Abstract. Mud volcanoes are fluid escape structures allowing for surface venting of hydrocarbons (mostly gas but also liquid
15 condensates and oils) and water/sediment slurries. For a better understanding of Mud volcanoes dynamics, the characterization of the fluid dynamics within mud volcanoes conduits, the presence, extent, and depth of the fluid reservoirs as well as the connection among aquifers, conduits, and mud reservoirs play a key role. To this aim, we performed a geoelectrical survey in the *Regional Nature Reserve of the Nirano Salse*, located at the edge of the Northern Apennines (Fiorano Modenese, Italy), an area characterized by several active mud fluid vents. This study, for the first time, images the resistivity structure of the subsoil
20 along two perpendicular cross sections down to a depth of 250 m. The electrical models show a clear difference between the Northern and Southern sectors of the area, where the last hosts the main discontinuities. Shallow reservoirs, where fluids muds accumulate are spatially associate to the main fault/fracture controlling the migration routes associated with surface venting and converge at depth towards a common clayey horizon. There is no evidence of a shallow mud caldera below the *Nirano* area. These findings represent a step forward in the comprehension of the *Nirano Salse* plumbing system and in pinpointing
25 local site hazards, which promotes safer tourist access to the area along restricted routes.

1 Introduction

Mud volcanoes are fluid escape structures allowing for surface venting of hydrocarbons (mostly gas but also liquid condensates and oils) and water/sediment slurries. Their shape varies in size over different orders of magnitude from centimeters to several
30 hundreds of meters (Manga & Wang, 2015). Mud volcanoes are associated with “mud volcanism” processes (Martinelli & Judd, 2004) that may be quite different ranging from liquefaction due to sediment overpressure and compaction to leakage

from poorly sealed hydrocarbon reservoirs (Kopf, 2002). Worldwide, they are broadly distributed on land and on the sea bottom (Milkov, 2005; Mazzini & Etiope, 2017), especially in contractional areas and fast subsiding basins. Most mud volcanoes are cold seeps, but some are also present in geothermal areas (Amici et al., 2013). Mud transport mechanisms are a matter of debate being associated both with mud-dyke-sill complexes or with diapirs (Tingay, 2009; Roberts, 2011).

Mud volcanoes are usually associated with quiet and continuous eruptions (Tingay, 2009) but sometimes they explode in dangerous and disruptive events. They are hazardous phenomena, because as of today, it is impossible to define the parameters for modelling the recurrency intervals of the extreme events (Gattuso et al., 2021). Azerbaijan hosts some mud volcanoes displaying the most violent eruptions worldwide; the Lobkatan mud volcano, for example, explodes every 3-5 years in spectacular eruptions, which send detritus and breccia rafts into the Caspian Sea (Mazzini et al., 2021; Wang & Manga, 2021). In recent times (2006-2016), the massive eruption of the Indonesian Lusi mud volcano, triggered by the drilling of a borehole, continued for years with peak mud flows of 180000 m³/day that caused burial of nearby villages and the displacement of 60000 people (Mazzini et al., 2007; Tingay, 2015). Some historically recorded explosive events occurred at the Salsa di Montegibbio (Sassuolo, Italy), the largest mud volcano in Italy (Borgatti et al., 2019), were reported by Plinius (*Historiae Naturalis*) in roman times (50 a.d.) and later (1592-1835) by Biasutti (1907), Govi (1906) and Stöhr (1867). Recently (2014), a sudden massive expulsion of fluids at the Macalube di Aragona mud volcano (Agrigento, Italy) caused the death of two children (Gattuso et al., 2021). Mud volcanoes, therefore, represent potential geohazards, especially where these features are located next to populated areas or where they are tourist destinations.

Mud volcanoes are natural hydrocarbon seeps and as such are important indicators in hydrocarbon exploration where they give hints about the level of hydrocarbon maturity and the presence of structural highs related to mud diapirism (Warren et al., 2010), fault traps, and their spill-points (Milkov, 2005; Mazzini & Etiope, 2017). Large mud volcanoes provinces are also associated with giant hydrocarbon accumulations and many onshore fields in Europe, Caribbean, Caspian Basin, and Caucasus were discovered by drilling on natural seeps indication (Mazzini & Etiope, 2017). In Azerbaijan, mud volcanoes are associated with structural traps and their feeders are rooted in or below the reservoirs forming an interconnected plumbing system (Planke et al., 2003). The relationships between production from reservoirs and activity in nearby mud volcanoes is also an issue of interest; usually, the decrease in fluid pressure during exploitation causes diminishing in mud volcanism processes but, in some cases, there is no effect whatsoever (Mazzini & Etiope, 2017).

