon (Δ SOC) stock of bulk soils and physical fractions
390 (n = 4) at QualiAgro and La Cage experiments. The error bars represent the standard deviations. Grouped
391 bars with different letters are significantly different between agricultural practices (Tukey-HSD, p <
392 0.05). CON-QA: conventional agriculture without organic inputs, BIOW: biowaste compost, MSW:
393 municipal solid waste compost, FYM: farmyard manure, CON-LC: conventional agriculture, CA:
394 conservation agriculture and ORG: organic agriculture. The POM fraction is the sum of the cPOM,
395 fPOM, cSand and fSand fractions, while the MAOM fraction is the sum of the cSilt, fSilt and Clay
396 fractions.

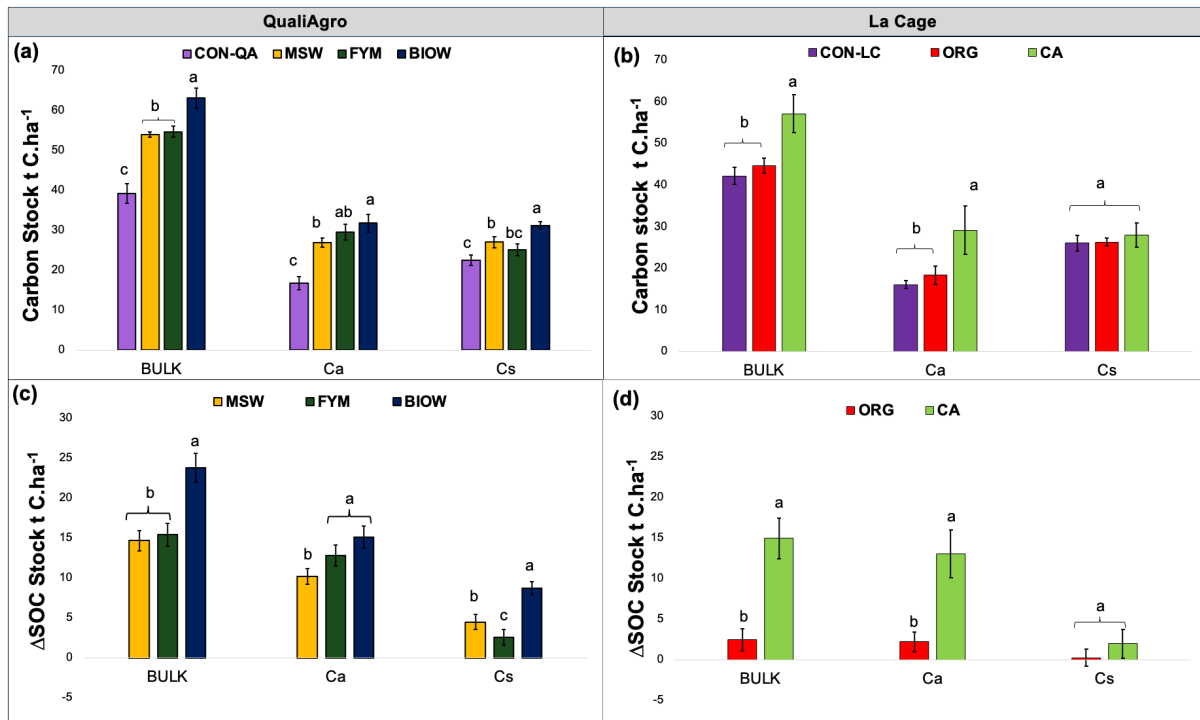

397

398 **Estimating stable and active SOC pools with the PARTY_{SOC} model**

399 The PARTY_{SOC} machine learning model was used to estimate the proportion of stable SOC under
400 the different managements. The distribution of organic carbon stocks in the active and stable pools are
401 shown in Fig. 3. In conventional controls, 38-43% of the soil carbon is found in the active pool, versus
402 57-62% in the stable pool. The organic wastes products (OWPs) application significantly increased the
403 size of the active pool relative to conventional control (Fig. 3a, ANOVA, p<0.05). It was of $31.87 \pm$
404 $2.23 \text{ t C. ha}^{-1}$ in BIOW compared to $29.62 \pm 1.97 \text{ t C. ha}^{-1}$ in FYM, $26.97 \pm 1.07 \text{ t C. ha}^{-1}$ in MSW and
405 $16.76 \pm 1.69 \text{ t C. ha}^{-1}$ in CON-QA. The OWPs application significantly increased the size of the stable
406 SOC pool in the BIOW ($31.29 \pm 0.91 \text{ t C. ha}^{-1}$) and MSW ($25.15 \pm 1.36 \text{ t C. ha}^{-1}$) treatments compared
407 to the FYM ($25.15 \pm 1.44 \text{ t C. ha}^{-1}$) and CON-QA ($22.55 \pm 1.31 \text{ t C. ha}^{-1}$) which were statistically similar.
408 Contrastingly, at La Cage experiment, 20 years of contrasted management had no significant effect on
409 the size of the stable SOC pool ($28.02 \pm 2.95 \text{ t C. ha}^{-1}$, $26.31 \pm 0.93 \text{ t C. ha}^{-1}$, and $26.08 \pm 1.89 \text{ t C. ha}^{-1}$
410 for CA, ORG, and CON-LC respectively). However, CA significantly increased the size of the active
411 pool ($29.15 \pm 5.79 \text{ t C. ha}^{-1}$) compared to ORG and CON-LC in which it was similar ($18.35 \pm 3.47 \text{ t C.}$
