## 46 Abstract

47  
48 The accurate identification of elemental carbon (EC) source in aerosol based on  
49 radiocarbon ( $^{14}\text{C}$ ) depends on the method of EC **isolation**. The lack of aerosol EC  
50 reference materials with "true"  $^{14}\text{C}$  values makes it impossible to evaluate the  
51 accuracy of various methods for the analysis of  $^{14}\text{C}$ -EC in aerosols. In this study, EC  
52 **isolation** methods were evaluated by using samples of mixed biomass burning, vehicle  
53 exhaust and coal-combustion. The results show that  $^{14}\text{C}$ -EC was not only related to  
54 the **isolation** method but also to the types and proportions of biomass sources in the  
55 sample. The **hydropyrolysis (Hypy)** method, which can be used to **isolate** a highly  
56 stable portion of  $\text{EC}_{\text{Hypy}}$  and avoid charring, is a more effective and stable approach  
57 for the matrix-independent  $^{14}\text{C}$  quantification of EC in aerosols. The  $^{13}\text{C}$ - $\text{EC}_{\text{Hypy}}$  and  
58 non-fossil  $\text{EC}_{\text{Hypy}}$  values of SRM1649b **were** -24.9‰ and 11‰, respectively.  
59  
60  
61

## 62 1. Introduction

63  
64 The elemental carbon (EC) or black carbon (BC) fraction of carbonaceous aerosols  
65 (CAs) is derived from the incomplete combustion of fossil fuels or biomass and is  
66 responsible for an overall warming effect of the Earth by either absorbing incoming  
67 solar radiation in the atmosphere or reducing the albedo of surface materials (i.e.,  
68 snow and ice) (Fuzzi et al., 2006; Schwarz et al., 2015; Szidat, 2009; Szidat et al.,  
69 2004a; Szidat et al., 2009). The limited understanding of EC aerosol emissions **results**  
70 **in** poorly constrained **estimates of their contribution to** anthropogenic climate  
71 warming that globally may be second only to  $\text{CO}_2$  and regionally, such as over East  
72 Asia, the dominant driver of climate change (Chen et al., 2013). Therefore, detailed  
73 knowledge of the sources of EC is necessary for the implementation of mitigation  
74 strategies for EC reduction. Carbon isotope ( $^{14}\text{C}$  and  $^{13}\text{C}$ ) analysis is a powerful tool  
75 for unambiguously distinguishing the carbon sources of EC (Currie, 2000; Szidat,  
76 2009; Szidat et al., 2009; Gustafsson et al., 2009; Kirillova et al., 2013; Liu et al.,  
77 2013; Zencak et al., 2007; Zhang et al., 2019b). Carbon isotope source apportionment  
78 requires the physical **isolation** of **organic carbon (OC)** and EC, which is complicated  
79 by the fact that there is no sharp boundary between **OC** and EC in carbonaceous  
80 aerosols (Elmquist et al., 2006). Therefore, one of the large challenges of this method  
81 is the **isolation** of EC for  $^{14}\text{C}$  and  $^{13}\text{C}$  analysis.  
82

83 Based on the thermal stability of EC, several methods for **isolating** OC and EC  
84 from aerosols have been developed. An intercomparison of 9 laboratories for  $^{14}\text{C}$   
85 analysis of carbonaceous aerosol samples was conducted in a previous study, and  $^{14}\text{C}$   
86 analysis of EC revealed a large deviation of 28-79% between the approaches as a  
87 consequence of the different **isolation** techniques (Szidat et al., 2013). Due to the  
88 **application of the** same principle as aerosol OC and EC measurement, thermo-optical  
89 **isolation**, also named oxygen-based OC-EC **isolation**, has gradually become the main  
90 method for EC **isolation** in recent years. Although the  $^{14}\text{C}$  results of EC between three  
91 independent laboratory methods showed good agreement, the recovery of EC differed  
92 greatly (Zenker et al., 2017). Recently, hydropyrolysis (Hypy) has been introduced as  
93 an EC **isolation** method (Meredith et al., 2012; Zhang et al., 2019b). A comparison  
94 study of  $^{14}\text{C}$ -EC in aerosol samples **isolated** using the two-step heating method  
95 (CTO-375),  $\text{EC}_{\text{He/O}_2\text{-475}}$  method and Hypy method was also conducted (Zhang et al.,