Mud volcanoes have also important meaning in different historical and societal contexts (Giambastiani et al., 2022). Geotourists interested in visiting mud volcanoes are numerous throughout the world (Italy, Colombia, Trinidad, Azerbaijan, Georgia, Turkmenistan, and Indonesia) for the scenery or for recreational mud bathing due to the beneficial properties of mud for the skin. Mud volcanoes have also a religious significance for the Hindus and for the Temple of Fire worshippers (Ateshgah, near Baku in Azerbaijan), and they were revered at different times by Zoroastrians, Hindus, and Sikhs (Gamkrelidze et al., 2021). The combination of human activities such as geo-tourism, religious worshipping, proximity settlements and mud volcanoes may lead to situations of risk where the fluid emissions are a geohazard.

65 In the context of mud volcanoes, fluid emissions are geohazards mostly because they can release violently large amounts of
mud and hydrocarbons and may degrade the soil causing caving and quick-sand effects. Furthermore, they might dissociate
gas hydrates in submarine environments (Mazzini & Etiope, 2017). Explosive eruption of mud volcanoes with methane self-
igniting phenomena in Azerbaijan are rather common. Tall mud columns ejections up to several and tens of meters have been
70 causing serious risks for the people in their proximity (Mazzini & Etiope, 2017). Mud pools with diameters in the order of a
few meters, not-existent rims, and depth that can reach 15 m (Giambastiani et al., 2022) may potentially be deadly sinks for
persons and animals. It is therefore necessary to characterize the fluid dynamics within mud volcanoes conduits, the presence,
extent, and depth of the fluid reservoirs as well as the connection among aquifers, conduits, and mud reservoirs. Given that it
is difficult to image fluid sources and conduits below a sedimentary cover, geophysical investigations have the potential to
75 greatly contribute to this characterization.

Electromagnetics methods are useful where there is contrast in apparent resistivity due to the presence of mud volcano fluids.
Transient Electromagnetic (TEM) and the radiomagnetotelluric methods (RMT) were applied by Adrian et al. (2015) at mud
volcanoes in Perikishkul (Azerbaijan) who observed resistivity variations at shallow (< 10 m with RMT) and intermediate
depths (150 m with TEM) directly below the surface emissions. Three-D electrical resistivity imaging of mud volcanoes in
80 New Zealand by Zeyen et al. (2011) shows pipe like structures connected to a deep reservoir; the pipe structures occur along
a major strike-slip fault plane, which controls fluids surface venting. Geoelectric methods are often combined with other
geophysical and geological investigations. A multidisciplinary approach of shallow seismic, georesistivity, and
hydrogeochemical surveys was employed (Rainone et al., 2015) near Pineto (Central Italy). The survey results show that the
mud reservoirs are not just below the mud volcano, but they are in a fractured zone at 60 m distance from the vent suggesting
85 the presence of a high-permeability connection (fracture zone) just below the surface clay deposits.

Several seismic surveys above mud volcanoes have been performed and reported in the literature. Albarello et al. (2012)
estimated methane emissions at mud volcanoes in Azerbaijan by measuring the seismic tremor at the surface and identified
energy bursts that could be related to bubbling at depth. Evans (2007) using industry acquired seismic reflection data, well
data, and satellite imagery characterized the geophysical expression of large mud volcanoes (diameter > 500m) in the South
90 Caspian Basin and was able to identify a sequence of wedge-shaped layers of erupted sediments with regularly interlayered
bedding, which could be useful to characterize the temporal time history and recurrency periods of the mud eruptions. Kirkham
(Kirkham, 2016) also used 3D seismic to characterize mud volcanoes geometry and seismic character, timing and distribution,
source regions and depletion zones, and understand the mechanisms behind the formation of conduits and ultimately the
geometry of extruded bodies in the Nile Delta. This latter study was particularly effective in identifying seal bypass conduits
95 through which large quantities of mud were extruded to the surface.

