26 were not cited in the main-text.

27 **Introduction:** This supplement contains additional information on the comparative analysis.

28 **Text S1. Water-soluble ion mass concentration and hygroscopicity of OC-Ca**

29 In this study, we concluded that the OC-Ca partly accounts for the calcium enrichment over
30 the Ross Sea, Antarctica, by combining the IGAC and SPAMS datasets.

31 In terms of IGAC datasets, it should be clarified that the water-soluble ion mass concentration
32 included the pure inorganic part (e.g., pure sea salt, NaCl) and mixed organic-inorganic part (e.g.,
33 gel-like particles) (Quinn et al., 2015). Numerous studies have reported that primary sea spray
34 aerosols (SSAs) exhibit moderate hygroscopicity and water solubility due to a certain water-soluble
35 organic fraction (~ 25%, by mass), such as carboxylates, lipopolysaccharides (LPSs), humic
36 substances, and galactose (Oppo et al., 1999; Quinn et al., 2015; Schill et al., 2015; Cochran et al.,
37 2017). In particular, LPSs, which are preferentially transferred to submicron SSAs during bubble
38 bursting, exhibit a certain solubility of 5 g L⁻¹ in pure water. (Facchini et al., 2008; Schill et al.,
39 2015). Oppo et al. (1999) indicated that humic substances are also an important pool of water-
40 soluble natural surfactants (40-60%) in marine surfactant organic matter. Therefore, both organic
41 and inorganic parts with a water-soluble nature could be retained, contributing to the water-soluble
42 ion mass concentration (e.g., Ca²⁺).

43 In terms of SPAMS datasets, we inferred that the OC-Ca is of biogenic origin and may be
44 associated with marine microgels (i.e., gel-like particles). If so, these gel-like particles are most
45 likely water-insoluble and/or slightly water-soluble (Leck and Bigg, 2010; Orellana et al., 2011).
46 Under the stimulation of environment factors (pH, temperature, chemical compounds, pollutants,
47 and UV radiation), their physicochemical properties would be changed (e.g., the cleavage of
48 polymers results in enhanced water-solubility) (Orellana and Verdugo, 2003; Orellana et al., 2011).
49 Although we did not measure the hygroscopicity of the OC-Ca particle type in this study, we

50 considered the OC-Ca to be hygroscopic to some extent, based on the results of Cochran et al. (2017).
51 Those authors concluded that the mixture of sea salt with organic matter (i.e., the single-particle
52 types of SS-OC and OC) can also exhibit a certain hygroscopicity (hygroscopicity parameter, 0.50-
53 1.27).

54 **Text S2. A brief description of the in-situ Gas and Aerosol Compositions monitoring system**
55 **and the single-particle aerosol mass spectrometer**

56 The aerosol water-soluble ion mass concentrations with an aerodynamic diameter of 10 μm
57 were provided by an in-situ Gas and Aerosol Compositions monitoring system. The detailed
58 analytical discipline and methodology were described in previous studies (Yan et al., 2019; Yan et
59 al., 2020b). Briefly, the IGAC system consisted of three main units, including a Wet Annular
60 Denuder (WAD), a Scrub and Impact Aerosol Collector (SIAC), and an ion chromatograph (IC,
61 Dionex ICS-3000). Gases and aerosols were passed through WAD with a sampling flow of 16.7 L
62 min^{-1} . Two concentric Pyrex glass cylinders with a length of 50 cm and inner and outer diameters
63 of 1.8 and 2.44 cm were assembled to WAD, in which the inner walls of the annulus were wetted
64 with ultrapure water ($18.2 \text{ M}\Omega \text{ cm}^{-1}$). This part was responsible for the collection of acidic and basic
65 gases by diffusion and absorption of downward flowing aqueous solution. The SIAC had a length
66 of 23 cm and diameter of 4.75 cm, which was positioned at an angle to facilitate the collection of
67 enlarged particles. The collected particles were separated firstly, continually enlarged by vapor
68 steam, and then accelerated through a conical-shaped impaction nozzle and collected on an
69 impaction plate. Each aerosol sample was collected for 55 minutes and injected for 5 minutes. The
70 particles were subsequently analyzed for cations and anions by using an ion chromatography (IC)

71 system (Dionex ICS-3000). The injection loop size was 500 μL for both anions and cations. The
72 target ion concentrations were calibrated with a coefficient of determination (r^2) above 0.99 by using
73 standard solutions (0.1-2000 $\mu\text{g L}^{-1}$). The detection limits for Na, Cl, Ca, K, and Mg were 0.03, 0.03,
74 0.019, 0.011, and 0.042 $\mu\text{g L}^{-1}$ (aqueous solution), respectively. The systematic error of the IC
75 systems was generally less than 5%.

76 Single-particle mass spectral fingerprints and vacuum aerodynamic diameter (D_{va}) lengths
77 ranging from 0.2 to 2 μm were provided by SPAMS (Li et al., 2011). Briefly, the aerosols were
78 drawn into an aerodynamic lens, forming a collimated particle beam and were then accelerated in
79 an accelerating electric field and passed through two continuous laser beams (Nd: YAG laser, 532
80 nm). The obtained time of flight (TOF) and velocity of individual particles were used to calculate
81 the D_{va} based on a calibration curve. Subsequently, particles with a specific velocity were desorbed
82 and ionized by triggering a pulse laser (an Nd: YAG laser, 266 nm, 0.6 ± 0.06 mJ was used in this
83 study). The ion fragments were recorded using a TOF mass spectrometer. Prior to the use of SPAMS,
84 standard polystyrene latex spheres (Duke Scientific Corp., Palo Alto, CA) and PbCl_2 and NaNO_3
85 (Sigma-Aldrich) were used for the size and mass spectral calibration, respectively.

86 **Text S3. Uncertainty analysis and quality assurance of datasets**

87 **IGAC:** The water-soluble ion mass concentrations were analyzed by using an ion
88 chromatography (IC) system (Dionex ICS-3000) within an in-situ Gas and Aerosol Compositions
89 monitoring system (IGAC, Model S-611). Before the sampling, a known concentration of LiBr was
90 used as an internal standard by adding to the aerosol liquid samples to determine the stability of the
91 IGAC system. The changes in the internal standard were within 5%. Subsequently, the IC was

92 calibrated by using six to eight concentrations of stand solutions (0.1-2000 $\mu\text{g L}^{-1}$), depending on
 93 the target species and concentrations, in which the R^2 was above 0.99. The calibration curves for
 94 each ion could be found in our previous studies (Yan et al., 2019; Yan et al., 2020a; Yan et al., 2020b).
 95 The uncertainty of the IC systems was generally less than 5% for all analyzed ionic species. The
 96 detection limits for Na^+ , Cl^- , Ca^{2+} , K^+ , and Mg^{2+} were 0.03, 0.03, 0.019, 0.011, and 0.042 $\mu\text{g L}^{-1}$
 97 (aqueous solution), respectively. During the whole sampling period (hourly temporal resolution),
 98 the detection rate for Na^+ , Cl^- , Ca^{2+} , K^+ , and Mg^{2+} were 98.5% (1178 of 1196), 92.6% (1108 of
 99 1196), 88.2% (1055 of 1196), 98.9% (1183 of 1196), and 98.5% (1178 of 1196), respectively. All
 100 values below the detection limit were omitted before analysis. The undetected rate for both Ca^{2+} and
 101 Na^+ was approximately 12%. Figure S13 shows the time series of observed ion mass concentrations
 102 and EF_{Ca} . The ion mass concentrations were above the detection limit. Particularly, the mean Na^+
 103 and Ca^{2+} mass concentrations were 364.64 ng m^{-3} (ranging from 6.66 to 4580.10 ng m^{-3}) and 21.20
 104 ng m^{-3} (ranging from 0.27 to 334.40 ng m^{-3}), respectively, which were far above (> 10 times) the
 105 detection limit. Such data indicate that the variations of EF_{Ca} would not suffer the increasing
 106 uncertainties when the ion mass concentrations near the detection limit. Thus, we suggest that the
 107 data on ion mass concentration is reliable and representative.

108 Given that the measured mass concentrations of Ca^{2+} and Na^+ were far above the detection
 109 limit, we only considered the systematic errors ($< 5\%$) of the mass concentrations of Ca^{2+} and Na^+ .

110 Based on the variations of extreme value, the uncertainty of each EF_{Ca} is calculated as below:

$$111 \quad \text{abs}\left(1 - \frac{\frac{0.95 * Ca_{conc}^{2+}}{1.05 * Na_{conc}^+} / 0.038}{\frac{Ca_{conc}^{2+}}{Na_{conc}^+} / 0.038}\right) \approx 9.5\% < \text{Unc}_{(\text{EF}_{\text{Ca}})} < \text{abs}\left(1 - \frac{\frac{1.05 * Ca_{conc}^{2+}}{0.95 * Na_{conc}^+} / 0.038}{\frac{Ca_{conc}^{2+}}{Na_{conc}^+} / 0.038}\right) \approx 10.5\%$$

112 Where Ca_{conc}^{2+} and Na_{conc}^+ represent the observed ion mass concentration of Ca^{2+} and Na^+ ,
 113 respectively. 0.038 is the ratio of Ca^{2+} to Na^+ in seawater. 0.95 and 1.05 represent the variations of

114 extreme value. The largest uncertainty of EF_{Ca} ($Unc_{(EF_{Ca})}$) would be estimated lower than 11%.