2019b). However, the  $^{14}\text{C}$  intercomparisons of all studies were mainly restricted to ambient filter samples or urban dust (SRM 1649a/b), for which the “true”  $^{14}\text{C}$  activity of EC is not known. As the literature emphasizes (Dasari et al., 2022), even when methods give similar results, it may still be unclear whether the methods give accurate results. In the worst case, if the methods give different results, then it is impossible to determine which method (if any) gives an accurate value (Zenker et al., 2017). Therefore, the key to evaluating the accuracy of different isolation methods is to obtain suitable EC reference materials for the  $^{14}\text{C}$  analysis of aerosols.

Carbonaceous aerosols are mainly composed of primary emissions from fossil fuel and biomass combustion and secondary organic compounds (Huang et al., 2014; Zhang et al., 2015). In general, secondary organic aerosols are relatively easy to isolate from EC using methods such as water or organic solvent extraction. However, it is difficult to isolate insoluble OC from EC in primary combustion products. Biomass burning, coal combustion and traffic emissions are the main primary sources of EC in aerosols (Bond et al., 2013). In this study, six samples were synthesized artificially by using biomass combustion (corn straw or pine wood), coal combustion and motor vehicle exhaust samples according to the relative content of fossil carbon and modern carbon in actual aerosols in this study. The theoretical calculated values of the EC contents and EC carbon isotopes in six synthetic samples were determined based on the measured isotopes of each source sample and the elemental carbon/total carbon (EC/TC) measured by using the thermal-optical transmittance (TOT) method. And the calculated  $^{14}\text{C}$  value of EC can be taken as the “true”  $^{14}\text{C}$ -EC value. Consequently, four EC isolation methods, including Hypy (Zhang et al., 2019b), CTO-375 (Liu et al., 2013),  $\text{EC}_{\text{He/O}_2\text{-475}}$  (Liu et al., 2017) and  $\text{EC}_{\text{LARA}}$  (Zenker et al., 2017), were selected for EC isolation, and then the EC contents and EC carbon isotopes were compared to the corresponding theoretical calculated value of each synthetic sample. The accuracy of each isolation method was evaluated based on the recovery of the EC contents and carbon isotopes. Finally, the EC contents and EC carbon isotopes ( $^{14}\text{C}$  and  $^{13}\text{C}$ ) of urban dust (SRM 1649b) were determined by the isolation method with the best accuracy.

## 2. Materials and Methods

### 2.1. Sample collection

Corn straw (*Zea mays*, C4 plant, with a carbon isotope composition that differs significantly from fossil fuels), pine wood (*Pinus tabulaeformis* Carr. woody plant), one type of raw coal in chunks sourced from Yanzhou (YZ) in Shandong Province, and one type of gasoline truck exhaust were selected as the representative sources for biomass burning, coal combustion and vehicle exhaust. Corn straw and pine wood combustion products were collected through a sampling system. Coal was combusted in a high-efficiency stove, and  $\text{PM}_{2.5}$  emissions were collected using a dilution sampling system. Vehicle exhaust particles were collected using the on-board emission measurement system. A description of the detailed sampling information was provided in a previous report (Zhang et al., 2019b).

### 2.2. EC isolation method

**CTO-375 method:** To achieve the complete removal of the OC from the  $\text{EC}_{\text{CTO375}}$

146 fraction, the samples were treated by vaporizing the OC at 375 °C in a muffle furnace  
147 in the presence of air using a shorter isolation time of 4 h (Liu et al., 2013).

148  
149 **EC<sub>He/O2-475</sub> method:** The EC<sub>He/O2-475</sub> fractions in the samples were purified in the  
150 commercial OC-EC analyzer as follows: 120 s at 200 °C, 150 s at 300 °C, and 180 s at  
151 475 °C in an oxidative atmosphere (10% oxygen, 90% helium), followed by 180 s at  
152 650 °C in helium. Details of the handling methods were described in a previous report  
153 (Liu et al., 2017).