Mauri et al. (2018) employing on-land gravimetric surveys at the Lusi mud volcano in Indonesia have shown that this
geophysical methodology is effective in characterizing sediment density variations within the basin and in the mud edifice,
which can then be related to the presence of fault and fracture systems. A three-dimensional deep electrical tomography survey

was also performed at the Lusi mud volcano in Indonesia, by Mazzini et al., (2021) who point out the presence of a fault and
100 fracture system just underneath the volcano (Mauri et al., 2018) and image a region where a mix of groundwater, mud breccia,
hydrocarbons, and boiling hydrothermal fluids are stored below the subsided area in proximity of the major vent.
Geodetic surveys are, also important for mud volcanism characterization. Satellite Differential Interferometry Synthetic
Aperture Radar (DInSAR) has been useful for detecting pre-eruptive ground deformation in Azerbaijan mud volcanoes by
Antonielli et al. (2014) who have shown that inflation (vertical uplift up to 20 cm) and subsidence could be related to the mud
105 flowing in shallow reservoirs.
The objective of our work is to use deep geoelectric tomography surveys at the Nirano Salse in Italy to characterize the fluid
dynamics within mud volcanoes conduits, the presence, extent, and depth of the fluid reservoirs as well as the connection
among aquifers, conduits, and mud reservoirs. This is necessary to assess the risk level due to mud venting geohazards in this
natural reserve, which every year is visited by tens of thousands of school students and tourists. This study, for the first time,
110 presents a clear image of the subsoil along two perpendicular cross sections down to a depth of 250 m imaging structures of
which nothing was known before. Furthermore, this geophysical investigation well integrates with already existing geophysics
in the area such as that of Accaino et al. (2007) based on 3D seismic data and 2D geoelectric tomography and of Antunes et
al. (2022) who used P wave analysis of drumbeat signals and vertical to horizontal seismic amplitude to detect mud movement
in the subsoil.
115 Our study, by imaging low resistivity subsurface aquifers/reservoirs where high salinity fluids muds concentrate and the
fault/fracture-controlled migration routes associated with surface venting, represent a step forward in the comprehension of
the Nirano Salse plumbing system previously only inferred, based on hydrogeologic data, by Giambastiani et al. (2022).

2 Geological introduction to the area

The Regional Nature Reserve of the *Nirano Salse* (*Nirano Salse* from now on) is located at the edge of the Northern Apennines
120 (Fiorano Modenese, Italy), an area that is characterized by several active mud fluid vents.

The *Nirano Salse*, known since the Roman Times, are in a beautiful and scenic landscape of Northern Italy. With a surface of
approximately 75,000 m², *the Nirano Salse* is one of the largest mud volcano areas of Italy and Europe, as well as one of the
most visited (more than 50000 visitors each year).

The *Nirano Salse* are located within a geomorphological bowl (Fig. 1.a), which resembles a collapsed caldera. The diameter
125 of the bowl is about 800 m and the difference in elevation between the bowl's rim and its bottom is about 50-60 m. The
structure is almost completely circular except in the SE corner where a small creek cuts across the rim and two relatively NW-
SE oriented steep ridges border the southwestern flank of the circular structure. Mud pools and gryphons are located within
the caldera-like structure in three major groups two in the northern part and one in the southern part of the bowl.

There are several individual active cones, gryphons, and subcircular pools distributed at the base of the caldera within an area
130 of recently extruded mud that is free of vegetation. The specific number and location of the cones is rather constant over time

except some small local changes in vents activity. Volcano morphology at the site depends mostly on the characteristics of extrusion style (abrupt Strombolian-type eruptions forming gryphons), persistence of degassing produced by the rising to the surface of salty and muddy water mixed with gas (mostly CH₄), and connection with groundwater aquifers (mud pools) (Giambastiani et al., 2022).