412 ha^{-1} and $16.14 \pm 0.97 \text{ t C. ha}^{-1}$ respectively) (Fig. 3b).

413

414

416

417 **Fig. 3** Soil organic carbon stock and additional carbon (Δ SOC) stock of bulk soils, active carbon (Ca)
 418 and stable carbon (Cs) ($n = 4$) at QualiAgro and La Cage experiments. The error bars represent the
 419 standard deviations. Grouped bars with different letters are significantly different between agricultural
 420 practices (Tukey-HSD, $p < 0.05$). CON-QA: conventional agriculture without organic inputs, BIOW:
 421 biowaste compost, MSW: municipal solid waste compost, FYM: farmyard manure, CON-LC:
 422 conventional agriculture, CA: conservation agriculture and ORG: organic agriculture.

423

424 The results of additional carbon (i.e., the difference between the active or stable carbon pool of
 425 agroecological practices and the active or stable carbon pool of conventional control) distribution in the
 426 active and stable carbon pools are shown in Figs. 3c and 3d. In the QualiAgro experiment, BIOW (15.85
 427 ± 1.48 t C. ha⁻¹) and FYM (13.36 ± 1.16 t C. ha⁻¹) had similar active carbon pool size, higher than in the
 428 MSW (12.34 ± 0.75 t C. ha⁻¹). This active pool, represented 63-83 % of the additional carbon storage
 429 (Fig. 4c). Additional stable carbon pools ordered as follows: BIOW (8.74 ± 0.79 t C. ha⁻¹) > MSW (4.51
 430 ± 0.94 t C. ha⁻¹) > FYM (2.60 ± 0.97 t C. ha⁻¹) and represented between 17% (FYM) to 37% (BIOW) of
 431 the additional carbon. At La Cage, 87% (CA) to 91% (ORG) of the additional carbon was in the active
 432 pool versus 9% (ORG) to 13% (CA) in the stable pool (Fig. 4d).

433

434 **Carbon mineralization kinetics**

435 At the end of soil incubation (day 484), the cumulative amounts of mineralized carbon expressed
 436 as percent soil organic carbon (%SOC) at La Cage experiment, differed significantly between the 3
 437 cropping systems, i.e., 12.60 ± 0.29 %SOC in ORG versus 11.52 ± 1.19 %SOC in CA and 10.21 ± 1.36
 438 %SOC in CON-LC (Fig. 4b). In the QualiAgro experiment, the specific carbon mineralization kinetics
 439 were significantly higher on the conventional control (CON-QA) without organic inputs compared to
 440 the soils receiving OWPs, where the mineralization carbon of the MSW and FYM plots were statistically
 441 identical but higher than the BIOW plot (Fig. 4a).