154  
155 **EC<sub>LARA</sub> method:** A punch of the water-extracted filter was treated with a  
156 thermo-optical OC-EC analyzer using the first three steps of the “Swiss 4S protocol”  
157 to remove all remaining water-insoluble OC, giving a residue that constituted the  
158 EC<sub>LARA</sub> sample (Zenker et al., 2017; Zhang et al., 2015).

159  
160 **Hydropyrolysis:** Each sample was mixed fully with ammonium  
161 dioxydithiomolybdate [(NH<sub>4</sub>)<sub>2</sub>MoO<sub>2</sub>S<sub>2</sub>] as a catalyst to reach a nominal molybdenum  
162 loading of more than 20% of sample carbon weight. The samples were first heated in  
163 the reactor tube from ambient temperature to 250 °C at a rate of 300 °C min<sup>-1</sup> and then  
164 from 300 °C to the final temperature (550 °C) at 8 °C min<sup>-1</sup>; samples were then held  
165 for 5 min under a hydrogen pressure of 15 MPa and a flow rate of 5.0 L/min. The  
166 resulting residue was the EC<sub>Hypy</sub> sample (Zhang et al., 2019b).

## 167 168 **2.3. OC/EC and carbon isotopes analysis**

169  
170 The OC and EC were analyzed by a laboratory OC/EC analyzer (Sunset Laboratory,  
171 USA) using the NIOSH2 thermal protocol (Maenhaut et al., 2005; Salma et al., 2004).  
172 Methods of <sup>13</sup>C and <sup>14</sup>C analysis for all samples were described in the SI (Liu et al.,  
173 2013; Liu et al., 2017).

## 174 175 **2.4. Nuclear Magnetic Resonance (NMR) and Field Emission Scanning Electron 176 Microscopy (FESEM) analysis**

177 NMR experiments were performed with an AVANCE III 400-MHz NMR  
178 spectrometer (Bruker, Billerica, MA, USA). FESEM experiments were analyzed by  
179 the field emission scanning electron microscope (Hitachi su8010, Hitachi, Japan).  
180 Detailed experimental methods of NMR and FESEM analysis were described in the  
181 SI (Zhang et al., 2019b; Chen et al., 2020).

## 182 183 **3. Results and discussion**

### 184 185 **3.1. Comparison of EC purified by different methods**

186  
187 The six synthetic known samples were made by biomass combustion (corn straw or  
188 pine wood), coal combustion and motor vehicle exhaust (Table S1). The hybrid  
189 samples were produced according to the proportioning principle, based on the  
190 approximate proportions (Figure S1 and Table S2). The average deviations of carbon  
191 content, <sup>13</sup>C<sub>TC</sub> and *f<sub>M</sub>*(TC) of the hybrid samples between the theoretical values and  
192 the test values were 0.30%, -0.12‰ and 0.03, respectively (Table S3), and there was  
193 no significant difference (T-test, P=0.77, 0.96 and 0.49, respectively). These results  
194 show that the samples were well mixed and were therefore suitable for the method  
195 comparison experiments.

196

197 Before comparing EC recovery rates, it is necessary to obtain relatively accurate  
198 EC concentrations. The EC/TC ratios of the four combustion source samples were  
199 analyzed by the TOT method (Table S4). The EC/TC results of the four combustion  
200 source samples processed using the four **isolation** methods (**CTO-375**, **EC<sub>He/O2-475</sub>**,  
201 **EC<sub>LARA</sub>** and **Hypy**) are listed in Table S4. **The** amount of EC obtained by the  
202 CTO-375 method is obviously lower than the results of the other three methods. For  
203 example, due to the high content of soot in the vehicle exhaust, the amount of EC can  
204 reach about 20%, while the amount of EC in other source samples is less than 10%  
205 (Hammes et al., 2007). **It indicates that the CTO-375 method has obvious defects in**  
206 **the quantitative analysis of EC content in aerosols. Therefore, this method is not**  
207 **suitable for isolating EC to isotopes analysis.** The EC/TC ratios of the coal  
208 combustion and motor vehicle exhaust obtained by the other three methods are lower  
209 than those of the TOT method, and the EC/TC ratios of the pine burning samples are  
210 higher than those of the TOT method. Among the above four methods, the result  
211 obtained by the Hypy method is the closest to the result of the TOT method. For the  
212 corn straw combustion samples, the Hypy and EC<sub>LARA</sub> methods are lower than the  
213 TOT method, but the results obtained by the EC<sub>He/O2-475</sub> are higher than the TOT  
214 method. **On the one hand, this difference is the problem of the method itself. Each**  
215 **method only isolates a specific part of the EC continuum, rather than all the**  
216 **components of the EC continuum** (Currie et al., 2002; de la Rosa et al., 2011; Schmidt  
217 et al., 2001). On the other hand, the different **isolation** effect of the method is due to  
218 the difference of the organic carbon structure in the source sample.