135 The Nirano Salse fluid venting occurs in the Plio-Pleistocene Argille Azzurre Fm (FAA) (Fig. 1.b), which in the south-eastern part of the area are just a thin veneer of transgressive clays (less than 50 m) above the Tortonian Termina Fm, which includes clay breccia, marls, and sandstone (0-600 m in thickness). Below the Termina Fm, the turbiditic well-layered Burdigalian-Langhian Pantano Fm (about 200 m in thickness) represents the maximum limit to which the geoelectric survey can extend to. The stratigraphic sequence below the FAA is deformed by two systems of high angle faults; one NW-SE oriented with vertical offsets and one oriented NE-SW with apparent strike-slip offsets (mostly left-lateral) (Gasperi et al., 2005).

140 The Nirano mud volcanoes have been interpreted so far as to be just above a NW-SE blind thrust anticline (Bonini, 2008; Bonini, 2009; Bonini, 2012). The gas emissions would be the surface expression of fluids escaping from a deep leaky reservoir (about 1.5 km depth) located in permeable Epiligurian units of Eocene-Miocene Age (Bonini, 2007; Bonini, 2008). Any gas accumulation within a subsurface reservoir would increase the pore pressure due to buoyancy (Dasgupta & Mukherjee, 2020);
145 if the sealing unit is of poor quality, the gas may rise towards the surface either following faults and fracture zones or fingering through poorly consolidated mud sediments.

