8 **Abstract**

9 The last deglaciation (21000 to 8000 years BP) of the Eurasian ice sheet (EIS), is thought to have been responsible
10 for a sea level rise of about 20 meters. While many studies have examined the timing and rate of the EIS retreat
11 during this period, many questions remain about the key processes that triggered the EIS deglaciation 21,000 years
12 ago. Due to its large marine-based parts in the Barents-Kara and British Isles sectors, EIS is often considered as a
13 potential analog of the current West Antarctic ice sheet (WAIS). Identifying the mechanisms that drove the EIS
14 evolution might provide a better understanding of the processes at play in the West Antarctic destabilization. To
15 investigate the relative impact of key drivers on the EIS destabilization we used the three-dimensional ice sheet
16 model GRISLI (version 2.0) forced by climatic fields from five PMP3/PMIP4 LGM simulations. In this study,
17 we performed sensitivity experiments to test the response of the simulated Eurasian ice sheets to surface climate,
18 oceanic temperatures (and thus basal melting under floating ice tongues) and sea level perturbations. Our results
19 highlight that the EIS retreat is primarily triggered by atmospheric warming. Increased atmospheric temperatures
20 further amplify the sensitivity of the ice sheets to sub-shelf melting. These results contradict those of previous
21 modelling studies mentioning the central role of basal melting on the deglaciation of the marine-based Barents-
22 Kara ice sheet. However, we argue that the differences with previous works are mainly related to differences in
23 the methodology followed to generate the initial LGM ice sheet. We conclude that being primarily sensitive to the
24 atmospheric forcing, the Eurasian ice sheet cannot be considered as a direct analogue of the present-day West
25 Antarctic ice sheet. However, because of the expected rise in atmospheric temperatures, risk of hydrofracturing is
26 increasing and could ultimately put the WAIS in a configuration similar to the pas Eurasian ice sheet.

34 **1 Introduction**

35 During the last glacial maximum (LGM, 26-19 ka), the Eurasian ice complex was formed by the coalescence of
36 three distinct ice sheets covering the British Isles, Fennoscandia and the Barents and Kara Seas. While the
37 Fennoscandian ice sheet (FIS) was mostly grounded on the bedrock, the British Isles (BIIS) and Barents-Kara
38 (BKIS) were mostly lying below sea level.

39 The Eurasian ice sheet (EIS) was influenced by various climate regimes with large differences between the western
40 and eastern edges. Due to heat and moisture sources from the North Atlantic current, the British Isles and western
41 Scandinavia were dominated by relatively warm and wet conditions contrasting with the more continental and
42 drier climate in the eastern part of the EIS (Tierney et al., 2020). These various climatic influences prevailing over
43 the three different ice sheets forming the Eurasian ice complex, may have resulted in different responses to
44 variations in atmospheric and oceanic conditions. Over the last decade an active field of research has developed to
45 identify the mechanisms behind the retreat of the Eurasian ice sheet during the last deglaciation, although no clear
46 consensus has yet been reached. According to the recent study of Sejrup et al. (2022) the onset of the northern
47 hemisphere deglaciation was primarily triggered by summer ablation resulting from increased summer insolation
48 at 65 °N, and thus by changes in surface mass balance (SMB), defined as the difference between snow/ice
49 accumulation and ablation.

50 On the other hand, studies based on modeling approaches suggest that the retreat of the marine-based ice sheets
51 could be driven by dynamical processes triggered by the melting of ice shelves (Pattyn et al., 2018). In fact, the
52 relationship between oceanic temperatures and ice sheet mass balance has been confirmed and widely documented
53 for the present-day WAIS. In particular, it has been shown that ocean warming plays a crucial role in accelerating
54 Antarctic mass loss by enhancing basal melting and ice shelf thinning (Pritchard et al., 2012, Konrad et al., 2018,
55 Pattyn et al., 2018; Rignot et al., 2019). This process may trigger a marine ice sheet instability when the bedrock
56 is sloping towards the ice sheet interior. This instability translates into a sustained retreat of the grounding line and
57 a significant glacier acceleration (Schoof, 2012). As large parts of BIIS and BKIS are marine based, their evolution
58 could be driven by sub-shelf melting and potentially by the subsequent marine ice sheet instability. Based on the
59 analysis of benthic and planktic foraminiferal assemblages, ice-rafted debris and radiocarbon dating, Rasmussen
60 and Thomsen (2021) showed that the retreat of the ice in the Svalbard-Barents sector followed the deglacial
61 oceanic, but also atmospheric, temperature changes. Relying on a first-order thermomechanical ice sheet model
62 constrained by a variety of geomorphological, geophysical and geochronological data, Patton et al. (2017) found
63 that the BIIS receded quite quickly in response to moderate increases in surface temperature. By contrast, the BKIS
64 was rather affected by a combination of reduced precipitation and increased rates of iceberg calving. Other
65 modeling studies have attempted to simulate the dynamics of the EIS during the last glacial period and the last
66 deglaciation with the objective of better understanding the evolution of the ice sheet (Petrini et al., 2020; Alvarez-
67 Solas et al., 2019). In a way similar to what is currently observed in West Antarctica, they suggest that large EIS
68 variations are primarily due to the warming of the Atlantic Ocean leading to increased basal melting in the vicinity
69 of the grounding line (Petrini et al., 2020; Alvarez-Solas et al., 2019). However, the models on which these studies
70 are based have no specific treatment for computing ice velocities at the grounding line, making questionable their
71 representation of the grounding line migration.

72 Because of the diversity of mechanisms that may have influenced the evolution of the three Eurasian ice sheets,
73 the Eurasian ice complex is an interesting case study to investigate the different mechanisms responsible for the
74 ice sheet retreat. As both BKIS and BIIS are marine-based (Svendsen et al., 2004, Gandy et al., 2018, 2021), they
75 are likely to be more sensitive to oceanic temperature variations. Special attention can be given to BKIS because
76 it has often been considered as a potential analogue of the present-day WAIS (Gudlaugsson et al., 2017,
77 Andreassen and Winsborrow, 2009, Mercer, 1970) due to common features such as the ice volume and a bedrock
78 largely grounded below sea level with an upstream deepening (Amante et al., 2009). As a result, in-depth
79 investigations of the BKIS behavior at the LGM can help to better understand the present-day changes and future
80 evolution of West Antarctica.

81 This wide range of hypotheses regarding the different processes responsible for the EIS destabilization (i.e
82 atmospheric climate, oceanic climate or both) confirms that there is still a lot of unknowns in the EIS dynamics
83 during the last deglaciation and that the debate is not closed. Progress has been made in ice sheet modeling with
84 the development of new generation models computing the full Stocks flow equations. For example, with a refined
85 model resolution near the grounding line, Gandy et al., (2018, 2021) have quantified the impact of oceanic
86 temperatures on the grounding line dynamics and investigated the potential occurrence and effect of the marine
87 ice sheet instability. However, as the computation time is considerably increased, they focus only on specific
88 sectors (i.e. North Sea) and thus do not consider the impact of the other interconnected ice sheets.

89 In this paper, we present simulations of the entire Eurasian ice complex during the LGM using the three-
90 dimensional GRISLI2.0 (GRenoble Ice Shelf and Land Ice) ice sheet model (Quiquet et al., 2018). GRISLI2.0
91 includes an explicit calculation of the ice flux at the grounding line derived from the analytical formulation
92 provided by Tsai et al. (2015), which is expected to account for the representation of the marine ice sheet instability.
93 Our ultimate objective is to identify the key mechanisms leading to the EIS deglaciation. Starting from its LGM
94 geometry, we investigate the EIS sensitivity to perturbations of surface air temperature, precipitation rate, basal
95 melting, and sea level to better understand their relative contribution to the EIS destabilization. In this work, the
96 GRISLI2.0 ice sheet model was forced by a panel of ten different climates from the Paleoclimate Modelling
97 Intercomparison Project (PMIP) database (Abe-Ouchi et al., 2015; Kageyama et al., 2021).

98 The paper is organized as follows. Section 2 provides a description of the basic equations of the GRISLI2.0 ice
99 sheet model. It also includes a presentation of the climate forcing and the experimental setup of the LGM and
100 sensitivity experiments. Section 3 compares our different reconstructions of the EIS at the LGM. The results of
101 the sensitivity experiments are presented in section 4 and discussed in section 5. Concluding remarks are given in
102 section 6.

105 **Figure 1:** Map of the Eurasian Ice Sheet at the LGM. The white line is the most credible ice extent of the Eurasian
106 ice sheet at the LGM according to the DATED-1 compilation (Hughes et al., 2016). Dark blue shaded areas
107 correspond to the location of the main ice streams (Dowdeswell et al., 2016; Stokes and Clark, 2001), and dotted
108 black lines are delimitations between the Fennoscandian, the Barents-Kara, and the British Isles ice sheets.