442

443 Overall, these two experiments show opposite trends. On the one hand, higher carbon
 444 mineralization under agroecological practices (ORG and CA) in La Cage experiment relative to the
 445 conventional control (CON-LC), and on the other hand, lower carbon mineralization under
 446 agroecological practices (MSW, FYM and BIOW) in QualiAgro experiment relative to the conventional
 447 control (CON-QA). Moreover, the percentage of additional carbon mineralized (% Δ SOC) at La Cage in
 448 CA (15% of Δ SOC) and ORG (57% of Δ SOC) was higher than at QualiAgro (4-5% of Δ SOC) (Figs. 4c
 449 and 4d). It must be noted however that the additional carbon stock was very small in the ORG treatment,
 450 which numerically explains the high % Δ SOC calculated value.

451

452

453 **Fig. 4.** Distribution of total carbon and additional carbon in carbon kinetic pools [C_{min} (carbon
454 mineralized), Active and Stable carbon] or fractions [POM and MAOM] under agricultural practices.
455 The error bars represent the standard errors. Grouped bars with different letters are significantly different
456 between agricultural practices (Tukey-HSD, $p < 0.05$).

457

458 **4 Discussion**

459 **Both POM-C and MAOM-C are sensitive to management**

460 The observed distribution of SOC in the fractions, i.e., most of the SOC (70-80%) being located
461 in the fine fraction (<50 μm), regardless of the agricultural practice implemented (Figs. 4a and 4b), is in
462 agreement with the literature (Christensen, 1985;1987; Balesdent, 1996; Baldock and Skjemstad, 2000;
463 Jolivet et al., 2003; Carter et al., 2003; Beare et al., 2014, Curtin et al., 2016, Poeplau et al., 2018).

464

465 Many studies have indicated that the POM-C fraction is more sensitive to land use and
466 management changes than the MAOM-C fraction (Cambardella and Elliot, 1992, Elliot et al., 1994,
467 Bayer et al., 2001, Salvo et al., 2010). However, our study showed that both POM-C and MAOM-C
468 fractions were both highly sensitive to the implementation of agroecological practices ca. 20 years. The
469 application of OWP resulted in additional soil organic carbon both as POM-C (34-40% of ΔSOC) and
470 MAOM-C (60-66% of ΔSOC), while conservation and organic agriculture resulted in additional organic
471 carbon mainly as MAOM-C (77-84% of ΔSOC) and less as POM-C (16-23% of ΔSOC). A significant
472 proportion of the additional carbon is associated with soil minerals, particularly in the clay fraction (See
473 Table. S1 and Table. S2).

474

475 Studies comparing no-tillage versus conventional tillage management showed in the surface layer
476 an increase in the POM-C fraction with no-tillage and no difference in MAOM-C (Wander et al., 1998,
477 Hussain et al., 1999; Carbonell-Bojollo et al., 2015; Samson et al., 2020). A recent meta-analysis by
478 Prairie et al. (2023) indicated that no-tillage increased both POM-C and MAOM-C fractions in soils
479 when this practice was maintained up to 6 years. However, the increase in the MAOM-C fraction was
480 less important than that of the POM-C fraction. We therefore ascribe the observed increase of MAOM-
481 C at La Cage to the no-tillage and the introduction of cover crops and the diversification of species (e.g.,
482 legumes) in the rotation. Interestingly, an earlier analysis of SOC distribution at La Cage, after 5 years
483 of differentiation, showed a significant increase of POM-C in the conservation agriculture system, while
484 no change of POM-C in the organic system and no significant change of the MAOM-C (Balabane et al.,
485 2005), suggesting either that it took more than 5 years for the additional POM-C to be broken down and
486 biodegraded as MAOM-C, or that the introduction of alfalfa as the cover crop instead of fescue since