219

220 NMR spectroscopy is an essential tool for acquiring detailed structural  
221 characterization results of the complex natural organic matter. The four combustion  
222 source samples were characterized by using solid-state <sup>13</sup>C NMR (Figure S2 and  
223 Table S5). The <sup>13</sup>C NMR results show that the average lower limit estimate for  
224 organic oxygen (Kelemen et al., 2010) from biomass combustion is 37% higher than  
225 that for fossil combustion. This finding indicates that there are more  
226 oxygen-containing organic carbon components in biomass combustion samples. The  
227 more organic oxygen in the sample, the greater the sample's polarity, which  
228 contributes to the increased fraction of water-soluble components in biomass  
229 combustion **compared to the** fossil combustion samples. In the absence of oxygen,  
230 using an aromatization process based on the cleavage of O-alkylated carbons might  
231 overestimate the EC content analyzed by thermal-optical methods (Li et al., 2013).  
232 The fraction of methyls in the aliphatics (FMA) (**Chen et al., 2020**) and nonprotonated  
233 aromatics (Kelemen et al., 2010) in pine wood combustion are 22% and 12% higher,  
234 respectively, than those in corn straw. These findings indicate that the water solubility  
235 of pine wood combustion products is worse than that of corn straw, in addition to the  
236 fact that the aromatic structure of pine wood combustion materials is denser. The  
237 water-soluble components of the corn straw combustion products were high, such that  
238 OC charring has a greatly influenced EC **isolation** when using the EC<sub>He/O2-475</sub> method,  
239 while minimally impacting EC **isolation** following the water extraction EC<sub>LARA</sub>  
240 methods (**Zhang et al., 2012**).

241

242 By using FESEM in this study (Figure S3), it was observed that the pine wood  
243 samples contained a coke structure that was more **condensed** than the structure of the  
244 corn straw samples. In addition, a large number of soot structures were observed in  
245 the fossil source samples, indicating that fossil source samples are more **condensed**

246 than biomass samples.

247

248 In general, due to the differences between the **isolation** technologies, the EC/TC  
249 ratios of the six synthetic known samples (Table S4) revealed a deviation of  
250 approximately **-99%~+125%** between the calculated EC/TC ratios and the EC/TC  
251 ratios **isolated** by the four methods. The deviations **isolated** by the Hypy, EC<sub>LARA</sub>,  
252 EC<sub>He/O2-475</sub> and CTO-375 methods were approximately **-8%~+31%**, **-39%~+121%**,  
253 **-62%~+125%** and **-93%~-99%**, respectively. The result obtained by the Hypy method  
254 is closest to the TOT method, and the average value of the ratio is 1.1, which shows  
255 the advantages of stability and reliability in purifying EC.

256

### 257 **3.2. Comparison of carbon isotopes in EC**

258

259 The different EC recoveries of the source samples may lead to different carbon  
260 isotope results in the EC from the synthetic known samples. The theoretical EC/TC  
261 ratios and <sup>13</sup>C<sub>EC</sub> values of each hybrid sample were calculated according to the EC/TC  
262 (TOT) ratios and <sup>13</sup>C<sub>TC</sub> values in the combustion source and the relative proportion of  
263 each source, respectively (Table S3). In the calculation, it is assumed that the <sup>13</sup>C  
264 value in the EC is **very close with** that in the TC in each source sample. The <sup>13</sup>C  
265 results of the EC from the six synthetic known samples processed by the four **isolation**  
266 methods are shown in Table 1. No significant difference of <sup>13</sup>C was observed between  
267 the results of the four **isolation** methods and the corresponding theoretical calculation  
268 values of all samples (T-test, P>0.05), except for the samples (S1, S2 and S3)  
269 containing corn straw combustion material **isolated** using the EC<sub>He/O2-475</sub> method,  
270 which presented much higher <sup>13</sup>C values. This finding indicated that the EC **isolated**  
271 using the EC<sub>He/O2-475</sub> method contained more biomass carbon. The reason for this  
272 result may be that the organic carbon of combusted corn straw is charring during the  
273 EC **isolation** process. However, this phenomenon was not observed in the samples  
274 containing pine wood combustion, which may be the reason that the <sup>13</sup>C value of the  
275 pine wood combustion sample is close to that of coal combustion.