109 2. Model description and experimental set-up

110 2.1 The GRISLI ice sheet model

111 In this study, we use the 3D thermomechanical ice sheet model GRISLI2.0 (referred hereafter to as GRISLI) run
112 on a Cartesian grid with a horizontal resolution of 20 km x 20 km, corresponding to 177 x 257 grid points.

113 This ice sheet model was initially built to study the Antarctic ice sheet behavior during glacial-interglacial cycles
114 (Ritz et al. 2001). It was then adapted to the Northern Hemisphere ice sheets (e.g. Peyaud et al., 2007) and tested
115 under various climatic conditions (Ladant et al., 2014, Le clec'h et al. 2019, Colleoni et al., 2014, Beghin et al.
116 2014). GRISLI also took part in the Ice Sheet Model Intercomparison Project (ISMIP6) (Goelzer et al.; 2020,
117 Seroussi et al., 2020, Quiquet and Dumas, 2021a, 2021b) to investigate future sea level changes (Nowicki et al.
118 2020). A full description of GRISLI can be found in Quiquet et al. (2018). Here, we only remind the basic
119 principles of the model. The main modification in this new version of GRISLI compared to previous ones (Ritz et

120 al., 2001; Peyaud et al., 2007) is the implementation of analytical formulations of the flux at the grounding line
121 leading to a better representation of the grounding line migration.

122 The evolution of the ice sheet geometry depends on the ice sheet surface mass balance, ice dynamics and isostatic
123 adjustment. Assuming that ice is an incompressible material, changes in ice thickness with time are given by the
124 mass balance equation:

$$125 \quad \frac{dH}{dt} = SMB - B_{melt} - \nabla(UH) \quad (1)$$

126 with H being the local ice thickness, SMB the surface mass balance, B_{melt} the basal melting in grounded ice areas
127 and under the ice shelves, U the vertical average velocity, and $\nabla(UH)$ the ice flux divergence.

128 The ice velocity is calculated from the sum of the shallow ice approximation (SIA) and the shallow shelf
129 approximation (SSA) components (Winkelmann et al., 2011). Both approximations take advantage of the small
130 aspect ratio of the ice sheets (Hutter, 1983). The SIA assumes that the longitudinal shear stresses can be neglected
131 compared to the vertical shear stresses and holds for all ice sheet regions where the gravity-driven flow induces a
132 slow motion of the ice (Hutter, 1983). Conversely, the SSA neglects the vertical shear stresses compared to the
133 longitudinal shear stresses, which is generally valid for floating ice shelves (MacAyeal, 1989) and to some extent
134 for fast-flowing ice streams. As a result, the total ice sheet domain can be separated into three regions: floating ice
135 shelves where the ice velocity is computed with the SSA, cold-base areas governed by the SIA, and finally, the
136 temperate-base grounded ice, where the ice velocity is computed as the sum of the SIA and SSA components.

137 The basal friction for the temperate base areas is assumed to follow a linear friction law:

$$138 \quad \tau_b = -\beta U_b \quad (2)$$

139 where τ_b is the basal shear stress, U_b the basal velocity and β the basal drag coefficient. The basal drag coefficient
140 depends on the effective water pressure (N), i.e. the difference between water pressure and ice pressure, and on an
141 internal constant parameter ($C_f = 1.5 \cdot 10^{-6} \text{ m yr}^{-1}$):

$$142 \quad \beta = C_f N \quad (3)$$

143 At the base of the grounded ice sheet, the basal temperature is also critically dependent on the geothermal heat
144 flux which is given here by the distribution of Shapiro and Ritzwoller (2004).

145 To simulate artificially the effect of ice anisotropy on the ice velocity, most ice sheet models use an enhancement
146 factor in the nonlinear viscous flow law that relates deformation rates and stresses with values generally ranging
147 between 1 and 5. In GRISLI, two enhancement factors are considered (E_{SIA} and E_{SSA}). E_{SIA} is applied to the SIA
148 component of the velocity to increase ($E_{SIA} > 1$) the deformation induced by vertical shearing. Conversely E_{SSA} is
149 applied to the SSA component of the velocity to reduce ($E_{SSA} < 1$) the deformation due to longitudinal stresses. The
150 model parameters used in this study are the same as those used in Quiquet et al. (2021c) with the exception of E_{SIA}
151 and C_f fixed respectively to 5 (instead of 1.8) and $1.5 \cdot 10^{-6} \text{ m yr}^{-1}$ (instead of $1.5 \cdot 10^{-3} \text{ m yr}^{-1}$). Those parameters
152 have been chosen for a better match between the simulated EIS ice volume at the LGM and the geologically-
153 constrained reconstructions (see Section 2.3).

154 The horizontal resolution used in this study is too coarse to simulate explicitly the grounding line migration
155 (Durand et al., 2009). To circumvent this drawback, we use the analytical formulation from Tsai et al. (2015), in
156 which the ice flux at the grounding line is computed as a function of the ice thickness and a backforce coefficient
157 accounting for the buttressing effect of the ice shelves. In this way, a flow at the grounding line can be simulated
158 with a lower resolution allowing time saving in the simulations. Technical details on this implementation in the
159 GRISLI model are given in Quiquet et al. (2018).

160 At the ice shelf front, calving is computed using a simple ice thickness criterion by prescribing a minimal ice
161 thickness set to 250 m below which ice is calved.

162 **2.2 Climate forcing**

163 We forced GRISLI with the absolute climatic fields from general circulation model (GCM) outputs of the
164 PMIP3/PMIP4 database (Kageyama et al., 2021). All the GCMs for which LGM simulations were available at the
165 time of writing the manuscript have been selected (see Table 1).

166 Monthly surface air temperatures and solid monthly precipitation are used to compute the surface mass balance
167 defined as the difference between snow/ice accumulation and ablation. Ablation is calculated using a positive
168 degree-day (PDD) method following the formulation of Tarasov and Peltier (2002). Snow accumulation is
169 calculated from the total precipitation (rain and snow), considering only months where monthly temperatures are
170 under the melting point.

171 Due to the differences between GCM and GRISLI resolutions, the GCM outputs are bi-linearly interpolated onto
172 the ice sheet model grid. In addition, to account for orography differences between GRISLI and the GCMs, the
173 surface air temperatures of the GCMs are corrected using a constant vertical temperature gradient $\lambda = 7 \text{ }^\circ\text{C km}^{-1}$:

$$174 \quad T(t)_{GRISLI} = T_{GCM}^{LGM} - \lambda(S(t) - S_{GCM}^{LGM}) \quad (4)$$

175 where $T(t)_{GRISLI}$ is the time-dependent surface air temperature at the surface elevation $S(t)$ simulated by the ice
176 sheet model, and T_{GCM}^{LGM} and S_{GCM}^{LGM} are the LGM surface air temperature and orography computed by the GCMs.

177 This temperature correction induces a change in precipitation which is computed following the Clausius-Clapeyron
178 formulation for an ideal gas:

$$179 \quad pr(t)_{GRISLI} = pr_{GCM}^{LGM} * \exp(\omega * (T(t)_{GRISLI} - T_{GCM}^{LGM})) \quad (5)$$

180 where $pr(t)_{GRISLI}$ is the precipitation calculated by GRISLI at each time step and pr_{GCM}^{LGM} is the LGM precipitation
181 computed by the GCM and interpolated on the GRISLI grid. ω is the precipitation ratio to temperature change and
182 is fixed to $0.11 \text{ }^\circ\text{C}^{-1}$ (Quiquet et al., 2013).

183 Following DeConto and Pollard (2012), the sub-shelf melt rate (OM) is computed using ocean temperature and
184 salinity:

$$185 \quad OM = K_t \frac{\rho_w C_w}{\rho_i L_f} |T_o - T_f| (T_o - T_f) \quad (6)$$

186 where K_t is called the transfer factor and is set to $7 \text{ m yr}^{-1} \text{ }^\circ\text{C}^{-1}$ in the baseline experiments as in DeConto and
187 Pollard (2012), ρ_w the ocean water density, ρ_i ice density, L_f the latent heat of ice fusion, C_w the specific heat of

188 ocean water and T_o is the local ocean temperature. T_f is the local freezing point temperature, depending on the
 189 ocean salinity (S) and computed by the Beckmann and Goosse (2003) parameterization:

$$190 \quad T_f = 0.0939^\circ C - S \times 0.057^\circ C + z \times 7.6410^{-4}^\circ C \quad (7)$$

191 where z is the ocean depth.