3 Geophysical investigations in Nirano Salse area

3.1 Previous geophysical data

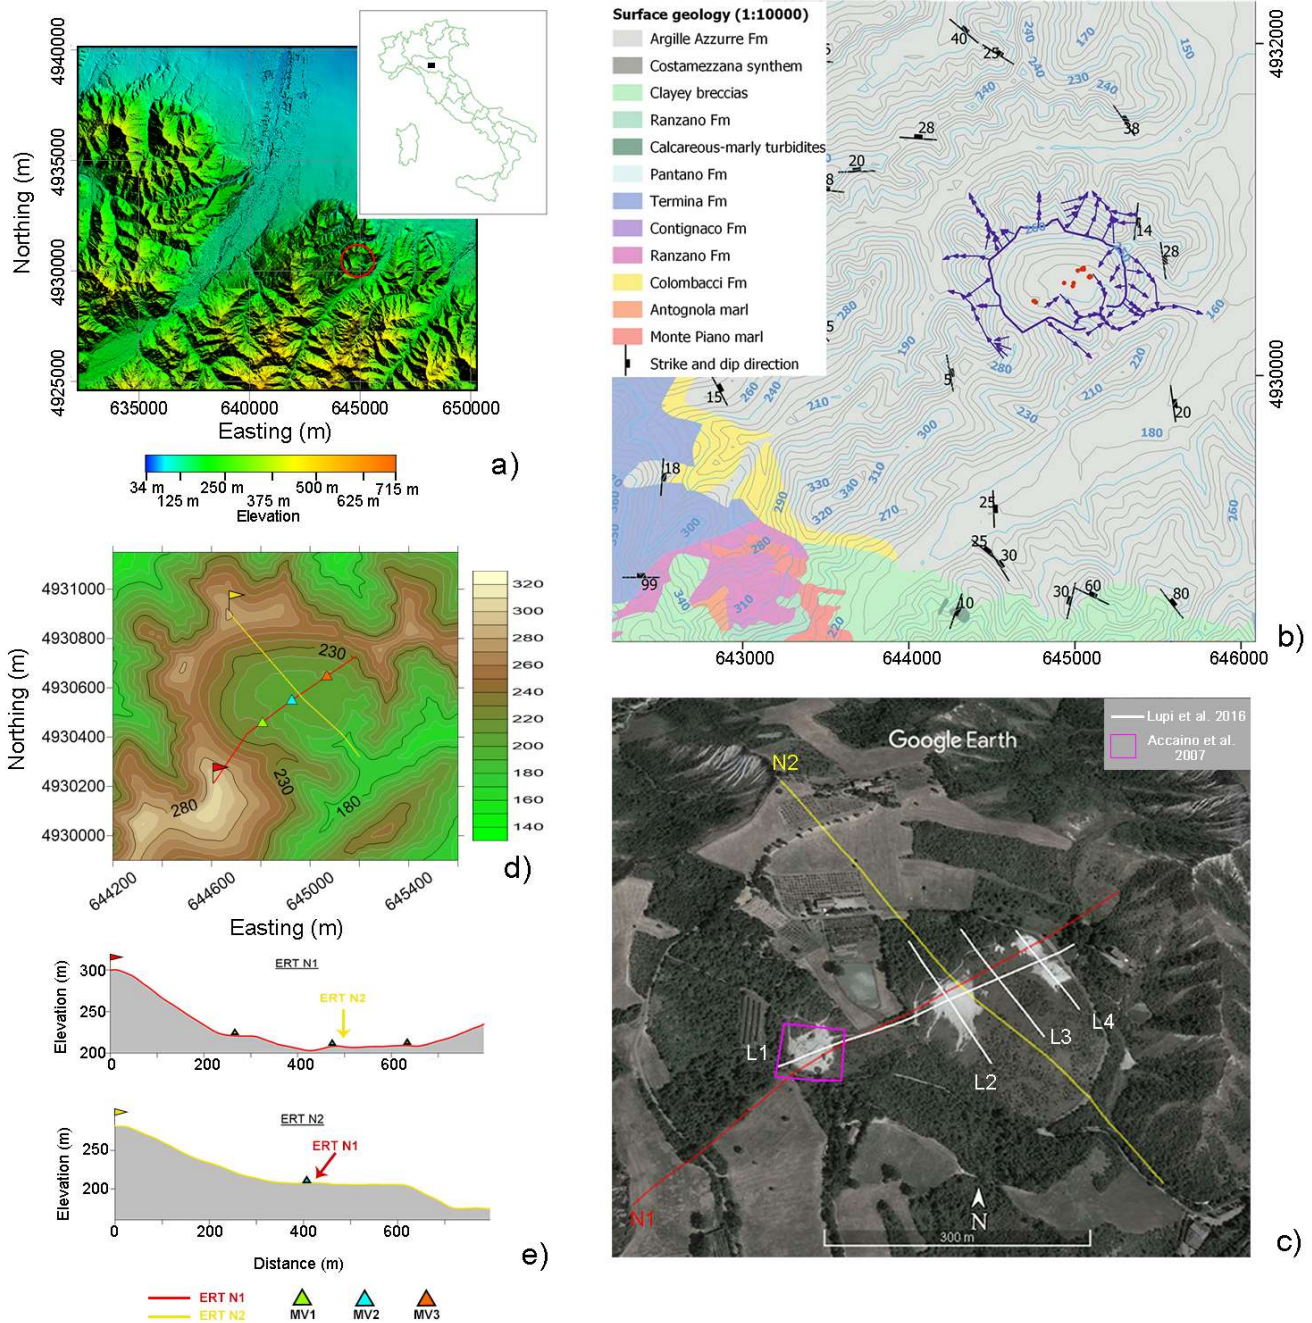

Several geophysical studies (Fig. 1.c) were conducted in the last decades to characterize the *Nirano Salse* subsoil and to address
150 some of the open issues regarding the fluid origins in the area. Most of them are small scale and relatively high-resolution studies, focused on the determination of the shallow (from the surface down to 50 m below the surface) subsoil structure for the identification of the superficial outlet of the volcanic conduits and chimneys and possible fluid reservoir. Accaino et al. (2007) performed tomographic inversion of first arrivals of 3D seismic data, and 2D geo-electrical surveys on the South-Westernmost mud volcano (here named MV1). Focusing on the geoelectrical data, the overall retrieved electrical properties
155 distribution was characterized by low resistivity values (from 3 to 5 Ωm) associated with fluid-saturated sediments occurring in the mud volcano area and higher resistivities (up to 40 Ωm) observed in the pelitic sediments surrounding the mud volcano apparatus. Moreover, the used interelectrode spacing, equal to 3 m, was enough to provide a resolution sufficient to identify the sub-vertical structures of the superficial outlet of the volcanic conduits and chimneys and a mud chamber at a depth of 25 m. Similar results were obtained by Lupi et al., (2016) who presented a more extended geoelectrical survey. In this latter study,
160 a longitudinal geoelectrical profile, passing near all principal mud volcanoes in the area and with an interelectrode spacing of 5 m, depicted dome-like reservoirs at about 20 m below the ground surface (ca. 50 m wide and more than 20 m thick) feeding the mud vents. The Authors supposed that the fluid transfer from the fluid reservoirs to the vents at the surface may occur