276

277 The <sup>14</sup>C results of the EC are shown in Table 1 and Figure 1. Fraction of Modern  
278 (*f<sub>M</sub>*) is used to express the proportion of biomass burning. The theoretical values of  
279 *f<sub>M</sub>*(EC) in the hybrid samples were obtained according to the proportion of fossil  
280 carbon and modern carbon in each sample in accordance with the EC/TC (TOT) ratios  
281 (Figure 1). The results show that the *f<sub>M</sub>* values obtained by different **isolation**  
282 methods are quite different, and are generally affected by the ratios of combustion source  
283 sample EC recovered by different methods. Due to the low recovery rate of EC by  
284 CTO-375 method, the *f<sub>M</sub>*(EC<sub>CTO-375</sub>) value is **irregular**. Generally, the *f<sub>M</sub>*(EC<sub>CTO-375</sub>)  
285 value obtained by this method is more than twice the theoretical value. For the  
286 EC<sub>He/O2-475</sub> method, due to the influence of biomass burning OC **charring** the  
287 *f<sub>M</sub>*(EC<sub>He/O2-475</sub>) value obtained by this method deviates greatly from the theoretical  
288 value. On the whole, *f<sub>M</sub>* values obtained by the Hypy and EC<sub>LARA</sub> methods are  
289 relatively close to the theoretical values, but the two methods have their own  
290 advantages in the two different sets of samples. For the combustion of herbaceous  
291 plants, the Hypy method has a low EC recovery rate for such source samples,  
292 resulting in a small *f<sub>M</sub>* value. For the combustion of woody combustion, due to the  
293 higher EC recovery rate by the Hypy method, the *f<sub>M</sub>*(EC<sub>Hypy</sub>) value is slightly higher

294 than that of samples containing herbaceous plants. For the EC<sub>LARA</sub> method, in the first  
295 group of samples with corn straw combustion, the EC recovery rate of each source  
296 sample is lower than the theoretical value, so that the  $f_M(\text{EC}_{\text{LARA}})$  value obtained by  
297 this method is the closest to the theoretical value. However, in the second group of  
298 samples containing woody combustion, the  $f_M(\text{EC}_{\text{LARA}})$  value obtained by this method  
299 was significantly higher than the theoretical value, due to the higher recovery rate of  
300 woody combustion EC by the EC<sub>LARA</sub> method. The results show that the  $f_M$  value of  
301 EC was not only related to the **isolation** method but also to the types and proportions  
302 of biomass sources in the sample.

303

304 The above results show that the type of biomass combustion affects the efficiency  
305 of the **isolation** method to purify black carbon and the accuracy of the radiocarbon test  
306 results. Charcoal, harvest residues and wood materials are the most common biomass  
307 fuels used as energy sources (Anenberg et al., 2013). From a global perspective, the  
308 types of biomass fuels are complex, but generally can be divided into two categories,  
309 herbaceous burning and woody plant burning, the ratio of the two types of biomass is  
310 about 58:42 (Table S6). Different regions have different proportions. According to the  
311 literature (Bond et al., 2004; Stevens et al., 2017; Streets et al., 2003; Zhang et al.,  
312 2019a), developed countries, such as Europe and North America, have a relatively  
313 high proportion of woody plants, while developing countries, such as Africa and Asia,  
314 have a relatively high proportion of herbaceous plants (Table S6). According to the  
315 recovery rate of different types of biomass combustion EC by different methods, the  
316 deviations that may be caused by the results of testing <sup>14</sup>C in different regions are  
317 estimated. The results are listed in Table S6. It can be seen that on a global scale, the  
318  $f_M$  value obtained by the Hypy method is the closest to the theoretical value. Therefore,  
319 the Hypy method is an effective and stable approach for matrix-independent <sup>14</sup>C  
320 quantification of EC avoiding charring in aerosols.