192 A difficulty related to the oceanic forcing fields is that the GCMs do not provide any oceanic information outside
 193 their land-sea mask and under the ice shelves. To fill these gaps, we performed a classical near neighbour horizontal
 194 extrapolation of temperature and salinity except that we perform this extrapolation within 10 sectors
 195 independently. These sectors roughly correspond to drainage basins (Fig. S1). The definition of these basins is
 196 based on bedrock topographic features and LGM ice elevation and is somehow comparable to the approach
 197 followed by Zwally et al. (2015) for Antarctica. The horizontal extrapolation is performed for each individual
 198 vertical layer, without any vertical interpolation. This extrapolation method provides information on temperature
 199 and salinity within the entire ice shelf cavity for each vertical level of the GCMs. These temperature and salinity
 200 fields are then used to compute the sub-shelf melt rate (Eq. 6), using a linear vertical interpolation between the two
 201 oceanic layers bounding the ice shelf depth. The only exception is when the PMIP3/PMIP4 simulations do not
 202 provide data in a given sector. In this case, a constant and homogeneous basal melting value of 0.1 m yr^{-1} is
 203 prescribed. This mainly occurs in the continental southern flanks of the Eurasian ice sheet.

204 In GRISLI, each grid point can either be a floating or a grounded ice point. To account for the fact that the sub-
 205 shelf melt rate is higher in the vicinity of the grounded line (Beckmann and Goose, 2003) and due to the coarse
 206 resolution of the model, we apply a fraction of the neighbouring floating sub-shelf melt rate to the last grounded
 207 point as in De Conto and Pollard (2012). This approach allows to take the potential influence of the ocean into
 208 account.

209 **Table 1:** PMIP3 and PMIP4 models used to force GRISLI. The fourth column indicates the choice of the ice sheet
 210 boundary condition at the LGM for each GCM simulation. ice sheet reconstructions used as a boundary condition
 211 of the GCM simulations at the LGM.

212 **2.3 LGM equilibrium**

213 As mentioned above, the main objective of the present paper is to investigate the mechanisms responsible for the
214 EIS retreat from its LGM configuration. To do this, a preliminary step is to build the EIS at the LGM.

215 We performed ten 100 000-years spin-up experiments (one for each GCM) forced by a constant LGM climate
216 provided by the ten GCMs. Simulations start with no ice sheet and the eustatic sea level is prescribed at 120 m
217 below the present level. The initial bedrock topography corresponds to the present-day topography from ETOPO1
218 (Amante et al., 2009). This procedure is required to obtain internal ice sheet conditions in equilibrium with the
219 climate forcing and to examine whether the LGM climate can build and maintain the EIS when it is used as input
220 to the GRISLI ice sheet model. From this climate forcing ensemble, we only selected those leading to LGM ice
221 sheets in a reasonable agreement with the most credible ice extent in the DATED-1 database (Hughes et al., 2016)
222 and with the geologically-constrained ice thickness reconstructions, namely ICE-6G_C (Peltier et al., 2015),
223 GLAC-1D (Briggs et al., 2014; Tarasov et al., 2012; Tarasov and Peltier, 2002), and ANU (Lambeck et al., 1995,
224 1996, 2010).

225 **2.4 Sensitivity experiments**

226 To quantify the relative importance of the three main drivers (i.e., surface mass balance, sub-shelf melt rate, and
227 sea level) of the EIS retreat, we applied time-constant perturbations on the atmospheric and oceanic GCM forcings,
228 and we changed the prescribed sea level. The perturbed simulations are run for 10000 years. We analysed the
229 response at year 1000 of the simulation to investigate the impacts of climate changes that may have occurred at
230 the beginning of the deglaciation and at year 10,000 to examine the sensitivity of EIS on longer time scales.

231 In the first series of experiments (EXP1), we investigate the effect of SMB changes by increasing surface air
232 temperatures. During the last deglaciation (21 – 8 ka), the mean annual global surface air temperature increased
233 by $4.5^{\circ} \pm 0.9^{\circ}$ (Annan et al., 2022). In order to simulate a range of anomalies representative of the onset of the last
234 deglaciation, we chose to apply perturbations from 1 to 5 °C to the mean annual GCM forcing fields, without
235 accounting for related changes in precipitation (see Eq 5). The increase in precipitation in response to increased
236 temperatures (Eq. 5) is considered in the second set of experiments (EXP2).

237 The third series of experiments (EXP3) is designed to assess the role of oceanic forcing on the EIS stability.
238 Because the basal melting below the ice shelves depends linearly on the Kt transfer coefficient and is a quadratic
239 function of the oceanic temperatures, we performed two sub-series of experiments by modifying either the Kt
240 values (EXP3.1) without modifying the oceanic temperatures, or by applying perturbations to the oceanic
241 temperatures (EXP3.2). Observations below the Antarctic ice shelves show that the basal melting rate ranges from
242 0 to 35 m yr⁻¹ for oceanic temperatures between -2 °C and 2 °C (Holland et al., 2008). This wide range of basal
243 melting rate values reflects the complexity of such a process that can only be partially represented with simple
244 parameterizations (Eq. 6). The Kt coefficient is thus largely uncertain. Therefore, to investigate changes in the EIS
245 sensitivity to the amplitude of basal melting, we first use a wide range of values for this transfer coefficient, i.e.
246 between 10 and 50 m yr⁻¹°C⁻¹.

247 The mean global sea surface temperature anomaly inferred from the MARGO project (MARGO project members,
248 2009) between the Late Holocene and the LGM is $1.9 \pm 1.8^{\circ}\text{C}$ consistent with the findings ($\sim 2.7^{\circ}\text{C}$) of Tierney et

249 al. (2020). In the early phase of the deglaciation, the ocean warming was probably less than that of the Late
250 Holocene. Therefore, for the EXP3.2 experiments, we first apply perturbations of 0.5°C, 1.0°C, 1.5°C to the
251 oceanic temperatures (same perturbation on all vertical levels) and we fix the K_t coefficient to $7 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$. In the
252 transient simulation of the last deglaciation performed by Liu et al. (2009), large increases in oceanic temperatures
253 are obtained. For example, a +9°C warming is obtained in the BJR sector at 500-600 m ocean depth and almost
254 7.5°C in the SA sector at 400-500 m. To reproduce the large increase in the subsurface ocean temperature obtained
255 in Liu et al. (2009), we performed additional sensitivity experiments with perturbations of 7.5°C and 10°C applied
256 in the entire oceanic column.

257 Atmospheric and oceanic temperatures are the two main factors potentially responsible for the destabilization of
258 marine ice sheets. Thus, the fourth series of experiments (EXP4) combines surface air temperature perturbations
259 ($\Delta T = +2^\circ\text{C}$, $+3^\circ\text{C}$, and $+4^\circ\text{C}$) with basal melting rate perturbations ($K_t = 10, 15$ and $25 \text{ m yr}^{-1} \text{ } ^\circ\text{C}^{-1}$).

260 Finally, in the fifth set of experiments (EXP5), we also explore the EIS sensitivity to sea level. Indeed, sea level
261 rise favors the retreat of the grounding line and is therefore another potential driver of the MISI. At the beginning
262 of the deglaciation, the global sea level increased by more than 10 m (Carlson and Clark, 2012) raising the global
263 sea level from -120 m to -110 m compared to the present-day eustatic sea level. This abrupt change may have
264 played an important role in the destabilisation of the ice sheet. On the other hand, Gowan et al., (2021) shows that
265 the local sea level around the EIS margin displays a significant spread at the LGM, from -70 m to -140 m,
266 compared to the present-day level and can abruptly change in response to variations in the land-ice mass
267 distribution. Consequently, to better explore the EIS sensitivity to both global mean sea level and local sea level
268 at the beginning of the last deglaciation, we apply moderate (-115 m, -110 m, and -105 m) and large (-90 m, -60 m,
269 -30 m, and 0 m) sea level perturbations with respect to the present day.

270 **3. Available ice sheet reconstructions and ice streams signature**

271 **3.1 Ice sheet geometry**

272 The DATED-1 database is based on evidence found in the existing literature and retrieved from various geological
273 materials (e.g., terrestrial plant macrofossils, foraminifera, speleothems, bones...) analyzed with a range of dating
274 methods. Based on these data, the DATED-1 compilation provides three different scenarios for the maximal,
275 minimal and most credible EIS extent. The GLAC-1D, ICE-6G_C, and ANU reconstructions are based on inverse
276 modeling approaches constrained by GPS data, relative sea level and geomorphological data.