115 **SPAMS:** Even though SPAMS has advantages for investigating the chemical characteristics
116 and evolutionary mechanisms of individual particles, it is still quite challenging for it to provide
117 quantitative evidence, as it is limited by the potential matrix effects, laser inhomogeneities, and
118 transmission efficiencies of the aerodynamic lenses (Qin et al., 2006; Pratt and Prather, 2012).
119 Nevertheless, the results via SPAMS are also reliable because of its broad datasets with high
120 temporal resolution. Therefore, the analyses of particle count, size, and chemical composition (by
121 peak area) can be considered semi-quantitative from a statistical perspective (Healy et al., 2012; Su
122 et al., 2021a; Zhang et al., 2021).

123 **Results:** The results of the Ca^{2+} , K^+ , and Mg^{2+} enrichment in SSAs calculated by ion mass
124 concentration (via IGAC) are not fully supported by SPAMS datasets, which is not surprising. We
125 propose three possible explanations for these results: (i) There is a difference in the size of collected
126 particles between SPAMS (0.2–2 μm) and IGAC ($\sim 10 \mu m$). In addition, SPAMS cannot measure
127 the Aitken-mode particles and measures only the tail of accumulation-mode particles (Sierau et al.,
128 2014). The hit rate of the SPAMS when measuring particles was relatively low ($\sim 11\%$). (ii) The
129 obtained type via IGAC (ion mass concentration) and SPAMS (mass spectral characteristics)
130 datasets are different. In particular, the datasets via SPAMS are semiquantitative due to the potential
131 matrix effects, laser inhomogeneities, and transmission efficiencies of the aerodynamic lens. (iii)
132 IGAC can only measure the water-soluble Ca^{2+} , however, the water solubility of OC-Ca may be low.

133 Although there is a discrepancy between the two instruments, we consider our results to be
134 reliable and representative. The quantitative results concluded by IGAC verify the enrichment of
135 Ca^{2+} , K^+ , and Mg^{2+} in the SSAs and subsequently reveal their dependence on and relevance to the

136 environmental factors. Previous studies have shown increasing Ca^{2+} enrichment in SSAs below 1
137 μm (Oppo et al., 1999; Hara et al., 2012; Cochran et al., 2016; Salter et al., 2016; Mukherjee et al.,
138 2020). Thus, the individual particle analysis of particle types ranging in size from 0.2 to 2 μm is
139 very appropriate for revealing the calcium distribution in SSAs. Our results successfully identify a
140 unique calcareous particle type (i.e., OC-Ca) and its specific mixing state, which provides some
141 qualitative and semi-quantitative insights into the mechanisms behind calcium enrichment.

142 **Text S4. Single-particle characteristics of other observed particles**

143 In this study, a total of $\sim 930,000$ particles with mass spectral information and D_{va} were
144 measured using SPAMS and manually clustered into the seven single-particle groups of SS (sea salt
145 aerosol), SS-aged (aged sea salt aerosol), SS-Bio (sea salt with biogenic organic matter), OC-Ca
146 (internally mixed organics with calcium), OC-K (internally mixed organics with potassium), OC
147 (organic-carbon-dominated), and EC (element carbon) (Table S2). Based on their different mass
148 spectral characteristics (Prather et al., 2013; Collins et al., 2014; Guasco et al., 2014; Su et al.,
149 2021b), we briefly describe all of them (except for OC-Ca) as follows (Figure S5):

150 SS is identified by prominent ion markers that are associated with Na and Cl (e.g., m/z 23 $[\text{Na}]^+$,
151 46 $[\text{Na}_2]^+$, 81 $[\text{Na}_2^{35}\text{Cl}]^+$, 83 $[\text{Na}_2^{37}\text{Cl}]^+$, -35 $[\text{Cl}^-]$, and -37 $[\text{Cl}^-]$), and smaller contributions of
152 other inorganic matter that are known to exist in sea water (i.e., Mg, K, Ca). SS accounted for 16.5%
153 of the particles obtained during the observation cruise, with a peak of $\sim 1.25 \mu\text{m}$ in D_{va} .

154 SS-aged can be regarded as SS with atmospheric aging, with additional characteristic peaks of
155 nitrate (m/z -46 $[\text{NO}_2]^-$ and -62 $[\text{NO}_3]^-$). SS-aged presented a similar size distribution as SS, with a
156 proportion of 8.1%.

157 SS-Bio is characterized by a large ratio of organic ion signatures of organic nitrogen (m/z -26
158 $[\text{CN}]^-$ and -42 $[\text{CNO}]^-$), phosphate (m/z -63 $[\text{PO}_2]^-$ and -79 $[\text{PO}_3]^-$), carbohydrate (m/z -45 $[\text{CHO}_2]^-$,
159 -59 $[\text{C}_2\text{H}_3\text{O}_2]^-$, and -73 $[\text{C}_3\text{H}_5\text{O}_2]^-$), siliceous materials (m/z -60 $[\text{SiO}_2]^-$), and organic carbon (m/z 27
160 $[\text{C}_2\text{H}_3]^+$ and 43 $[\text{C}_2\text{H}_3\text{O}_3]^+$), in addition to the aforementioned inorganic salt-related ion signature
161 (e.g., 23 $[\text{Na}]^+$). SS-Bio accounted for only 3.1% of the particles obtained during the observation
162 cruise, with a peak of $\sim 0.9 \mu\text{m}$ in D_{va} .

163 OC-K is identified by the dominant presence of K (m/z 39) and the aforementioned organic
164 species and exhibited the third largest proportion (13.7%). OC-K was scattered in the D_{va} range of
165 0.2 to 1.0 μm , peaking at 0.6 μm . Similar to OC-Ca, this chemical class may also be associated with
166 biogenic origin, which may originate from intact heterotrophic bacterial cells, fragments of cells,
167 and bacterial exudates (Gaston et al., 2011; Guasco et al., 2014; Sierau et al., 2014).

168 OC exhibits a significant proportion of organic signals of organic carbon and organic nitrogen.
169 This single-particle type may originate from not only heterogeneous nucleation with the oxidation
170 of monoterpene and isoprene but also anthropogenic emissions (e.g., ship emissions). However, we
171 suggest that it is more likely to be related to the biogenic origin of the bacteria and phytoplankton.

172 **Text S5. Potassium (K^+) and magnesium (Mg^{2+}) enrichment in SSAs induced by temperature,**
173 **wind speed, and sea ice**

174 The enrichment factors of K^+ (EF_{K}) and Mg^{2+} (EF_{Mg}) were calculated by using the same
175 equation described in the main text. Generally, the ratios of K^+ and Mg^{2+} to Na^+ in seawater are
176 0.0218 and 0.1112, respectively (Hara et al., 2012; Boreddy and Kawamura, 2015; Su et al., 2022).

177 During the observation cruise, EF_{K} (ranging from 0.20 to 75, with a median and mean of 1.19

178 and 3.61, respectively, $n > 1000$) and EF_{Mg} (ranging from 0.12 to 26.94, with a median and mean of
179 1.48 and 2.46, respectively, $n > 1000$) were also observed.

180 Figure S14 shows the enrichment factors of K^+ and Mg^{2+} with respect to sodium in bulk
181 aerosols at different ambient temperatures ($\geq -3.5^\circ C$ and $< -3.5^\circ C$), wind speeds ($\geq 7 \text{ m s}^{-1}$ and < 7
182 m s^{-1}), and sea ice fraction (with and without sea ice) during the whole sampling period. The results
183 were very similar to that of calcium (Ca^{2+}) enrichment in SSAs, which may present an analogous
184 enrichment mechanism by environmental factors (e.g., ambient temperature and wind speed with
185 sea ice) (Fig. S15).

186 We also inferred that the K^+ and Mg^{2+} enrichments in SSAs were also attributed to organically
187 internally mixed aerosols (e.g., OC-K and SS-Bio). We propose three possible explanations for this:
188 (i) If the released K^+ and Mg^{2+} are in the form of inorganic salts (e.g., KCl and $MgCl_2$) within SSAs,
189 they are likely to be associated with sea salt fractionation by precipitations of sylvite ca. $-33^\circ C$ and
190 $10 \text{ H}_2\text{O} \cdot \text{MgCl}_2$ ca. $-36^\circ C$ on the sea ice (Hara et al., 2012). However, the average and minimum
191 ambient temperatures during leg I were only $-4.1^\circ C$ and $\sim -8^\circ C$, respectively. Thus, sea salt
192 fractionation on sea ice is less likely. (ii) We observed a single-particle type of OC-K with abundant
193 K^+ (m/z 39) and organic ion signatures by using SPAMS during the cruise observations. Other
194 single-particle types involving K^+ (m/z 39) and Mg^{2+} (m/z 24) also exhibited some characteristic
195 organic peaks (e.g., in SS-Bio). (iii) K^+ and Mg^{2+} are also greatly capable of stabilizing organic
196 supramolecular structures in the form of organic ligands (i.e., marine microgels) (Gaston et al., 2011;
197 Cochran et al., 2016; Mukherjee et al., 2020). Based on the above discussion, we therefore suggest
198 that internally mixed potassium and magnesium organics contribute to corresponding enrichment in
199 SSAs. Analogous to OC-Ca, we also suggest that the marine microgels assembled by K^+ and Mg^{2+}

200 to exopolymer substances (EPSs) may be emitted to the atmosphere by low wind-blown sea ice.