487 2008 (i.e., 12 years later) resulted in more direct rhizodeposits inputs to MAOM-C. Indeed, according
488 to Autret et al. (2016), the estimated inputs from fescue were lower ($0.88 \text{ t C. ha}^{-1} \text{ yr}^{-1}$) than those
489 coming from alfalfa as a cover crop ($1.12 \text{ t C. ha}^{-1} \text{ yr}^{-1}$), about half of these amounts deriving from root
490 material. The cover crops and legume rotation in conservation agriculture and the legume rotations in
491 organic agriculture would likely have affected carbon input via the root system as dead roots (POM)
492 and rhizodeposits (MAOM). This would explain the high proportion of carbon associated with MAOM-
493 C. Typically, the cover crops characterized by low litter quality (e.g., grass) resulted in higher
494 accumulation of POM that was abundant in plant carbon, while cover crops with high litter quality (e.g.,
495 legumes) contributed to higher accumulation of SOC (Cotrufo et al., 2013), and of microbial necromass
496 carbon (Zhang et al., 2022) in MAOM-C. Thus, the high proportion of carbon in the MAOM-C at La
497 Cage (77-84% of ΔSOC) compared to QualiAgro (60-66% of ΔSOC) could be explained by the type
498 and quality of the carbon input. Because, the cover crops increase the time period in which plant roots
499 interact with the soil environment (Tiemann et al., 2015), they deliver an additional source of root litter
500 and exudates, providing greater diversity in belowground inputs (Austin et al., 2017). This promotes the
501 microbial growth and turnover in rhizosphere hotspots, processes that can enhance the formation of
502 MAOM (Kallenbach et al., 2016).

503

504 The recent meta-analysis, conducted by Zhang et al. (2022), indicated that the application of OWPs
505 significantly increases both MAOM and POM fractions in the soil relative to the control treatment,
506 which is consistent with our results. Peltre (2010) observed that the short-term application (4 times) of
507 the OWPs at QualiAgro increased the additional carbon only in the POM-C fraction, the MAOM-C
508 fraction $<50\mu\text{m}$ being unchanged. Paesch et al. (2016) later found that 7 successive applications of the
509 OWPs led to additional carbon in occluded small POM ($< 20\mu\text{m}$) and in the fine silt + clay fraction ($<$
510 $6.3 \mu\text{m}$). After 11 applications of OWPs we observed an increase in fine POM ($50\text{-}200\mu\text{m}$), coarse silt
511 ($20\text{-}50\mu\text{m}$) and MAOM-C ($<50 \mu\text{m}$). This series of results indicate that the application of the OWPs
512 increase in the short term the POM-C fraction and that in a longer term (> 10 years) the organic carbon
513 in the POM-C is transferred to the MAOM-C through biological activity in the soil. The transfer of
514 additional carbon from POM to MAOM is however slower at QualiAgro compared to La Cage. Cotrufo
515 et al. (2015), shows that POM and MAOM likely form under different biochemical and physical
516 pathways. While there is certainly some transfer from POM to MAOM, much of MAOM formation
517 occurs from dissolve organic matter (DOM) early during decomposition. There might just be a great
518 abundance of DOM and labile inputs int La Cage to explain greater MAOM formation.

519

520 **POM heterogeneity can hamper SOC stability assessments**

521 The POM in this study consists of crop residues and/or added manure or composts and microbial
522 residues. The agroecological practices with equivalent additional carbon stocks (MSW, FYM, CA)
523 showed after 20 years a higher proportion of additional carbon in POM-C under MSW (40% of Δ SOC)
524 and FYM (34% of Δ SOC) compared to CA (16% of Δ SOC). These results show that it is likely that
525 different management (e.g., OWPs application, no-tillage, cover crops and legume) alter the way gross
526 organic carbon inputs were distributed among the different organic carbon fractions. These results can
527 be explained by the fact that the decomposition rate of organic amendments and the SOC formed and
528 remaining in the long term vary according to the intrinsic quality of the amendment (Lashermes et al.,
529 2009). For example, Paustian et al. (1992) observed that high lignin content of FYM, which was more
530 recalcitrant to decomposition, resulted in greater accumulation of C than lower lignin amendments, such
531 as straw. Previous studies demonstrated that the OWPs generally are partially stabilized by the
532 composting and storage processes (Benbi and Khosa, 2014), unlike plant biomass, which is fresh OM.