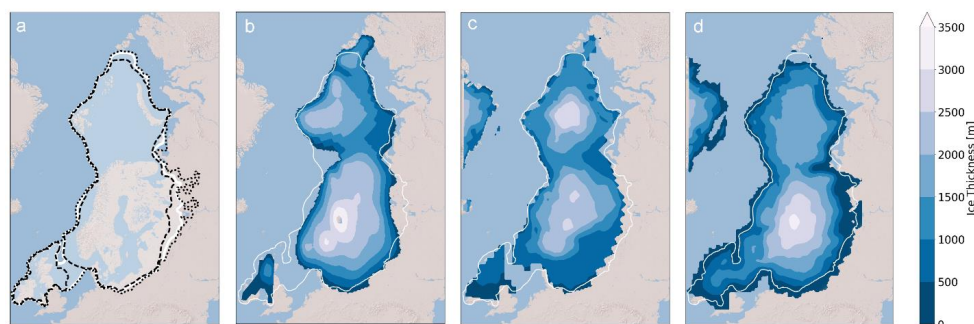

277 The main differences in the three DATED-1 scenarios at the LGM (Hughes et al., 2016) are related to the potential
278 BIIS-FIS connection (or disconnection), the southern continental limit of the FIS and the eastern limit of BKIS
279 (Fig. 2a). Only the minimum scenario suggests the absence of ice between the BIIS and FIS.

280 The GLAC-1D reconstruction agrees well with the most credible DATED-1 scenario, despite a slightly greater ice
281 extent in most of the Fennoscandian regions and a smaller extent in the Taymyr Peninsula (in the easternmost part
282 of the BKIS, Fig. 2d). This contrasts with the ANU and ICE-6G_C reconstructions whose ice limit goes beyond
283 that of the most credible DATED-1 scenario.

284 The differences between the three geologically-constrained reconstructions are due to differences in the inverse
285 methods used to estimate the ice thickness, to the geological and geomorphological data considered to infer the

286 ice extent, and to different choices regarding the Earth rheology. This translates into differences in the altitude of
287 the EIS. For example, in the ANU and GLAC-1D reconstructions, the FIS peaks at 3000-3500 m, while BKIS
288 does not exceed 2500 m (2000 m for GLAC-1D). By contrast, ICE-6G_C provides a larger ice thickness over the
289 BKIS sector (2500-3000 m) than over Fennoscandia.

290

291 **Figure 2:** a/ Ice sheet extent at the LGM derived from the DATED-1 compilation (Hughes et al., 2016). The
292 maximum and the minimum scenarios of the ice extent are represented by the dotted and the dashed lines
293 respectively. b/ Ice thickness at the LGM provided by the ANU reconstruction (Lambeck et al., 1995, 1996, 2010;
294 Abe-Ouchi et al., 2015). c/ Same as b/ for the ICE-6G_C reconstruction (Peltier et al., 2015). d/ Same as b/ for the
295 GLAC-1D reconstruction (Briggs et al., 2014; Tarasov et al., 2012; Tarasov and Peltier, 2002). In the four panels,
296 the white line corresponds to the most credible scenario of the ice extent at the LGM derived from the DATED-1
297 compilation (Hughes et al., 2016).

298 3.2 Ice stream signature

299 Ice streams also play a key role in ice sheet dynamics and in featuring ice sheet geometry (Pritchard et al., 2009).
300 It is therefore crucial that the dynamics of the simulated ice sheets is consistent with reconstructions. The signature
301 of ice streams can be inferred from geomorphological observations in the Barents Sea, in particular those of the
302 Bjornoyrenna (BJR) and Svyataya Anna (SA) ice streams (Fig. 1) (Polyak et al., 1997; Andreassen and
303 Winsborrow, 2009; Dowdeswell et al., 2016,2021; Szuman et al., 2021). Other geomorphological observations
304 strongly suggest the existence of paleo ice streams in the FIS, such as the Mid-Norwegian (MN) ice stream (Stokes
305 and Clark, 2001), and the Norwegian Channel (NC) ice stream between the FIS and BIIS (Sejrup et al., 1994;
306 Svendsen et al., 2015; Stokes and Clark, 2001).

307 4. Results

308 4.1 LGM equilibrium

309 At the end of the 100 000-year spin-up simulations, a wide range of ice sheet geometries is obtained (Fig. 3).
310 Simulations performed with CNRM-CM5, MRI-CGM3 and MIROC-ES2L do not succeed in building an ice sheet
311 over Eurasia.

312 This is primarily explained by high positive summer surface air temperatures simulated by the three models in
313 most parts of the EIS compared to the other models, with temperature anomalies ranging between +4.7°C and

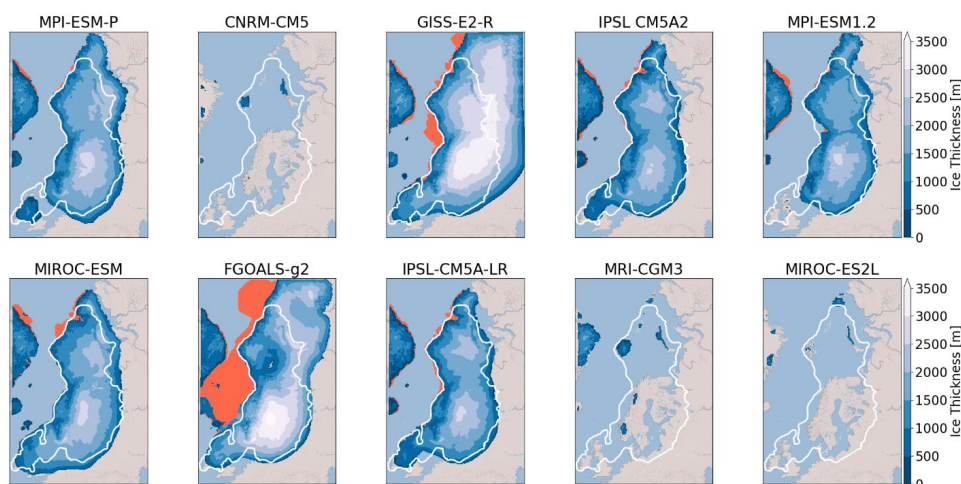

314 +11.7°C (Fig. 4). Conversely, with the GISS-E2-R and FGOALS-g2 models, significant ice thickness is built east
315 and south of BKIS because of strong negative mean summer temperatures in this area (Fig. 4).

316 Therefore, we discarded these models and only selected those (MPI-ESM-P, MIROC-ESM, IPSL-CM5A2, IPSL-
317 CM5-LR, and MPI-ESM1.2) providing ice sheet geometries in a relatively good agreement with the
318 reconstructions.

319 The five selected ice sheets do not show significant differences (Fig 3). The FIS peaks at 2500-3000 m, while the
320 BKIS is lower (2000 – 2500 m) due to a drier atmosphere compared to that overlying the Fennoscandian region
321 (Fig. 5). The simulated FIS agrees with the ICE-6G_C reconstruction despite a flatter dome simulated with MPI-
322 ESM-P, about 500 m lower compared to GLAC-1D and ANU. Conversely, the BKIS maximum altitude simulated
323 by GRISLI is underestimated compared to ICE-6G_C while it is in good agreement with the two other
324 reconstructions. The BKIS margins bordering the Greenland and Norwegian Seas and the Arctic Ocean generally
325 match with the most credible DATED-1 scenario of the ice extent. However, in the five GRISLI simulations, the
326 ice extent is too large in the eastern and southern edges compared to DATED-1.

327 The most likely cause of this mismatch is related to the imprint of the ice sheet reconstructions used as boundary
328 conditions of GCM simulations. Indeed, both the ice sheet reconstruction used for PMIP3 simulations (not shown)
329 and ICE-6G_C (Fig. 2c) used in PMIP4 runs overestimate the ice extent in the region of the Taimyr Peninsula.
330 This results in an enhanced cooling favoring the simulated ice expansion in this area. This effect can be amplified
331 by the projections of the ice sheet reconstructions on the coarser GCM grid that may produce an artificial spread
332 of the ice sheet mask, causing further a too extended cooling. Another source of disagreement between DATED-
333 1 and the simulated ice sheets can be due to the representation the jet stream and planetary waves in the coarse
334 resolution climate models, such as the PMIP models. Indeed, such large-scale atmospheric features directly impact
335 the simulated precipitation and temperatures and may cause too much precipitation or too much cooling if
336 improperly represented (Löfverström and Liakka, 2018).