201 **Text S6. Further correlation analysis between mass concentration of Ca²⁺, single-particle type**
202 **of OC-Ca, and single-particle type of SS**

203 We noted there was a relatively poor correlation ($r = 0.51$, $p < 0.05$) between sodium and
204 calcium mass concentrations, probably indicating some differences in their origin, chemical form,
205 and water solubility (Fig. S9). As discussed in the main text, we concluded that there were four
206 possible origins for water-soluble Ca²⁺ collected by IGAC, including (1) sea salt fractionation (i.e.,
207 ikaite, CaCO₃·6H₂O), (2) long-range transport of dust or anthropogenic emissions, (3) coexistence
208 with sea salt aerosol (i.e., the single-particle type of SS-Ca) and (4) calcium internally mixed
209 organics (OC-Ca). The first two origins were excluded based on the discussion in the main text and
210 Text S4.

211 In terms of the third possible origin (i.e., coexistence with sea salt aerosols), we noted that there
212 were relatively poor correlations between the SS-Ca ($r = 0.21$, $p < 0.05$, by count and $r = 0.03$, $p <$
213 0.05 , by peak area of m/z 40 [Ca]⁺) and mass concentration of Ca²⁺ (Table S5). This indicated that
214 the single-particle type of SS-Ca had a certain contribution to the water-soluble mass concentration
215 of Ca²⁺. We suggest that this part of calcium is inorganic and water-soluble because we did not
216 observe organic signals (e.g., organic nitrogen, phosphate, and carbohydrate). This may not be the
217 major reason for the Ca²⁺ enrichment in SSA.

218 We suggest that OC-Ca may be important for the higher EF_{Ca} observed, which is supported by
219 the increased correlations between the OC-Ca (by count and by peak area of m/z 40 [Ca]⁺) and mass
220 concentration of Ca²⁺ that varied with increasing EF_{Ca} (Table S5). Considering the possible influence

221 of water-soluble components (e.g., CaCl_2 , $\text{Ca}(\text{NO}_3)_2$, and CaSO_4), we classified OC-Ca into two
222 parts: OC-Ca-Organic (~ 147, 000, by count) and OC-Ca-Inorganic (~ 283, 000, by count) (Fig.
223 S12). Compared to the former, the latter presented typical inorganic ion characteristic peaks of
224 chloride (m/z -35 and -37), nitrate (m/z -62), and sulfate (m/z -97) and was probably more water-
225 soluble. We noted that both presented similar variations in which the correlations between the OC-
226 Ca (by count and by peak area of m/z 40 $[\text{Ca}]^+$) and mass concentration of Ca^{2+} varied with
227 increasing EF_{Ca} (Table S5). However, OC-Ca-Organic exhibited stronger correlations than did OC-
228 Ca-Inorganic ($r = 0.51$ vs. $r = 0.28$, $p < 0.05$, by count and $r = 0.51$ vs. 0.31 , $p < 0.05$, by peak area
229 of m/z 40 $[\text{Ca}]^+$, respectively), which may emphasize the importance of OC-Ca-Organic to the
230 enrichment of Ca^{2+} . That is, the potential contribution of organically complexed calcium may be
231 ignored, when considering the calcium enrichment in SSAs based on water-soluble Ca^{2+} .

232 Direct measuring the hygroscopicity of the OC-Ca remained a technical challenge in this study.
233 Nevertheless, we could infer that OC-Ca was hygroscopic to some extent, based on the results from
234 Cochran et al. (2017), because they concluded that the mixture of sea salt with organic matter (i.e.,
235 the single-particle type of SS-OC and OC) can also exhibit a certain hygroscopicity (hygroscopicity
236 parameter, 0.50-1.27).

237 **Text S7. Multiple linear and random forest regression**

238 Multiple linear and random forest analyses were applied to describe the relative contribution
239 of possible factors to the variations in EF_{Ca} . In multiple linear models, two of the most common
240 measures of model fit are the residual standard error and proportion of variance explained (R^2), by
241 using least squares fit. In contrast, random forest with nonlinear multiple regression has been widely

242 applied to predict and reproduce the importance of factors, by building multiple decision trees
243 (Lundberg et al., 2020; Zhang et al., 2021; Song et al., 2022).

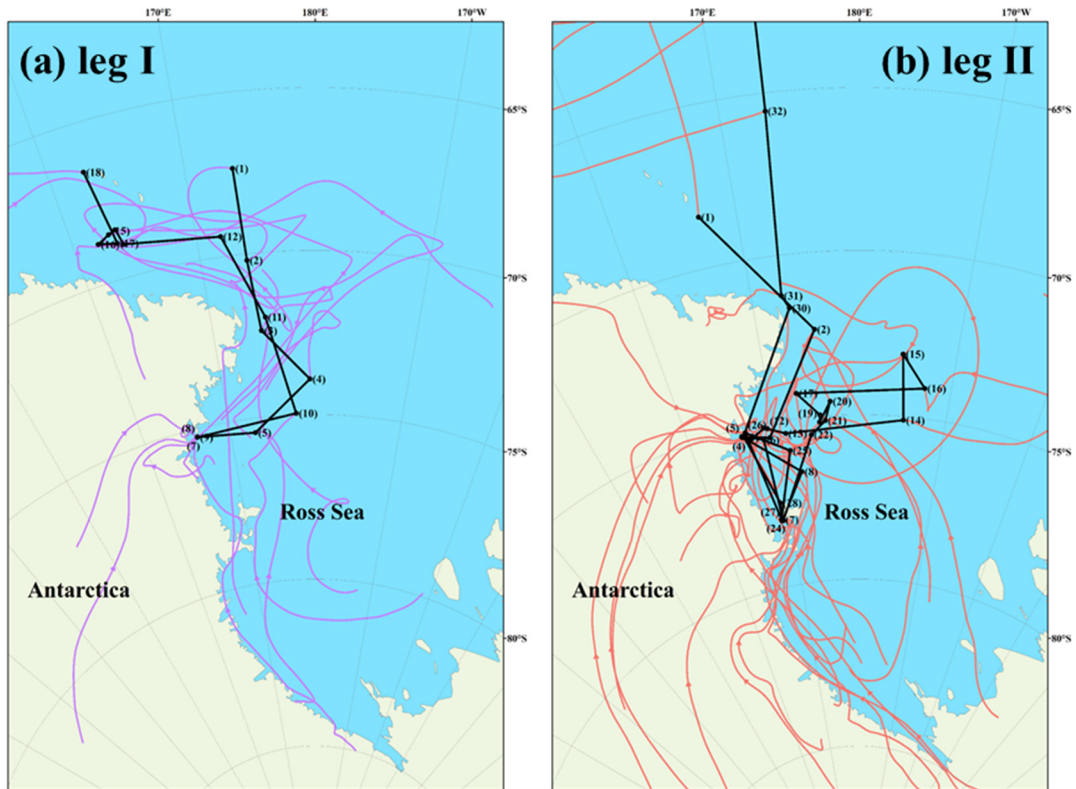

244 We attempted to estimate the relative importance of the impact factors on EF_{Ca} , including the
245 environmental factors (ambient temperature, wind speed, and chlorophyll-a concentration), particle
246 types (SS-Ca and OC-Ca, by count), and relative fraction of organics in the OC-Ca particles. The
247 multiple linear regression and random forest analysis were applied. As shown in Fig. S16, EF_{Ca}
248 could not be well predicted by those possible factors for the sea ice period ($r^2 = 0.19$, $p < 0.01$) and
249 whole sampling period ($r^2 = 0.15$, $p < 0.01$), which may be ascribed to other unknown mechanisms
250 and/or OC-Ca with low water solubility. Future studies are needed to explore the mechanisms of
251 calcium enrichment in SSAs.

252 **Text S8. A comparative analysis of chemical composition, particle size and counts, and mixing**
253 **state via SPAMS between leg I and leg II**

254 Based on the SPAMS datasets, we found that there was a minimal change in chemical
255 composition (Figs. S17 and S18), particle size (Fig. S19) and counts (Fig. S20), and mixing state
256 (Figs. S21 and S22) of the obtained particles (especially SS-Bio, OC-Ca, and OC-K) during leg I
257 (sea ice period) and leg II (period without Sea ice). This suggests that the existence of sea ice may
258 play an insignificant role in the intrinsic physicochemical properties of the obtained particles
259 ranging from 0.2 to 2 μm .