321

### 322 3.3. Carbon isotopes of EC in SRM 1649b

323

324 SRM 1649a/b, urban dust, was used to check the quality of EC or EC isotope  
325 measurement method (Currie et al., 2002; Liu et al., 2013; Szidat et al., 2004b; Reddy  
326 et al., 2002; Heal et al., 2011). SRM 1649b was prepared from the same particulate  
327 material that was issued in 1982 as SRM 1649 and re-issued in 1999 as SRM 1649a,  
328 and the only difference is that the bulk material was sieved to a smaller particle size  
329 fraction<sup>47</sup>. Therefore, the  $f_M$  and  $\delta^{13}\text{C}$  of TC in SRM 1649b obtained in this study was  
330 consistent with SRM 1649a reported by Szidat et al (Szidat et al., 2004b). EC/TC  
331 ratios,  $f_M\text{-EC}$  and  $\delta^{13}\text{C}\text{-EC}$  of SRM1649b **isolated** using Hypy method in this study  
332 and archived data **from the literature** using different **isolation** methods are listed in  
333 **Table 2**. The EC/TC ratios varied from 7.5% to 46% determined by the different  
334 analyzing methods. However, the value of about ~28% obtained in this study is in  
335 good agreement with that obtained by Hypy method (Meredith et al., 2012) and by  
336 TOT method (Currie et al., 2002). The  $f_M$  and  $\delta^{13}\text{C}$  of EC in SRM 1649a ranged from  
337 0.038 to 0.153 and from -26.55‰ to -24.8‰ respectively reported by the previous  
338 research using the different **isolation** methods except Hypy (Currie et al., 2002). The  
339 corresponding values of 0.11 and -24.9‰ treated by Hypy method in this study are  
340 just in the range of archived data. Therefore, the values of <sup>13</sup>C and <sup>14</sup>C of EC<sub>Hypy</sub> in  
341 SRM 1649b provide a definite and comparable reference for the future research  
342 methods.

343

#### 344 **4. Conclusions**

345  
346 Carbon isotope ( $^{14}\text{C}$  and  $^{13}\text{C}$ ) analysis is a powerful tool for distinguishing the  
347 carbon sources in carbonaceous aerosols. As addressed in this work, one main  
348 challenge of this method is the isolation of EC or BC for carbon isotope analysis. In  
349 this study, six synthetic known samples were collected, including biomass combustion  
350 (corn straw or pine wood) and coal combustion products and motor vehicle exhaust.  
351 These samples were then used to evaluate four EC isolation methods, which included  
352 the Hypy, CTO-375,  $\text{EC}_{\text{He/O}_2-475}$  and  $\text{EC}_{\text{LARA}}$  methods. The results demonstrated the  
353 Hypy method was in good agreement with the thermo-optical (TOT) method for the  
354 quantification of EC. And the  $\text{EC}_{\text{FM}}$  values depended not only on the isolation method  
355 but also on the types and proportions of the biomass sources in the samples. The Hypy  
356 method is the most appropriate EC isolation method of the four methods reported here,  
357 followed by the  $\text{EC}_{\text{LARA}}$  method. The Hypy method, which can be used to isolate a  
358 highly stable portion of  $\text{EC}_{\text{Hypy}}$  and avoid charring, is a more effective and stable  
359 approach for the matrix-independent  $^{14}\text{C}$  quantification of EC in aerosols. The  $\text{EC}_{\text{Hypy}}$   
360 of SRM1649b sample was isolated by the Hypy method. The results indicated that the  
361  $^{13}\text{C}$ - $\text{EC}_{\text{Hypy}}$  and non-fossil  $\text{EC}_{\text{Hypy}}$  values of SRM1649b were -24.9‰ and 11%,  
362 respectively. These two isotope values was able to provide a valuable reference for  
363 other EC isolation methods.