337

338 **Figure 3:** Ice thickness at the end of the 100 000-year simulation for the different GCMs used as forcing of the

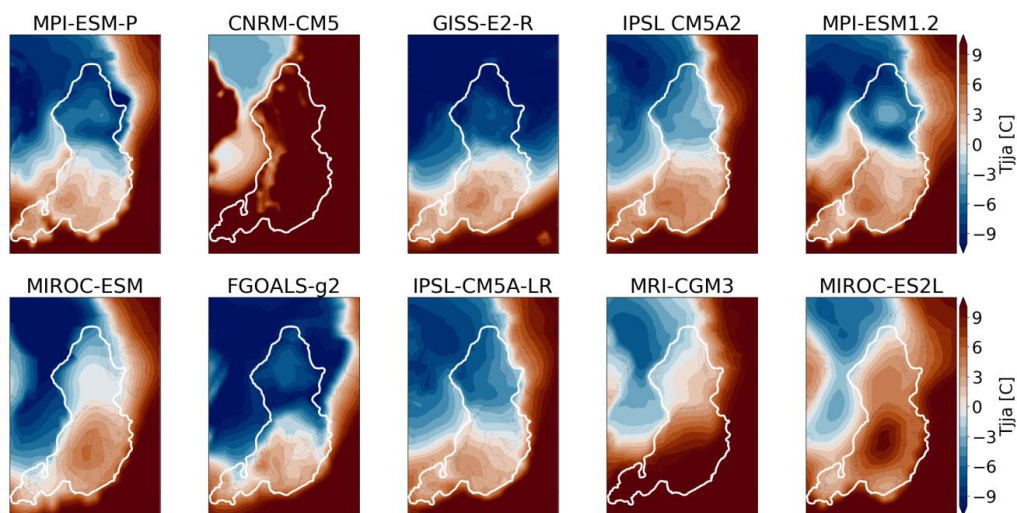

339 GRISLI ice sheet model. The white line is the most credible extent derived from the DATED-1 compilation and
340 the orange shaded areas are the simulated ice shelves.

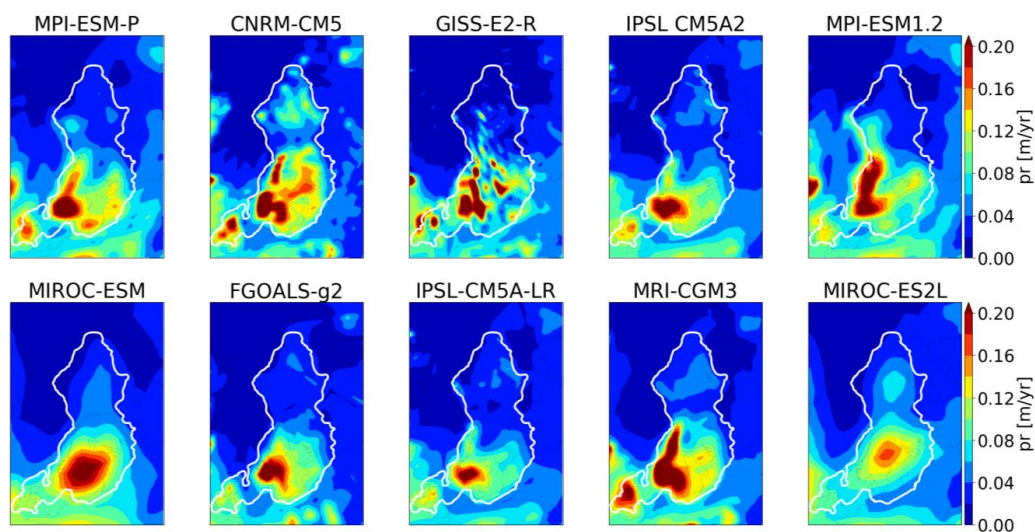

341 For the five selected GCMs, areas with high ice velocities are simulated in the BKIS region (Fig. 6). The highest
342 velocities are obtained for the SA, BJR, NC and MN ice streams and can exceed 1000 m yr^{-1} . In addition, the BJR
343 ice stream shows a large extension from the center of BKIS, with velocities between 75 to 200 m yr^{-1} , to the edge
344 of BKIS. The location of the main fast flowing areas is consistent with empirical evidence based on observations
345 of submarine landforms (Dowdeswell et al., 2016; Stokes and Clark, 2001). It is also interesting to mention that
346 ice velocities of similar magnitude in the present-day Antarctic and Greenland ice sheets have been revealed thanks
347 to radar observations (Solgaard et al., 2021; Mougnot et al., 2019).

348 Overall, our five remaining simulated ice sheets show a reasonable agreement with the different reconstructions
349 constrained by geological and geomorphological observations, both in terms of ice extent and ice thickness as well
350 as dynamical characteristics. The observed differences with the reconstructions remain within the range of
351 uncertainties, which is itself illustrated by the differences between the three reconstructions GLAC-1D, ANU and
352 ICE-6G_C and by the three ice extent scenarios from the DATED-1 compilation.

353 This allows us to use the five spin-up GRISLI experiments (forced by MPI-ESM-P, MIROC-ESM, IPSL-CM5A2,
354 IPSL-CM5-LR, and MPI-ESM1.2) as a starting point to test the sensitivity of the EIS to atmospheric, oceanic and
355 sea level forcings.

356
357 **Figure 4:** Mean summer (JJA) surface air temperature at 21 ka simulated by each GCM at the sea level and
358 interpolated on the GRISLI grid. The white line represents the ice extent as defined by the most credible DATED-
359 1 scenario.

360
361 **Figure 5:** Same as Figure 4 for the mean annual precipitation.

362
363 **Figure 6:** Simulated ice velocities at the end of the 100 000-year LGM simulation. The solid white line represents
364 the most credible ice extent from the DATED-1 compilation.

365 4.2. Sensitivity experiments

366 In the following, we investigate the sensitivity of the Eurasian ice sheet to the potential drivers of ice sheet retreat:
367 atmospheric changes responsible for SMB changes (i.e., temperature and snow accumulation to the first order),
368 oceanic changes (sub-shelf melt rate) and sea level changes.

369 4.2.1 EXP1: Surface air temperature

370 The aim of this section is to investigate the sensitivity of EIS to a temperature rise. For each temperature
371 perturbation ($T_{\text{add}} = 1$ to 5°C) applied uniformly on the monthly mean surface air temperatures, Figure 7 displays
372 for the multi-model mean the percentage of the ice thickness lost after 1000 years with respect to the initial
373 configuration. The results are plotted for the largest ice sheet mask. This mask corresponds to all areas where ice
374 has been simulated in at least one of the 5 simulations. This means that multi-model means are computed with 1,
375 2, 3, 4 or 5 models involved, depending on the ice sheet mask of each individual model.

376 For $T_{\text{add}} = 1\text{ }^{\circ}\text{C}$, the response of the Eurasian ice sheets is weak, except for the British Isles sector (Fig 7) for which
377 mean JJA temperatures of the five selected GCMs are close to the melting point (Fig. 4). Substantial ice losses are
378 also simulated in the FIS margins for temperature rise greater than $1\text{ }^{\circ}\text{C}$ leading to a progressive retreat of the edge
379 of the ice sheet as the temperature increases. The sensitivity of the BIIS and FIS regions to these temperature
380 perturbations is explained by a shift from positive to negative SMB values when temperature increases (Fig. SP2).
381 By contrast, as the BKIS is located in colder areas, larger temperature perturbations ($3\text{ to }5\text{ }^{\circ}\text{C}$) are necessary to
382 initiate the ice sheet's retreat. The southern BKIS margin appears the most sensitive region, followed by the region
383 of the SA ice stream. In the SA sector, ice thickness losses between 30 % ($T_{\text{add}} = +3^{\circ}\text{C}$) to 50 % ($T_{\text{add}} = +5^{\circ}\text{C}$)
384 are obtained. In the BJR sector, ice losses are only simulated for large temperature perturbations.

385 However, it is worth mentioning that for a given temperature perturbation, significant differences in the behavior
386 of the five simulated ice sheets can be observed. To illustrate these differences, we plotted for each simulation, the
387 percentage of the ice thickness lost after 1000 years with respect to the initial configuration (Fig SP3). The most
388 sensitive regions to surface air temperature, namely the FIS margins and the SA/BJR sectors, are the locations
389 where inter-model differences in ice thickness losses are the most significant and are amplified with temperature
390 increase. In the BJR sector, the retreat of the ice sheet is simulated for perturbations of 4°C with three GCM
391 forcings (MIROC-ESM, IPSL-CM5A-LR and IPSL-CM5A2, Fig SP3), while this sector is stable with the two
392 other forcings (MPI-ESM-P and MPI-ESM1.2) under this temperature perturbation. In the SA sector, the MIROC-
393 ESM-P forcing produces a retreat from a temperature anomaly of 2°C , but for the IPSL-CM5A-LR and IPSL-
394 CM5A2 forcings the retreat is only triggered for $T_{\text{add}} = 3\text{ }^{\circ}\text{C}$. By contrast, the two versions of the MPI-ESM
395 produce a more stable ice sheet in the SA sector since, even with a $5\text{ }^{\circ}\text{C}$ temperature perturbation, the ice retreat
396 is not triggered within the 1000 years of simulation.