260

261 2. Supplementary Figures

262

263 Figure S1

264 HYSPLIT back trajectories (72) arriving at the ship location (50 m above sea level) every day (0:00

265 local time) during leg I (purple solid line) and leg II (red solid-line). The black solid-lines indicate

266 the cruise track of the R/V *Xuelong*. The marked numbers indicate the ship location at the local time

267 0:00 during the whole observation. For example, "(1)" in leg I refers to the ship location at 0:00, on

268 2 December 2017, and so on.

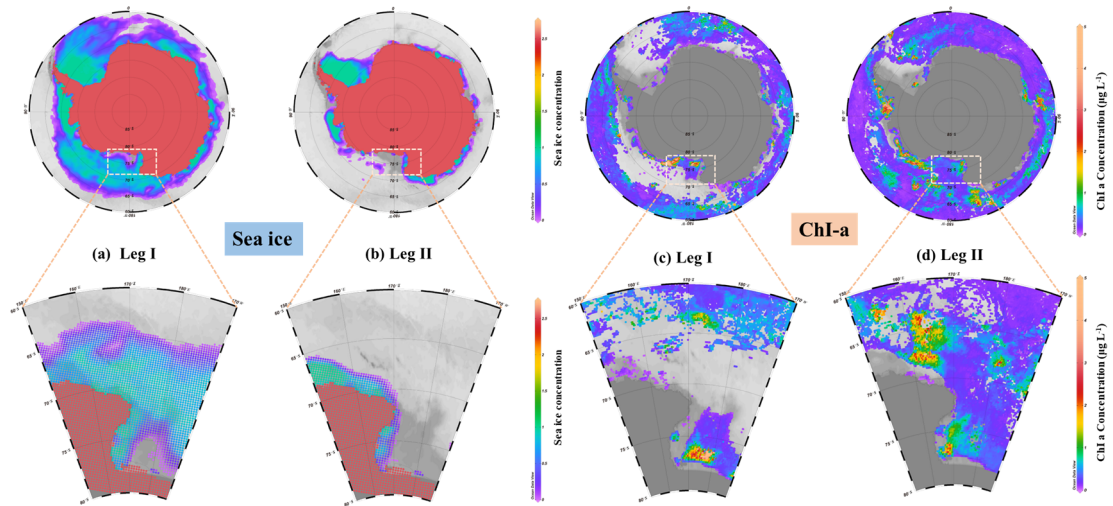

269

270 Figure S2

272 mass concentrations, and single-particle counts of individual particle types.

273

274 Figure S3

275 Average sea ice fraction and chlorophyll-a concentration during leg I (a and c) and leg II (b and d)

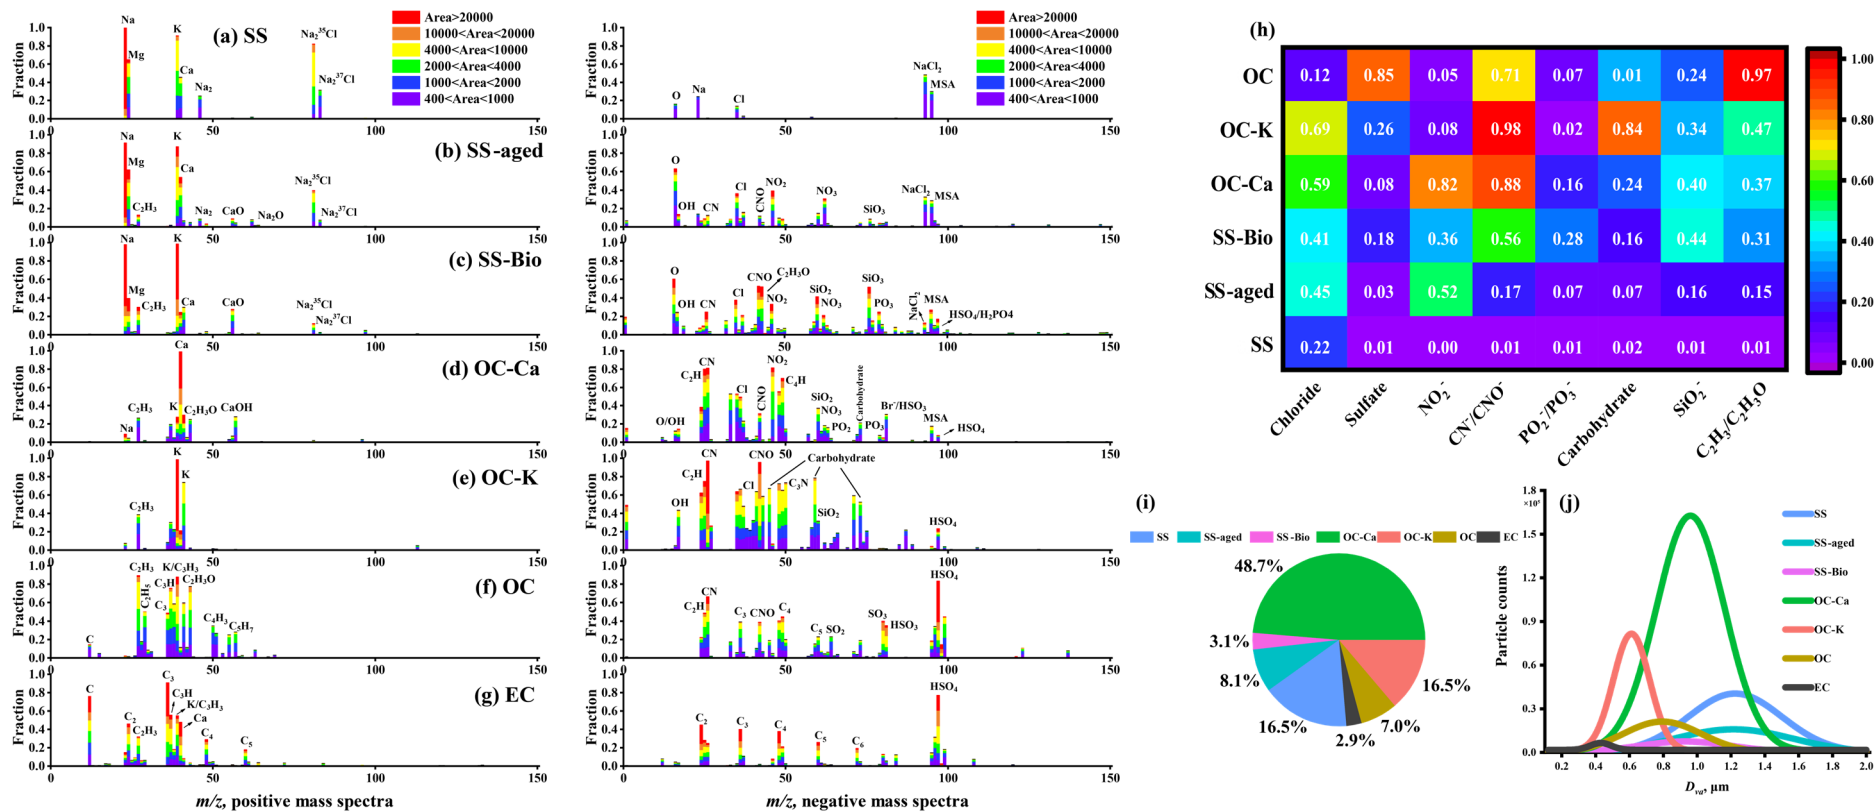

276 from a satellite. This figure was created by using Ocean Data View (Schlitzer, 2002).

277

278 Figure S4

279 An in situ Gas and Aerosol Composition monitoring system (IGAC) was used to determine the
280 gaseous and aerosol water-soluble ion mass concentrations (red frame, left). A Single Particle
281 Aerosol Mass Spectrometer (SPAMS) was used to measure the chemical compositions, mixing
282 states and particle size of individual particles (green frame, right).