165 along narrow conduits that are beyond the resolution limits of the conducted ERT survey they performed. The conductive domes positively correlate with the presence of high permeability areas that act as preferential leakage pathways for gas migration as observed by Sciarra et al. (2019). Finally, Giambastiani et al. (2022) assumed that these permeable areas are none other than shallow aquifers with variable size and thickness possibly leaking to the surface along faults formed during the subsidence of the area and the formation of the caldera-like morphology (bowl).

To the Authors knowledge, no other geophysical data acquired or describing the Nirano Salse area are available or published at the present time.

170 3.2 New geophysical data

To gather information both on the lateral and in-depth structure of the Nirano Salse area, and to investigate a possible deep connection between the conductive domes found by Lupi et al. (2016), two ERT profiles (ERT_N1 and ERT_N2 in what follows) were acquired along orthogonal transects passing by the mud volcanoes area and extending from “rim” to “rim” of the caldera-like structure (Figure 1.d, 1.e). The length of the profiles was conditioned by the harsh topography over the “rims” which limited the profile extension to 820 m with an interelectrode spacing of 20 m and a total of 42 electrodes deployed. Profile ERT_N1 trace overlaps Lupi et al. (2016), ERT survey to allow a direct comparison between the previously acquired geoelectrical data and the one that we present here. Along each of the profiles, data were acquired in Wenner-Schlumberger (WS), Dipole-Dipole (both in direct and reverse configurations) (DD and DD-rev) and Pole-Dipole (PD) by using a Syscal Pro 48 ch (Iris instruments). To perform pole-dipole surveys, a remote pole was placed ~2.5 km away from the crossing point of the ERT profiles. Among standard arrays, DD is the most advocated for the study of lateral resistivity contrast, but it is also the one with the lower S/N ratio, WS should provide a better vertical resolution and a good S/N ratio while P-DD has an intermediate lateral and vertical resolution, a good S/N ratio, and a deeper investigation depth. For a comprehensive review of the arrays' characteristics in terms of resolution, investigation depth and sensitivity to noise see Dahlin & Zhou, (2004), or Martorana et al. (2017).

185

Figure 1: panel a: location of the Nirano Salse area. Panel b): surface drainage basin of Nirano, contour lines, and the surface geology modified from the Emilia-Romagna survey geology map, scale 1:10000. (Coordinate reference system: WGS 84/UTM Zone 32N). Blue lines with arrows indicate the drainage network in the Nirano area (modified from Giambastiani et al., 2022). Panel c): locations of the previous geophysical surveys. Panel d): ERT profiles locations on top of a DEM. The red line indicates the position of ERT N1 profile. The yellow line indicates the position of ERT N2 profile. The red and the yellow flags indicate the location of the first

190

electrode on both profiles. Green, cyan and orange triangles indicate, respectively, the location of MV1, MV2 and MV3. Lower panels: Elevation profiles corresponding to ERT N1 and ERT N2 profile traces.

195 Electrode-ground contact resistance values were checked before measurement and, where necessary, lowered by using salty water. During acquisition, these values were stored to better identify noisy/bad data presence. In fact, as reported in Zhou & Dahlin, (2003), the contact resistance values storage may be fundamental in evaluating whenever or not anomalous data must be considered outliers or not. ERT error outliers, in fact, are often correlated with high contact resistances for some of the electrodes used in a measurement. Moreover, the influence of the measurement errors on the geoelectric data inversion will also be accounted for by integrating the errors in the inversion procedure.