397 The lower sensitivity of BJR sector, compared to the SA sector, can be explained (at least partly) by the topography
398 differences between these two regions. Actually, the initial topography of each GCM (not shown) exhibits a trough
399 in the SA sector which does not appear in the region of the BJR ice stream. The lower surface topography in the
400 SA sector is accompanied by higher surface temperatures and thus to larger ice losses when temperature
401 perturbations are applied (Fig. SP3). Moreover, the difference in the sensitivity of the BJR and SA sectors can be
402 also explained by the higher precipitation rate in the BJR sector (between $0.2\text{ to }0.5\text{ m yr}^{-1}$ for the BJR ice stream
403 and less than 0.2 m yr^{-1} for the SA sector, Fig. 5), which can partly counteract the effect of temperature increase
404 on ice mass loss.

405
406 **Figure 7:** Multi-model mean of the ice thickness lost after 1000 GRISLI model years in the EXP1 experiments
407 with respect to the ice thickness of the LGM ice sheet (red: 100% lost). The results are plotted on the largest ice

408 sheet mask. The white line corresponds to the common ice sheet mask of the five models, i.e., where the multi-
409 model mean is computed on the 5 models.

410 To better understand the effect of precipitation on the EIS stability, the EXP2 combines the precipitation and
411 surface air temperature perturbations. The results obtained in the EXP2 experiments are shown in figure SP4. For
412 BIIS and FIS, a similar behavior to EXP1 is observed, albeit with less ice melt due to increased accumulation as a
413 result of increased temperatures. On the contrary, in EXP2, a large difference with EXP1 is simulated for BKIS,
414 where only the ice sheet margins show sensitivity to increased temperature and precipitation. While an inland ice
415 loss between 20% and 50% was simulated in EXP1 in some places, it is generally limited to less than 10% in
416 EXP2. This result shows the significant role of precipitation to counteract the ice loss due to an increase in surface
417 air temperature.

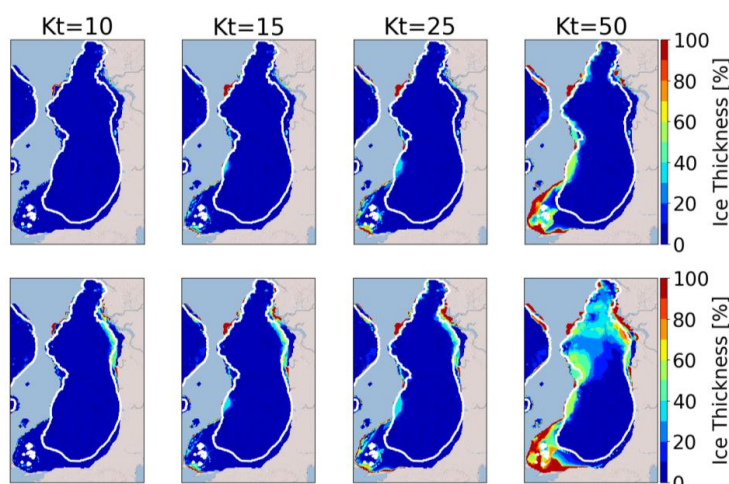

418 **4.2.2 EXP3: Basal melting**

419 Besides changes in SMB, another factor that can destabilize a marine ice sheet is the basal melting under the ice
420 shelves (Pritchard et al., 2012). In the LGM experiments, the numerical K_t value is fixed to $7 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ and leads
421 to basal melting rates in the BJR and SA sectors of 3.1 m yr^{-1} and 0.7 m yr^{-1} respectively. To investigate the effect
422 of increased basal melting that likely occurred during the last deglaciation as a response of increased ocean
423 temperatures, we performed sensitivity experiments by first changing the K_t value (EXP3.1). The sensitivity to
424 oceanic temperatures (EXP3.2) will be discussed later.

425 Figure 8 displays the percentage of ice thickness losses (with respect to the initial configuration) for K_t ranging
426 from $10 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ to $50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$. After 1000 years of simulation, no change in ice thickness is observed for K_t
427 $= 10 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$. For higher K_t values ($15 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ and $25 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$), ice losses between 30% to 40% are
428 simulated in the MN ice stream sector, and 100% of the ice shelf in the south of SA sector is melted (see Fig 3
429 showing the presence of ice shelves at the end of the spin-up experiment). This corresponds to basal melting rates
430 (multi-model mean) near the grounding line ranging from 7.5 m yr^{-1} ($K_t = 15 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$) to 10.4 m yr^{-1} ($K_t = 25$
431 $\text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$) in the MN sector and from 1.7 m yr^{-1} ($K_t = 15 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$) to 2.9 m yr^{-1} ($K_t = 25 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$) in the SA
432 sector. However, these changes are restricted to small areas, and the ice loss is not significant enough to firmly
433 indicate a noticeable sensitivity to basal melting. Perturbations with K_t values above $25 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ are necessary
434 to observe significant changes in the EIS configuration. In particular, for $K_t = 50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$, the ice is entirely
435 melted near the BIIS margins, and less than 50% of the ice remains in the regions of MN, SA and BJR ice streams.
436 Nonetheless, only the simulations forced by MPI-ESM-P, MPI-ESM1.2 and MIROC-ESM show a sensitivity to
437 basal melting in BJR, MN and SA sectors (Fig. SP5). Depending on the GCM forcing, the simulated basal melting
438 values range between 25.7 and 28.7 m yr^{-1} , 24.4 and 28.2 m yr^{-1} and between 11.2 and 13.4 m yr^{-1} for the BJR,
439 MN and SA sectors respectively. By contrast, very small values are obtained with IPSL-CM5A2 (0.2 m yr^{-1} to 0.5
440 m yr^{-1}) and IPSL-CM5A-LR models (0.5 m yr^{-1}). This can be explained by the cold oceanic temperatures near the
441 BJR sector compared to those simulated by the three other GCMs (Fig SP6). These results show that the basal
442 melting has the ability to destabilize the BKIS when it exceeds a certain threshold. Results inferred from the
443 simulations forced by MPI-ESM-P, MPI-ESM1.2 and MIROC-ESM suggest that this threshold is obtained for K_t
444 values between 25 and $50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$, corresponding to basal melting rates at the grounding line between 10.4
445 m yr^{-1} and 28.7 m yr^{-1} for the BJR sector and between 6.2 and 13.4 m yr^{-1} for the SA sector. By comparison, a basal
446 melting rate of 22 m yr^{-1} has been observed thanks to radar measurements in the mouth of the Mercer/Whillans Ice

447 Stream located in the West Antarctic ice sheet (Marsh et al., 2016). Providing that K_t values are greater than 25 m
448 $^{\circ}\text{C}^{-1} \text{yr}^{-1}$ (or close to 50 m $^{\circ}\text{C}^{-1} \text{yr}^{-1}$), the region of the BJR ice stream responds to basal melting perturbations with
449 basal melting rates similar to those observed in some parts of WAIS. However, the ice loss is restricted to the very
450 edge of the ice sheet and the BKIS retreat is negligible. This raises the question as to whether the basal melting
451 exerts a stronger influence on longer time scales. Therefore, we also investigated the ice sheet behavior after 10 000
452 model years.

453

454 **Figure 8:** Multi-model mean of the ice thickness lost after 1000 (top) and 10 000 (bottom) GRISLI model years
455 in the EXP3.1 experiments with respect to the ice thickness of the LGM ice sheet. (red: 100% lost). The white line
456 corresponds to the common ice sheet mask of the five models, i.e., where the multi-model mean is computed on
457 the 5 models.

458 A similar behavior is observed after 10 000 years for K_t between 10 and 25 m $^{\circ}\text{C}^{-1} \text{yr}^{-1}$, with the exception of the
459 southern part of BKIS bordering the Kara Sea where a 30% to 50% ice thickness decrease, with respect to the
460 initial one, is obtained. For $K_t=50$ m $^{\circ}\text{C}^{-1} \text{yr}^{-1}$, more than 40% of ice loss is simulated for BKIS, and up to 60% in
461 the BJR sector. As previously mentioned, this large ice thickness decrease in the center of BKIS is highly GCM-
462 dependent, and is only observed in simulations forced by the MIROC and MPI models (Fig. SP5

463 As the basal melting parameterization is expressed as a quadratic function of the oceanic temperatures, we may
464 expect a different sensitivity of EIS when the oceanic temperatures increase (EXP3.2). Results of the EXP3.2
465 experiments are shown in figure SP7. Perturbations of oceanic temperatures between +0.5 $^{\circ}\text{C}$ and +1.5 $^{\circ}\text{C}$ lead to
466 basal melting rates at the grounding line of the BJR sector of less than 3.8 m yr^{-1} . This is well below the threshold
467 suggested by the results of the EXP3.1 experiments (between 10.4 and 30 m yr^{-1}), and no significant ice loss is
468 simulated after 10 000 years of simulation.