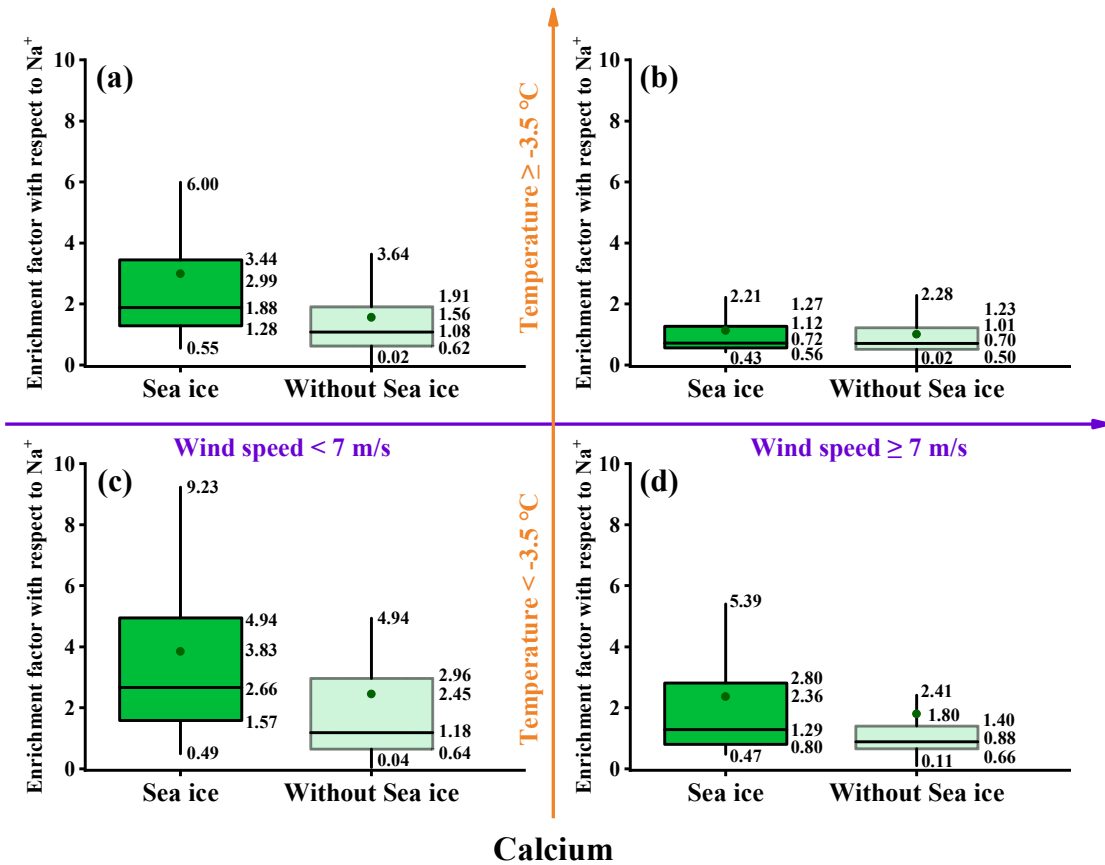

283

284 Figure S5

285 (a) – (g) Average digitalized single-particle mass spectra for seven classes of collected particles. (h) Hot plot of number fractions for major species of obtained single-

286 particle types, including chloride (m/z -35 and -37), sulfate (m/z -97), nitro-containing organic species (m/z -46), organic nitrogen (m/z -26 or -42), phosphate (m/z -63
287 or -79), carbohydrate (m/z -45, -59, or -73), siliceous materials (m/z -60), and organic carbon (m/z -27 or 43). (i) Relative proportion of different single-particle types
288 during the cruise observations. (j) Unscaled size-resolved number distributions of all individual particles.

289 A total of $\sim 580,000$ calcium-containing particles (m/z 40 $[\text{Ca}]^+$) were observed during cruise observations, accounting for $\sim 62\%$ of the total obtained particles.
290 These calcium-containing particles were scattered among all the obtained particle types, with proportion of $\sim 48\%$, $\sim 56\%$, $\sim 25\%$, $\sim 22\%$, $\sim 100\%$, $\sim 12\%$, and $\sim 49\%$ for
291 SS, SS-aged, SS-Bio, OC-K, OC-Ca, OC, and EC, respectively. In particular, the SS-Ca and OC-Ca particle types accounted for $\sim 12\%$ and $\sim 72\%$ of the total of
292 calcium-containing particles and $\sim 7\%$ and $\sim 50\%$ of the total obtained particles, respectively.

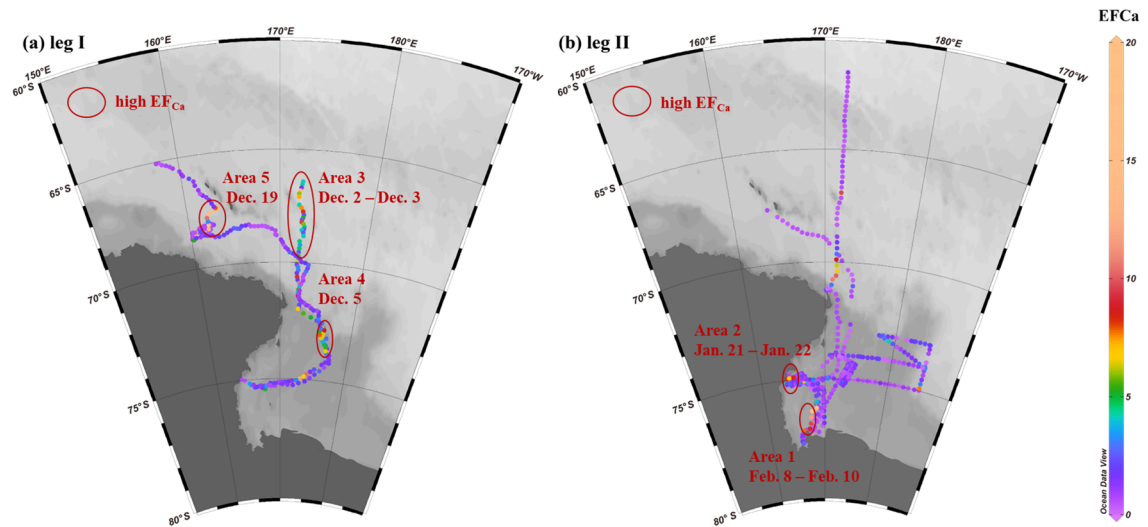

Calcium

293

294 Figure S6

295 A box and whisker plot of hourly Ca^{2+} enrichment factors (EF_{Ca}) with respect to Na^+ at different
 296 ambient temperatures, wind speeds, and sea ice fraction. In the box and whisker plots, the marked
 297 values from top to bottom are the 90th and 75th percentiles, mean, median, and 25th and 10th
 298 percentiles, respectively.

299 In comparison with the bubble charts (Fig. 1 in main text), the box and whisker plot present similar
 300 intensions in different forms.

301

302 Figure S7

303 A comparative analysis of the EF_{Ca} values between leg I and leg II of the R/V *Xuelong* cruise over

304 the Ross Sea, Antarctica. We manually classified the five high EF_{Ca} areas (marked in red), which

305 could be seen in detail in Table S4.

306

307 Figure S8

308 Correlation analysis between EF_{Ca} and chlorophyll-a concentration during leg II.

309

310 Figure S9

311 (a) Correlation analysis between the single-particle peak area for species in OC-Ca. There are

312 relatively high correlation coefficients ($r = 0.42\text{--}0.81$) between the peak area of Ca and organic

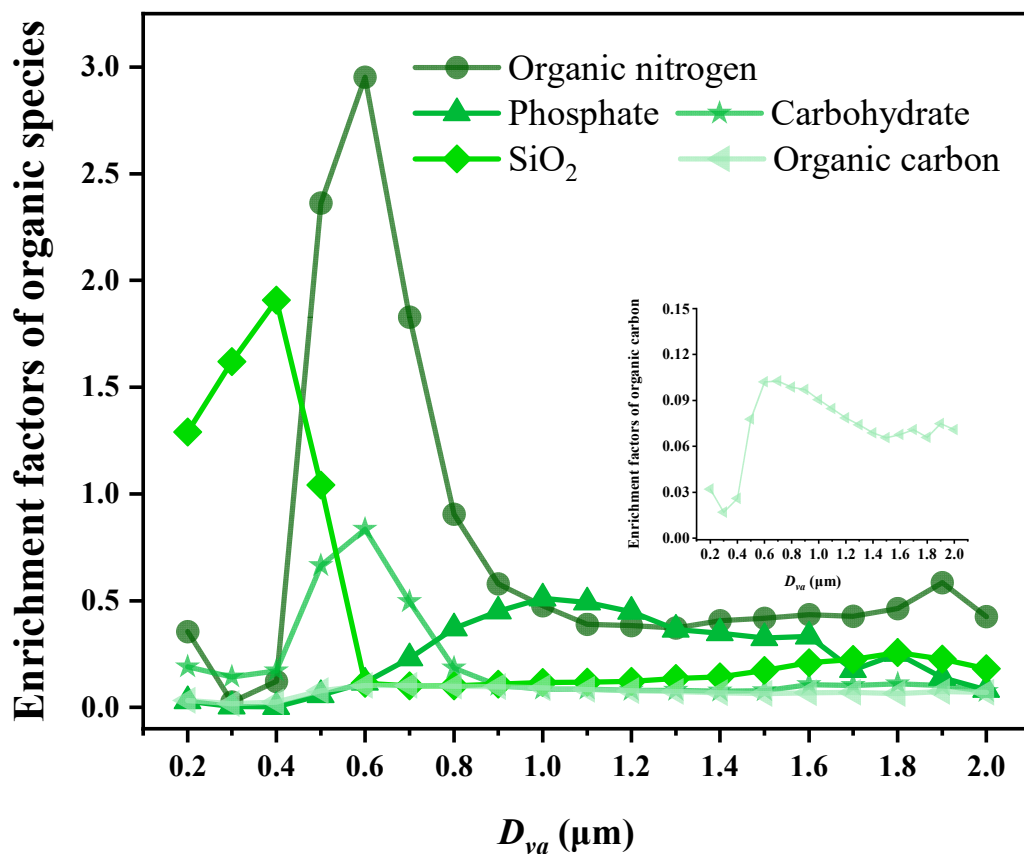

313 species (organic nitrogen, phosphate, carbohydrate, siliceous materials, and organic carbon). (b)

314 Correlation analysis between the OC-Ca (by count) and mass concentration of Ca²⁺. The first

315 (sodium) to fifth (chloride) refer to mass concentration. The sixth (OCK) to fourteenth (SS) refer to

316 single-particle types.