533

534 The incubations revealed that in La Cage experiment, a higher percentage of the additional carbon
535 was mineralized in conservation agriculture (15% of Δ SOC) over 484 days than additional carbon at
536 QualiAgro (4-5% of Δ SOC) (Figs. 4c and 4d). The low additional carbon mineralization at QualiAgro
537 raises questions about the degradability of POM derived from OWPs, which were in higher proportion
538 (34-40% of Δ SOC) than at La Cage experiment (16-23% of Δ SOC). It is therefore likely that the OWPs-
539 derived POM were more recalcitrant with higher mean residence times compared to plant-derived POM.
540 The mean residence time of < 20 years given to POM in the study by Balesdent, (1996) may not be
541 applicable to systems where pre-processed exogenous OM are applied, because in the formed is based
542 on situations where organic input were crop residues. Thus, we assume a greater chemical recalcitrance
543 of POM-C in plots receiving OWPs, thereby reducing decomposers activity and carbon transfer to the
544 fine soil fraction (<50 μ m).

545

546 **Different methods provide a contrasted evaluation of biogeochemical stability**

547 We used different methods to assess the biogeochemical stability of the additional carbon stored
548 in soil thanks to specific management options. The incubation method isolates carbon with mean
549 residence time (MRT) ranging from days to years (MRT < 2y in this case), while particle size and density
550 fractionation isolate carbon fractions ranging from years to decades (POM with MRT < 20y and MAOM
551 with MRT > 50y) and PARTY_{SOC} model based to RE thermal analysis that isolate carbon pools ranging
552 from decades to centuries (Active pool with MRT ~30-40y and Stable pool with MRT > 100y).

553

554 In the QualiAgro experiment, the incubations results indicate greater stability of additional carbon
555 compared to bulk SOC in the conventional control (i.e., lower specific carbon mineralization for soils
556 receiving OWPs relative to CON-QA). However, the results of particle size and density fractionation
557 and PARTY_{SOC} based to RE thermal analysis indicate that the additional carbon stored by OWPs
558 application is on average less stable than the soil carbon in the conventional control (CON-QA). This is
559 because, in these plots the additional carbon has a higher proportion of POM (MRT < 20y) and Active
560 carbon (MRT ~ 30-40y) than the conventional control (Figs. 4a and 4c). As the incubations target carbon
561 with MRT of the order of incubation length (i.e., MRT < 2y in this study), we posit that this difference
562 is due to the fact that the different methods do not target the carbon pools with the same MRT. Put
563 together, these results suggest that, on the scale of a few decades, soil additional carbon in QualiAgro
564 experiment is less stable than soil carbon in conventional control, but in a shorter term (i.e., MRT < 2y),
565 the additional carbon is quite resistant.

566

567 In La Cage experiment, the results of the incubations and the PARTY_{SOC} model based to RE
568 thermal analysis are consistent and indicate that the additional carbon stored by conservation agriculture
569 and organic agriculture is less stable than the soil carbon in the conventional control (CON-LC), whereas
570 the particle size and density fractionation indicates a more stable additional carbon, i.e., a higher
571 proportion of MAOM (MRT > 50 years) than the conventional control (Fig. 4). However, the study by
572 von Lützow et al. (2006) showed that MAOM does not have a unique mean residence time. For example,
573 land-use change (native and cropped lands) studies have indicated a decrease in carbon content in
574 MAOM-C over time (Balesdent et al., 1998, Yeasmin et al., 2019). Lutfalla et al. (2019), using samples
575 from 42 plots in Versailles, observed a decrease in carbon content in the clay fraction (< 2 µm) after 52
576 years of bare fallow conditions, thus questioning the long-term persistence of carbon associated with
577 clays and MAOM-C. Our results provide evidence that at least part of the carbon contained in MAOM
578 may not persist in soils over the long term as shown by others previously (e.g., Balesdent, 1987,
579 Keiluweit et al., 2015, Lutfalla et al., 2019, Chassé et al., 2021). We therefore hypothesize that the
580 additional carbon stored in the form of MAOM has a lower MRT than the MAOM in conventional
581 control.