469 For larger perturbations (+7.5 $^{\circ}\text{C}$ and +10 $^{\circ}\text{C}$), larger values of the basal melting rates are obtained in the BJR (11.6
470 and 17.5 m yr^{-1}), in the SA (10.8 and 15.6 m yr^{-1}) and in the MN sectors (11.5 and 17.4 m yr^{-1}) after 10 000 model
471 years. A perturbation of 7.5 $^{\circ}\text{C}$ does not trigger the ice retreat because of a too low basal melting. By contrast, when
472 the perturbation reaches +10 $^{\circ}\text{C}$, a similar behavior to that simulated with $K_t=50$ m $^{\circ}\text{C}^{-1} \text{yr}^{-1}$ (EXP3.1) is obtained.

473 On the other hand, for simulations forced by IPSL-CM5A2 and IPSL-CM5A-LR, an increase in oceanic
474 temperatures of +10°C allows us to observe a sensitivity of BKIS in the SA sector (see Fig SP8) after 1000 years
475 of simulations, which leads to a total retreat of the eastern part of BKIS after 10000 years.

476 These results show that the BJR, MN and SA regions are sensitive to sub-shelf melting providing that the basal
477 melt exceeds a certain threshold obtained for Kt values greater than 25 m °C⁻¹ yr⁻¹ (and greater than 10 m °C⁻¹ yr⁻¹
478 ¹ for the MN sector) or for a rise in oceanic temperature greater than 7.5°C. From the combination of EXP3.1 and
479 EXP3.2 experiments, it appears that the threshold is between 11.6 m yr⁻¹ and 17.5 m yr⁻¹ for the BJR sector,
480 between 6.2 and 13.4 m yr⁻¹ for the SA sector and lower than 7.5 m yr⁻¹ for the MN sector. Moreover, our results
481 also suggest that the large retreat of one single ice stream has the ability to favor the total retreat of the whole of
482 BKIS

483 **4.2.3 EXP4: Combined effects of basal melting and surface air temperatures**

484 Results presented in the previous section suggest that sub-shelf melting has only a poor impact on the EIS
485 destabilization for Kt perturbations below a certain threshold estimated to lie between 25 and 50 m °C⁻¹ yr⁻¹, or
486 below a +10°C increase of oceanic temperatures. However, increases in surface melting due to atmospheric
487 warming may lead to changes in the geometry of the grounded ice sheet and floating ice shelves. In turn, changes
488 in the EIS configuration may alter the EIS sensitivity to basal melting. To test this hypothesis, we combined surface
489 air temperature perturbations with basal melting perturbations (EXP4) and compared the results with those of the
490 EXP1 experiments. Figure 9 displays the difference in the total BKIS ice volume after 1000 years between EXP4
491 and EXP1 experiments ($\Delta V_{4,1}$) for different surface atmospheric temperature perturbations ($\Delta T = +2^\circ\text{C}$, $+3^\circ\text{C}$ and
492 $+4^\circ\text{C}$) and Kt values fixed to 25 and 50 m °C⁻¹ yr⁻¹ (negatives values are associated to a greater ice loss in EXP4
493 than in EXP1). For both Kt perturbations (Kt = 25 and 50 m °C⁻¹ yr⁻¹), no significant difference in the $\Delta V_{4,1}$ values
494 (computed for the different ΔT perturbations) is observed in simulations forced by IPSL-CM5A2 and IPSL-
495 CM5A-LR. This illustrates the poor sensitivity of BKIS to basal melting with the IPSL climate forcings. As
496 explained in section 4.2.2, this low sensitivity is due to the cold oceanic temperatures simulated in both IPSL
497 models (see Fig. SP6). For the three other simulations (forced by MIROC-ESM, MPI-ESM-P, and MPI-ESM1.2),
498 the ice volume difference is clearly amplified with higher ΔT levels, especially when the Kt transfer coefficient is
499 higher. For example, for Kt=50 m °C⁻¹ yr⁻¹, the difference in $\Delta V_{4,1}$ values between the initial ice sheet configuration
500 ($\Delta T = 0^\circ\text{C}$) and $\Delta T = 4^\circ\text{C}$ is ~60 000 km³ with MPI-ESM-P, against ~20 000 km³ when Kt=50 m °C⁻¹ yr⁻¹. A
501 similar behavior is observed for simulations forced by MIROC-ESM (~110 000 km³) and MPI-ESM1.2 (~60 000
502 km³). To better illustrate the impact of the combination of both temperature and basal melting perturbations, we
503 plotted the evolution of ice loss every 1kyr as simulated in the EXP1 ($\Delta T = +4^\circ\text{C}$), EXP3 (Kt=50 m °C⁻¹ yr⁻¹) and
504 EXP4 experiments in figures SP9 to SP11. For the simulation forced by MIROC-ESM (Fig. SP11), the largest part
505 of the deglaciation signal is dominated by increased atmospheric temperatures in the EXP4 (see Fig SP11).
506 Simulations forced by MPI-ESM-P and MPI-ESM1.2 have a different behaviour (Figs SP9 and SP10) and show a
507 significant difference between EXP1 and EXP4 and between EXP3 and EXP4. In the EXP3 experiment, the SA
508 sector appears to be highly sensitive, mainly due to high ocean temperatures (> 3°C, see fig SP6) in contrast to the
509 BJR sector where only a part has deglaciated after 10 000 years. However, in the EXP4 experiment, in which near-
510 surface temperature and basal melting are combined, BKIS starts to retreat after 1000 years and has almost entirely

511 melted after 10 000 years. This suggests that the BKIS deglaciation is initially triggered by surface warming but
512 is further amplified by basal melting.

513

514

515 **Figure 9:** Differences of the ice volume lost between EXP4 and EXP1 ($\Delta V_{4,1}$) after 1000 years for $K_t=25 \text{ m } ^\circ\text{C}^{-1}$
516 yr^{-1} (left) and $K_t=50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ (right).

517 **4.2.5 Exp5: Sea level**

518 In the previous simulations, the sea level forcing was fixed to -120 m (with respect to the present-day eustatic sea
519 level), corresponding to the estimated eustatic level at the LGM (Peltier et al., 2002). In this series of experiments,
520 we quantify the sensitivity of the EIS to different sea level forcings.

521 The multi-model mean difference between the ice thickness after 1000 GRISLI model years and the initial ice
522 thickness (sea level = -120 m) is displayed in Figure 10 for the different sea level elevations ranging from -115 m
523 to 0 m. After 1000 years of simulation, for sea levels ranging from -115 m to -105 m, no significant differences
524 are observed with respect to the reference simulation (i.e., -120 m). For larger perturbations, the MNIS sector
525 appears to be the most sensitive. As an example, for a sea level of -90 m, an ice loss of ~40 % is simulated in this
526 area, and an almost complete retreat is obtained for a sea level higher than -60m, with an ice thickness decrease of
527 up to 80%-100%. Although sea level elevations of -90 m and -60 m are considerably larger than the global mean
528 sea level at the LGM, they are consistent with the local sea level variations that could be as high as -70 m as
529 suggested by Gowan et al. (2021). However, for the other sectors (BJR, SA, NCIS), ice thickness decrease is only
530 obtained for sea levels higher than -30 m which is largely out of the range advanced by Gowan et al. (2021). As a
531 result, this series of experiments suggest that the elevation of sea level has only played a marginal role at the
532 beginning of the EIS deglaciation.

533

534 **Figure 10:** Multi-model mean of the ice thickness lost after 1000 model years in the EXP5 with respect to the ice
535 thickness of the LGM ice sheet. (red: 100% lost). The white line corresponds to the common ice sheet mask of the
536 five models, i.e., where the multi-model mean is computed on the 5 models.