317

318

319 Figure S10

320 Size-dependent single-particle peak area ratio of organic matter to calcium. Based on SPAMS, we

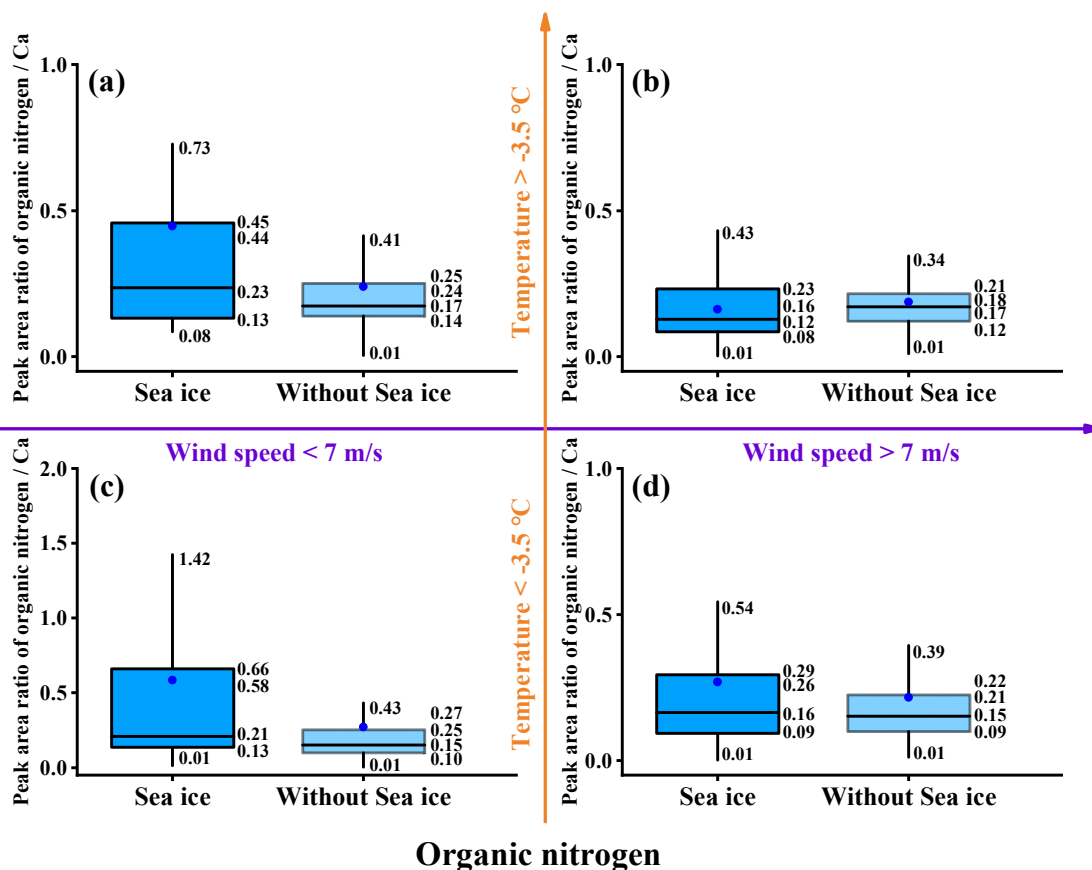

321 define the organic matter enrichment factors as the single-particle peak area ratio of organic species

322 to Ca (m/z 40) in OC-Ca. The single-particle counts of OC-Ca are 420, 000. The organic species

323 include organic nitrogen (m/z -26 and -42), phosphate (m/z -63 and -79), carbohydrate (m/z -45, -59,

324 and -73), siliceous materials (SiO_2 , m/z -60), and organic carbon (m/z 27 and 43).

325

326

327 Figure S11

328 A box and whisker plot of the peak area ratio of organic nitrogen (m/z -26 and -42) to Ca (m/z 40)

329 in OC-Ca at different ambient temperatures, wind speeds, and sea ice fraction. As described above,

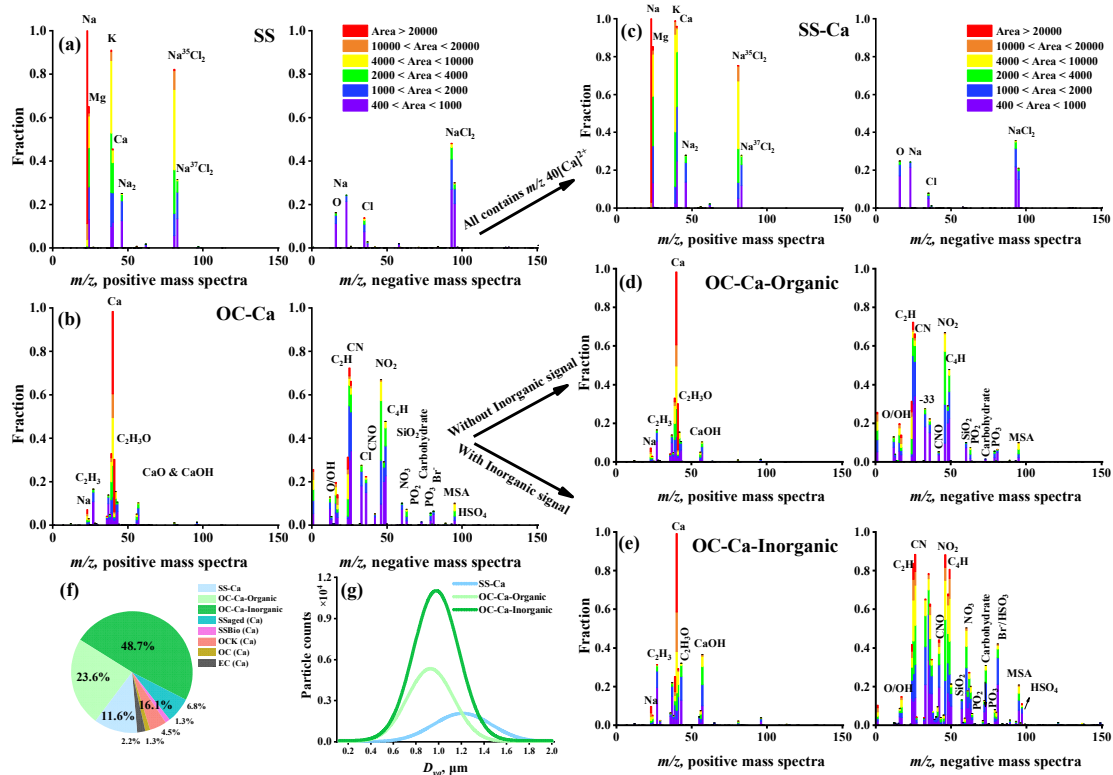

330 the organic nitrogen enrichment factor in OC-Ca (EF_{ON}) is defined as the single-particle peak area

331 ratio of organic nitrogen to calcium. We chose the organic nitrogen within OC-Ca for comparative

332 analysis because of its large number fraction (0.88). In the box and whisker plot, the marked values

333 from top to bottom are 90th and 75th percentiles, mean, median, and 25th and 10th percentiles,

334 respectively.

335

336 Figure S12

337 (a) and (b) Average digitalized single-particle mass spectra of chemical classes of SS and OC-Ca.

338 (c) Average digitalized single-particle mass spectra of SS-Ca that are refined by using m/z 40 [Ca]²⁺

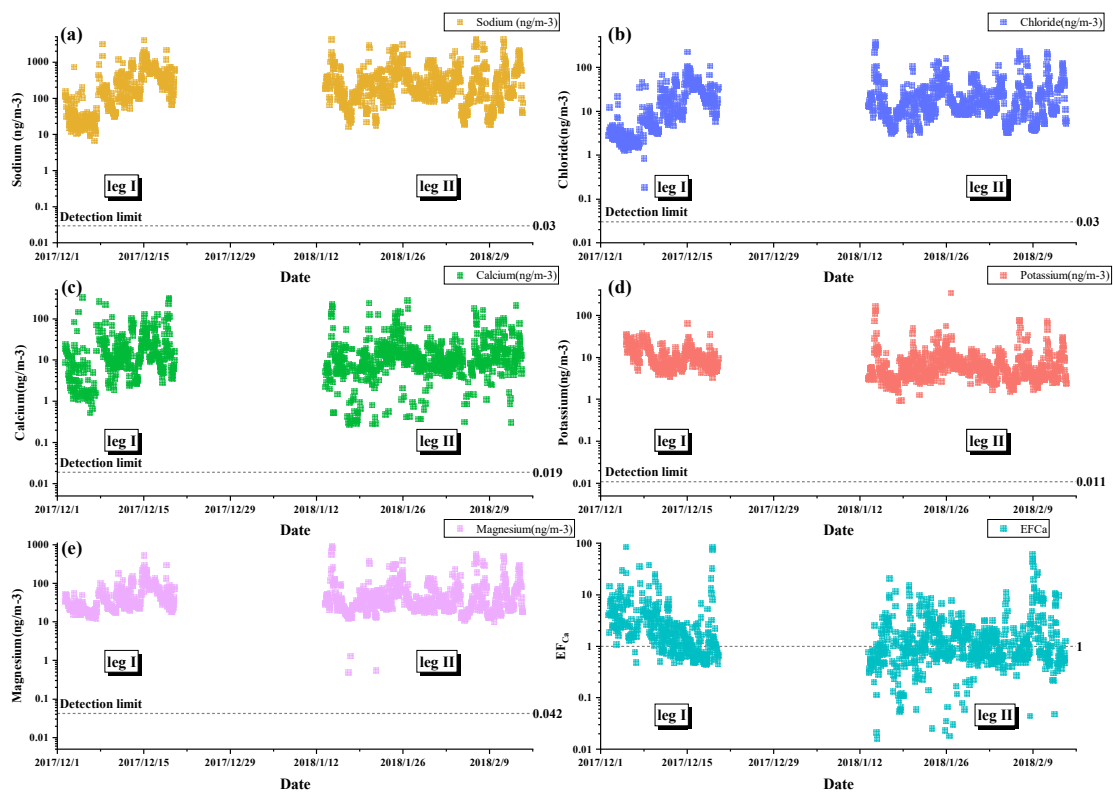

339 upon SS. (d) and (e) Average digitalized single-particle mass spectra of OC-Ca-Organic and OC-