582

583 Based on these results, our hypothesis that the biogeochemical stability of additional carbon is less
584 stable than the carbon in the conventional control is not always verified. However, considering that
585 MAOM is kinetically heterogeneous, then the results of these methods can be reconciled. So, the
586 additional carbon is overall less stable at a decadal or pluri-decadal timescale than the carbon stored in
587 the conventional control in both long-term experiments. Furthermore, taking all these elements and the
588 complementary nature of the methods into consideration, it emerges that the additional carbon stored

589 thanks to OWPs application is more stable in the short (MRT < 2y) and long term (MRT > 100y) than
590 the additional carbon enabled by alternative cropping systems, but less in the decadal and pluridecadal
591 time scale. The large time scale of SOM persistence shows that qualifying SOC simply as stable or labile
592 is not sufficient. It is essential to always associate a temporality with the biogeochemical stability that
593 is described in order to better assess the persistence of carbon in soils.

594

595 **5 Conclusion**

596 This study provided detailed information on the biogeochemical stability of additional carbon
597 via a multi-methods evaluation. Soils from the same experimental sites but under widely contrasting
598 management have resulted in contrasting carbon contents and stocks ca. 20 years of management. The
599 results of particle size and density fractionation and PARTY_{SOC} model suggests that the additional
600 carbon contained in MAOM may not persist in soils over the long term (> 50 years). Incubation, on the
601 other hand, provided information on the short-term stability of additional carbon (i.e., MRT <2 years).
602 Overall, the multi-methods evaluation showed that additional carbon was less stable at the decadal and
603 pluri-decadal time-scales than carbon under conventional controls. However, incubations and
604 PARTY_{SOC} model based to RE thermal analysis revealed that additional SOC in the QualiAgro
605 experiment was more stable in short- term (MRT < 2y) and long- term (MRT >100y) than that in La
606 Cage experiment. Additional SOC deriving from organic wastes, i.e., biomass that has been partially
607 decomposed and transformed through its processing (digestion by cattle, storage and composting) prior
608 to its incorporation in soil, would have a different biogeochemical stability than that deriving directly
609 from plant biomass. Widely used (incubation, particle size fractionation) and increasingly used methods
610 (RE) provide seemingly inconsistent assessments of the biogeochemical stability of SOC. These
611 apparent contradictions can be explained by the fact that they address different kinetic pools of organic
612 carbon. Care must be taken to specify which range of residence times are considered when using any
613 method intending to evaluate the biogeochemical stability of SOM, as well as when using the terms
614 stable or labile. As we found that the additional SOC stored thanks to the implementation of different
615 management options had contrasted biogeochemical stabilities, there is a need to evaluate the
616 biogeochemical stability of the additional SOC stored via other management options (e.g., agroforestry,
617 lengthening temporary leys, no tillage...).

621 **Data availability**

622 Data are available from the authors upon reasonable request.

623 **Supplement**

624 The supplement related to this article is available online at: xxxx

625 **Author contributions**

626 TPIK, CC, PB and SH designed the study. TPIK performed soil fractionation and long-term incubations.
627 FB and CP performed the RE6 thermal analyses and elementary analyses respectively. PB performed
628 the R codes to PARTYSOC machine learning model. TPIK wrote the R codes and performed all
629 statistical analyses. TPIK, CC, PB, SH and FB contributed to the interpretation of the results. CC
630 acquired the funding. TPIK prepared the manuscript with contributions from all coauthors.

631 **Competing interests**

632 The contact author has declared that none of the authors has any competing interests.

633 **Acknowledgements**

634 The QualiAgro field experiment forms part of the SOERE-PRO (network of long-term experiments
635 dedicated to the study of impacts of organic waste product recycling) integrated as a service of the
636 “Investment for future” infrastructure AnaEE-France, overseen by the French National Research
637 Agency (ANR-11-INBS-0001)’. The QualiAgro site is conducted within a collaboration between
638 INRAE and Veolia. The authors thank the personnel from the Unité expérimentale Versailles Grignon
639 INRAE and Michel Bertrand for the maintenance of and access to the La Cage long term experiment
640 and Fabien Ferchaud for the collaboration upon La Cage SOC stocks assessment. The authors also thank
641 Valérie Pouteau for help with incubation and fractionation and Florence Savignac with Rock-Eval®
642 thermal analyses.

643 **Financial support**

644 This research has been supported by the French Agence Nationale de la Recherche (StoreSoilC project,
645 grant [ANR- 17-CE32-0005](#)). C. Chenu also thanks the CLand programme (ANR-16-CONV-0003). T.