537 5. Discussion

538 The results of our experiments suggest that the EIS ice sheet is very sensitive to the atmospheric warming that may
539 have occurred at the beginning of the last deglaciation. By contrast, basal melting does not seem to be a key process
540 for triggering the retreat of the ice sheet. However, once the retreat has been initiated by the atmospheric warming,
541 basal melting has the capability of accelerating the retreat, as supported by the results of EXP4, providing that the
542 amount of basal melting is high enough. Nevertheless, these conclusions are strongly dependent on the ice-shelf
543 configurations. Indeed, unconfined ice shelves do not exert an efficient buttressing effect (i.e. the stress that the
544 ice shelves exert at the grounding line) and their removal has almost no impact on the dynamics of the grounded
545 ice sheet (Gundmundsson et al., 2013, Fürst et al., 2016). By contrast, thinning of confined ice shelves through
546 basal melting produce a weakening of the buttressing effect, implying an acceleration of the grounded ice streams
547 and ultimately a substantial ice discharge in the ocean. This sequence of events was observed in the Antarctic
548 Peninsula after the collapse of the Larsen B Ice Shelf in 2002 (Rignot et al., 2004; De Rydt et al., 2015). Moreover,
549 using a high-resolution ice sheet model (500 mx500 m near the grounding line), Gandy et al. (2018) showed the
550 significant impact of the melting of confined ice shelves on the destabilization of ice streams in Northwest Scotland
551 during the last deglaciation. In our study, the extent of the confined ice shelves in the simulated EIS at the end of
552 the spin-up experiments is very small (Fig. 3). This likely explains why the EIS appears poorly sensitive to basal
553 melting and why strong perturbations of the K_t coefficient or oceanic temperatures are required to simulate ice-
554 shelf thinning in the regions of the main ice streams.

555 The small sensitivity to the oceanic forcing simulated in the EXP3 experiments contradicts the conclusions of
556 previous modeling studies of the EIS behavior during the last glacial period (Alvarez-Solas et al., 2019) and the
557 last deglaciation (Petrini et al., 2020). Both conclude that oceanic temperatures are the main driver of the EIS
558 destabilization. Their findings are all the more surprising as they both use an ice-sheet model (GRISLI1.0) similar
559 to ours (GRISLI2.0). However, several differences can be noticed between their modeling approach and that of
560 the present study. First, GRISLI1.0 does not include a parameterization of the ice flux at the grounding line.
561 Therefore, it should be easier with our model to trigger the EIS retreat through basal melting because GRISLI2.0
562 includes key processes to simulate the marine ice sheet instability. To verify this issue, we performed additional
563 simulations similar to the EXP3 ones by removing the grounding line flux parameterization, and as expected,
564 results clearly show that the removal of this parameterization limits the ice loss (not shown). One of the most likely
565 explanation of the disagreement between our findings and those of previous studies (Alvarez-Solas et al., 2019;
566 Petrini et al., 2020) relies on the procedure followed in the spin-up experiments. Both built their initial state in the

567 same way. To favor the EIS build-up, they fixed the basal melting to 0.1 m yr^{-1} during their ice sheet spin-up.
568 Starting from the EIS configuration obtained at the end of the spin-up experiment, they used a linear (Alvarez-Solas
569 et al., 2019) or quadratic (Petrini et al., 2020) basal melting parameterization depending on oceanic temperature to
570 simulate the last glacial period (Alvarez-Solas et al., 2019) or the last deglaciation (Petrini et al., 2020) of EIS. In
571 doing so, there is a methodological inconsistency between the spin-up simulation and the subsequent experiments.
572 To investigate the effect of such inconsistency on the EIS deglaciation, we followed their spin-up methodology
573 (homogeneous basal melting) instead of the one described in Section 2.3. The resulting LGM ice sheets resemble
574 those presented in Sec. 3.1, except that the MIROC-ESM forcing produces large ice shelves in the Greenland and
575 Norwegian seas. We then applied the same perturbations as in EXP3 on these alternative ice sheets with a basal
576 melting parameterization depending on the oceanic temperature and salinity (see Eq7). We display in figure 11 the
577 percentage of ice thickness lost after 10000 years with respect to the initial configuration for K_t ranging from 15
578 to $50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$ for this new series of experiments. Compared to EXP3, we show that the EIS now presents a
579 much more significant sensitivity in the BIIS and FIS for a perturbation of $K_t=50 \text{ m } ^\circ\text{C}^{-1} \text{ yr}^{-1}$. These results illustrate
580 the extent to which the conclusions drawn for the driving mechanisms of the EIS destabilization are strongly
581 dependent on the initial state. However, we argue that the approach followed in the present paper is more consistent
582 as the basal melting parameterization is exactly the same for the spin-up procedure and the sensitivity experiments.

583 Finally, another difference that deserves to be mentioned is that Petrini et al. (2020) used a climate index (based
584 on the transient simulation of Liu et al., (2009). This method ensures that both the atmospheric and oceanic
585 temperatures increase concomitantly to their pre-industrial levels. As a result, we cannot exclude that the key role
586 of basal melting in their simulated deglaciation is not amplified by the effect of atmospheric warming, similarly to
587 the conclusions drawn from our EXP4 results.

588

589 **Figure 11:** Multi-model mean of the ice thickness loss compared to the initial ice sheet for different basal melting
590 perturbations. LGM ice sheets are built by fixing the basal melting to 0.1 m yr^{-1} (as in Petrini et al., 2020; Alvarez-
591 Solas et al., 2019). Note that the significant decrease in ice thickness in the Norwegian and Greenland seas is due
592 to the simulation of ice shelves in the new spin-up for the MIROC-ESM forcing (see Fig. SP12). These ice shelves
593 are extremely sensitive to a change in the basal melt. The white line indicates the areas where the multi-model
594 mean is done on the 5 models.

595 6. Conclusion

596 In this paper, we used off-line GRISLI2.0 simulations forced by PMIP3/PMIP4 models to investigate the key
597 mechanisms driving the retreat of the Eurasian ice complex at the beginning of the last deglaciation. We gave a
598 special attention to the understanding of the processes responsible for the destabilization of the marine-based parts

599 of the Eurasian ice sheets as GRISLI2.0 includes and explicit calculation of the ice flux at the grounding line which
600 is expected to account for the representation of the marine ice sheet instability. We first showed that, due to too
601 strong climate biases in some GCMs at the LGM, only 5 out of 10 GCMs succeeded in building an ice sheet in
602 agreement with the reconstructions.

603 The sensitivity experiments have been designed to test the response of the simulated Eurasian ice sheets to surface
604 climate, oceanic temperature and sea level perturbations. Our results highlight the high EIS sensitivity to a change
605 in surface atmospheric temperatures. While basal melting does not seem to be the main driver of the ice sheet
606 retreat, we showed that its effect is clearly amplified by the atmospheric warming.

607 These results contradict those of previous studies mentioning the central role of the ocean on the deglaciation of
608 BKIS. However, we argue that parts of this disagreement are related to the way the climatic forcing is done
609 (absolute climatic fields, anomalies or climatic indexes) and the procedure followed for building the initial state
610 of EIS and to the presence of confined or unconfined ice shelves at the LGM.

611 This study highlights several differences regarding the respective behaviors of the Eurasian ice sheet during the
612 last deglaciation and the present-day West Antarctic ice sheet. While EIS appears primarily sensitive to the
613 atmospheric forcing, WAIS is mainly driven by dynamic ice discharges triggered by the ocean warming. In
614 addition, WAIS is characterized by large areas of confined ice shelves exerting a buttressing effect on the grounded
615 ice whereas most of the ice shelves in our simulated LGM EIS are unconfined. However, as temperatures rise in
616 the future, larger amounts of meltwater will be produced on the surface of the ice shelves (Kittel et al., 2021),
617 favouring potentially the ice-shelf disintegration through hydrofracturing (Banwell et al., 2013; Lai et al., 2020).
618 Although, this process differs from basal melting, it could bring WAIS into a similar configuration to the past
619 Eurasian ice sheet.

620 **Data availability.** The source data of the experiments presented in the main text of the paper are available on the
621 Zenodo repository with the digital object identifier <https://doi.org/10.5281/zenodo.7528183> (van Aalderen et al,
622 2023).

623 **Author contributions.** All authors designed the study. VVA performed the numerical experiments. All authors
624 contributed to the analysis of model results. VVA and SC wrote the manuscript with inputs from CD and AQ.

625 **Competing interests.** The authors declare that they have no conflict of interest

626 **Acknowledgements.** Victor van Aalderen is funded by the French National Research Agency (Grant: ANR-19-
627 CE01-15). We acknowledge the World Climate Research Programme's Working Group on Coupled Modelling,
628 which is responsible for the Paleoclimate Modelling Intercomparison Project (PMIP) and we thank the climate
629 modeling groups (listed in Table 1 of this paper) for producing and making available their model output. This work
630 benefited from productive exchanges with N. Jourdain and D. Swingedouw.