340 Ca-Inorganic, which are classified by whether inorganic compounds (chloride (m/z -35 and -37),

341 nitrate (m/z -62), and sulfate (m/z -97) ion signals are present. (f) Relative proportion and (g)

342 unscaled size-resolved number distributions of single-particle types.

343 **Note:** Figures S13-S22 were used when discussing supplementary Text (S3, S5, S7, and S8) and
344 were not cited in the main-text.

345

346 Figure S13

347 The time series of observed ion mass concentrations and EF_{Ca} .

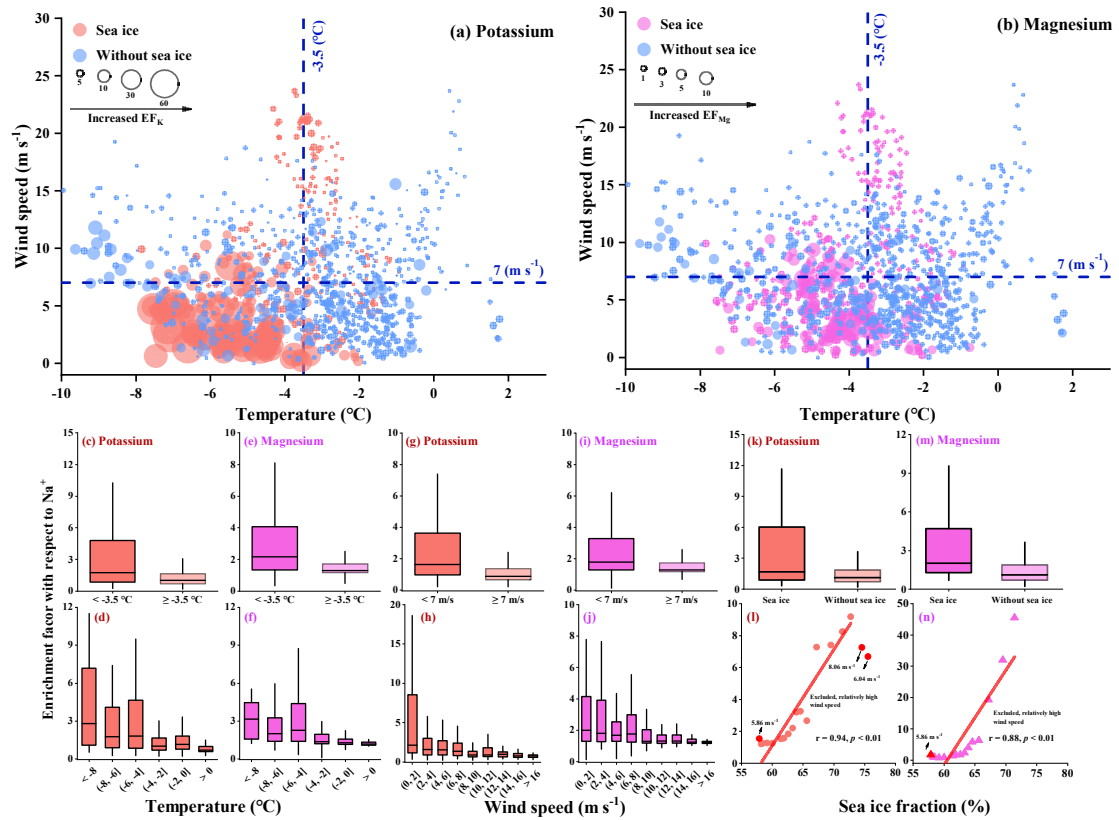

348

Potassium

Magnesium

349 Figure S14

350 Box and whisker plots of hourly Ca^{2+} enrichment factor (EF_{Ca}) with respect to Na^+ at different
 351 ambient temperatures, wind speeds, and sea ice fraction. In the box and whisker plots, the marked
 352 values from top to bottom are the 90th and 75th percentiles, mean, median, and 25th and 10th
 353 percentiles, respectively. In comparison with the bubble charts (Fig. S15), the box and whisker plots
 354 present similar intensions with different forms.

355

356 Figure S15

357 Bubble charts of hourly (a) K^+ and (b) Mg^{2+} enrichment factors with respect to Na^+ at the ambient
 358 temperatures, wind speeds, and sea ice fraction. The enrichment factors of K^+ and Mg^{2+} with respect
 359 to Na^+ varied as a function of the ambient temperature (c-f), wind speed (g-j), and sea ice fraction
 360 (k-n) during the cruise observation. In the box and whisker plot, the lower, median, and upper lines
 361 of the box denote the 25th, 50th and 75th percentiles, respectively.

362

363 Figure S16

364 The relative importance to the variation in EF_{Ca} , as determined by multilinear regression for (a) the
 365 whole sampling period and (c) the sea ice period. The error bars provide 90% confidence intervals
 366 with 100 bootstrap replicates to evaluate the results. The relative importance of the predictors in the
 367 random forest analysis for the EF_{Ca} for (b) the whole sampling period and (d) the sea ice period.
 368 The %IncMSE, which is used as an indicator for the relative contribution to the predicted variable,
 369 refers to the increased mean square-error when each independent variable is removed from the
 370 predictors.

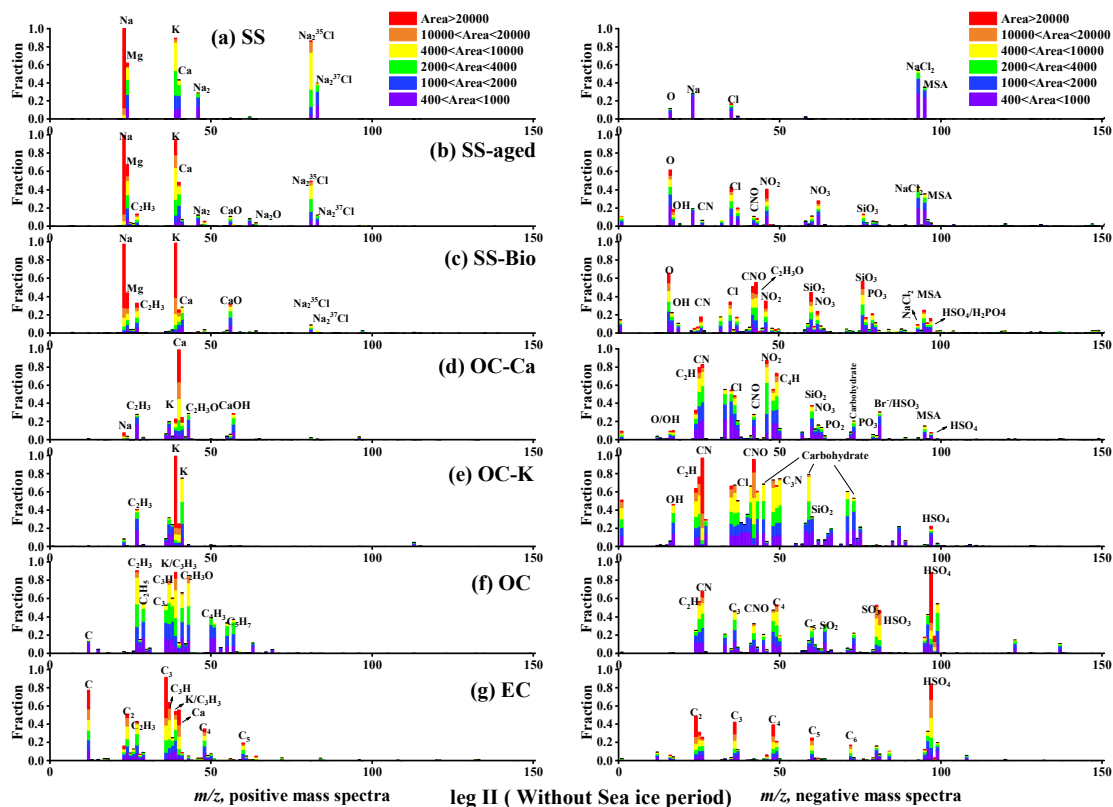

371

372 Figure S17

373 Average digitalized single-particle mass spectra for seven classes of collected particles during leg I

374 (sea ice period).

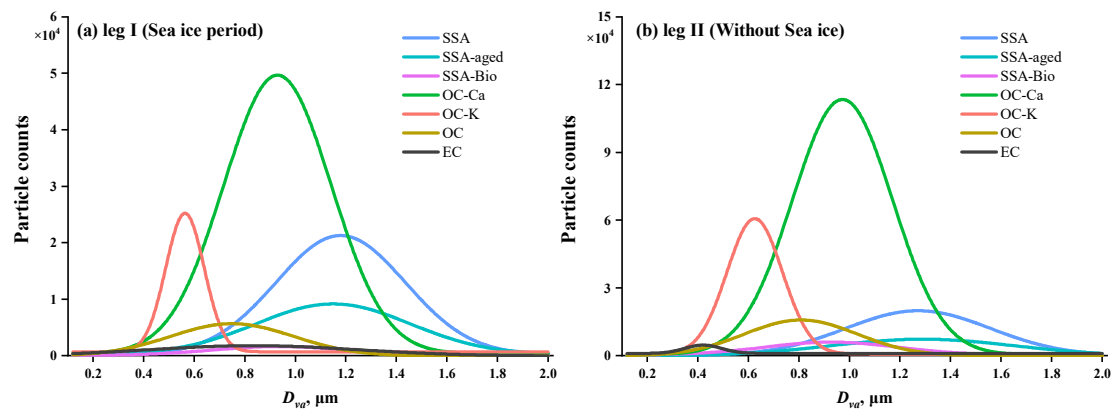

375

376 Figure S18

377 Average digitalized single-particle mass spectra for seven classes of collected particles during leg

378 II (period without sea ice).

379

380 Figure S19

381 Unscaled size-resolved number distributions of all individual particles during leg I (sea ice period)

382 and leg II (period without sea ice).

383

384 Figure S20

385 Relative proportion of different single-particle types during leg I (sea ice period) and leg II (period
 386 without sea ice). It is still quite a challenge to obtain quantitative measurements using SPAMS due
 387 to the potential inhomogeneities in the transmission efficiencies of the aerodynamic lenses and
 388 desorption/ionization, and the matrix effects of individual particles (Gross et al., 2000; Qin et al.,
 389 2006; Pratt and Prather, 2012). Therefore, it may not be straightforward to use the particle count in
 390 comparison with the absolute mass concentration. We noted that there was little difference in OC-
 391 Ca proportion during the periods of sea ice and without sea ice. The source of OC-Ca for the two
 392 periods may be explained by the low wind-blown sea ice and the blowing-snow from Antarctica
 393 (Fig. S1 and Table S1, the influence of air masses from Antarctic land, 40%), respectively. Another
 394 reason for that may be the resuspension of OC-Ca. Also, bubble bursts within open water and leads
 395 occurred in both periods.

396

397 Figure S21

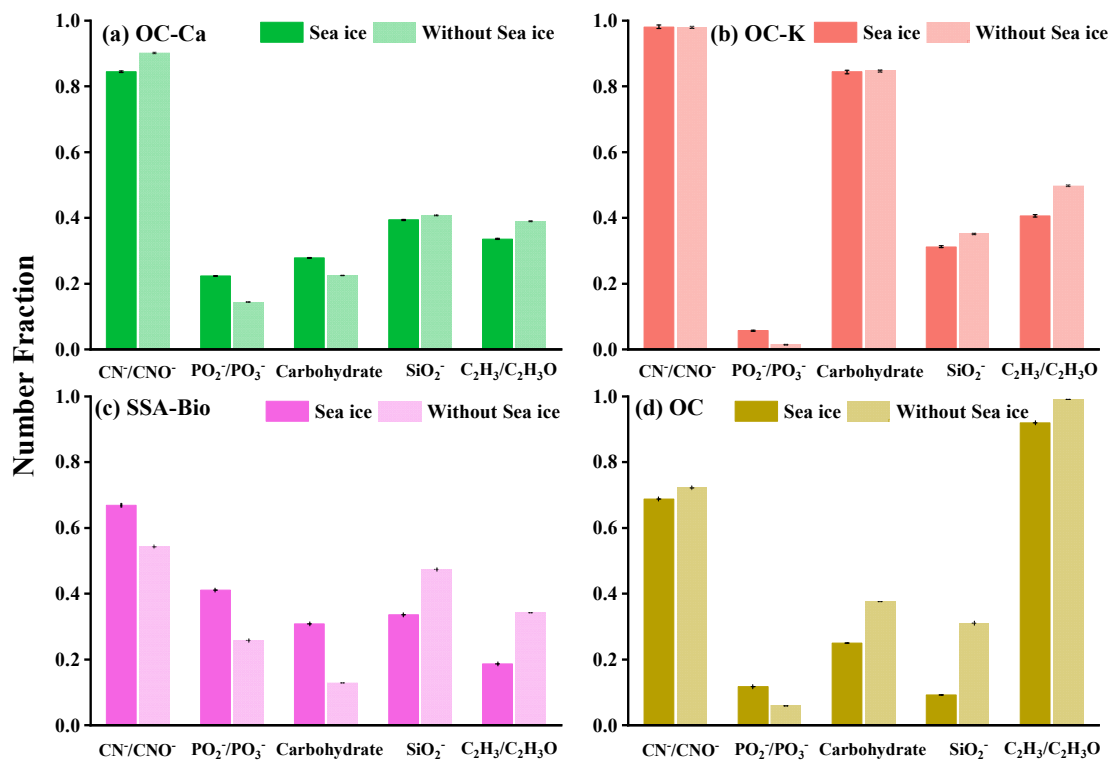

398 Hot plot of number fractions for major species of obtained single-particle types, including chloride

399 (m/z -35 and -37), sulfate (m/z -97), methanesulfonic acid (MSA, m/z -95), nitro-containing organic

400 species (m/z -46), organic nitrogen (m/z -26 or -42), phosphate (m/z -63 or -79), carbohydrate (m/z

401 -45, -59, or -73), siliceous materials (m/z -60), and organic carbon (m/z -27 or 43). (a) leg I (sea ice

402 period) and leg II (period without sea ice).

403

404 Figure S22

405 Comparison by number fractions for some typical organic chemical components of (a) OC-Ca, (b)

406 OC-K, and (c) SS-Bio during leg I (sea ice period) and leg II (period without Sea ice). The errors

407 are calculated assuming Poisson statistics for the obtained particles.

Sea ice fraction	54.60 ± 0.02	54.53 ± 0.00	74.28 ± 1.41	71.41	58.06 ± 0.25	64.91 ± 5.57	54.59 ± 0.08	58.38 ± 6.07
Chl-a concentration (µg L ⁻¹)	0.99 ± 1.65	0.10 ± 0.20	Unavailable	Unavailable	Unavailable	0.51 ± 0.29	0.44 ± 0.18	0.46 ± 0.23
72-Trajectory coverage (%)*								
Sea ice:	2%	1%	100%	100%	76%	78%	28%	48%
Open water:	0%	0%	0%	0%	22%	6%	32%	21%
Antarctic Land:	98%	99%	0%	0%	2%	16%	40%	31%

Note: (1) Area 1 and 2 are divided during the leg II, whereas the Area 3, 4, and 5 are divided during the leg I. (2) The values of sea ice intensity and chl-a concentration present with daily resolution. Others present with hourly resolution. (3) No sea ice coverage is equivalent to the sea ice fraction below 55. (4) 72-Trajectory coverage (%)* corresponds to fraction of air masses traveled over different surface type when the peak EFCa value from Area 1 to 5. For leg I, II, and the whole observation, this fraction was calculated with daily resolution.

421

422 Table S4

423 Average enrichment factors for specific cations and metrological parameters over the different areas

424 mentioned in Fig. S7. Although all of these areas exhibited significant Ca²⁺ enrichment in SSAs,

425 they may have varied due to synergetic environmental factors rather than a single factor. Ca²⁺

426 enrichment in SSA was notably observed with low wind speed, underscoring the effect of wind

427 speed. The back trajectories are labeled as sea ice, open water, and land, disregarding periods that

428 the air mass spent above the mixed layer height.

429 For the leg I, the major positive Ca²⁺ enrichment events were associated with Areas 3, 4, and 5. In

430 addition to the lower wind speed, lower temperature, and the presence of sea ice, the air masses

431 blew over the large fraction of sea-ice-covered ocean may play an important role in Ca²⁺ enrichment.

432 For the leg II, the major positive Ca²⁺ enrichment events were occurred in Areas 1 and 2, which

433 mainly associated with lower wind speed and temperature. The air masses were mostly from the

434 snow-covered Antarctic land.

435

EF _{Ca}	Count (Correlation coefficient, r)				Peak area (Correlation coefficient, r, <i>m/z</i> 40 [Ca] ²⁺)