200 Measurement errors can be derived mainly from the stacking procedure, from the repetition of the ERT measurement sequence or by comparing the direct measurements with the reciprocal ones. The stacking procedure is the simplest method of assessing a measurement error in a ERT and it consists in repeated measurements of the transfer resistance through several cycles of current injection. The repeatability of an ERT consists in performing the same complete ERT survey to obtain multiple and independent measurements of the transfer resistance from which to derive error estimates. The comparison of the direct
205 measurements with the reciprocal ones is based on the reciprocity principle which states that the switching of source/sink and observation locations would yield the same response (Parasnis, 1988). In practise, reciprocity checks for ERT are conducted by swapping the current and potential electrodes. A detailed comparison of stacking, repeatability, and reciprocal errors and of their utility to describe errors in measurements can be found in Tso et al. (2017). According to Tso et al. (2017), stacking errors are potentially an inadequate measure for describing the true quality of ERT measurements since they are generally
210 smaller than repeatability and reciprocal errors. Although stacking errors are the less reliable, due to survey time optimization, they are those mostly considered in standard ERT applications; reciprocal errors are often calculated for Dipole-Dipole measurements and repeatability is generally applied only in time lapse experiments.

With the aim to maximize all available information, we will first focus on the ERT_N1 geoelectrical profile where a comparison with the resistivity model obtained by Lupi et al., (2016) is also possible. As for our dataset, since reciprocal
215 measurements and relative estimates are available only for DD data, for the other configurations, only stacking errors will be considered. Therefore, we firstly analyse the Dipole-Dipole dataset comparing stacking and reciprocal error distributions as well as the results obtained by the inverse modelling using both type of error estimates. Successively, the reliability of all the available models will be evaluated by verifying their consistency.

220 3.2.1 ERT_N1 profile

3.2.1.1 Dipole-Dipole data inversion

The starting dataset was composed by 851 measurement points. The contact resistance values result all good with values well below 2 K Ω . By considering the whole datasets, without filtering out any measurements, the mean contact resistance was 0.37

$K\Omega \pm 1.54 K\Omega$ for the direct DD measurement and $0.17 K\Omega \pm 0.35 K\Omega$ for the reverse DD. The higher standard deviation
225 associated with the direct DD measurement can be ascribed to a not perfect contact of an electrode placed on a paved road
(intercepting ERT N1 profile at about 700 m, contact resistance equal to 28 $K\Omega$), which was lately improved by adding salty
water. Hence, it can be excluded that anomalous or negative resistivity data are associated to bad contact resistances.

As expected, and known from literature, stacking errors, calculated on direct DD measurements, are generally lower than
reciprocal errors (Fig. 2) (Tso et al., 2017). In the central portion of the experimental pseudosection, the different behaviour
230 of the error spatial distributions is striking with the reciprocal errors three times larger than the stacking errors. By limiting the
colour scale range of the stacking error map from 0% to 10% (not shown here), this last error spatial distribution clearly shows
the reversed “v” shape (Fig. 2a). This is a proof that the stacking errors tend to underestimate the effective measurement errors.
However, it may also indicate that the two different kinds of errors follow the same general spatial distribution. When
reciprocal or repeatability errors are not available, a cautious use of the stacking errors could be done by multiplying them by
235 a constant factor. In the present case, this factor could be equal to 2.4 which is the ratio between the median reciprocal errors
and the median stacking error. The effect of increasing the electrode spacing on data quality is also apparent in the distribution
of the percentage stacking errors. The deeper data show, on average, higher percentage stacking errors.

A preliminary filter stage was performed by discarding measurements with an associated percentage reciprocal error larger
than 40%. Most of the discarded data were localized in the surficial part of the pseudosection, between 300 m and 500 m along
240 the profile. An additional filtering stage was based on the observation of resistivity data as a profile plot. Data characterized
by abrupt resistivity variations and negative apparent resistivity values, probably due to the existence of large resistivity
contrasts (Lee & Cho, 2020), were also filtered out. In total, almost 10% of the original data was excluded during the filtering
stages with the filtered dataset characterized by a mean percentage reciprocal error of about 6%.

A similar procedure was repeated on the starting (unfiltered) dataset discarding measurements with an associated stacking
245 error larger than 15% and characterized by abrupt resistivity variations and negative apparent resistivity values. In total, almost
6% of the original data was excluded during the filtering stages with the filtered dataset characterized by a mean percentage
reciprocal error of about 2.5%.

The two adopted thresholds for the preliminary filtering stages (percentage reciprocal error larger than 40% and stacking error
larger than 15%) have been chosen on statistical basis in order to include all data whose errors were in the range [mean error
250 (percentage or stacking) $\pm 2\sigma$ (standard deviations)].

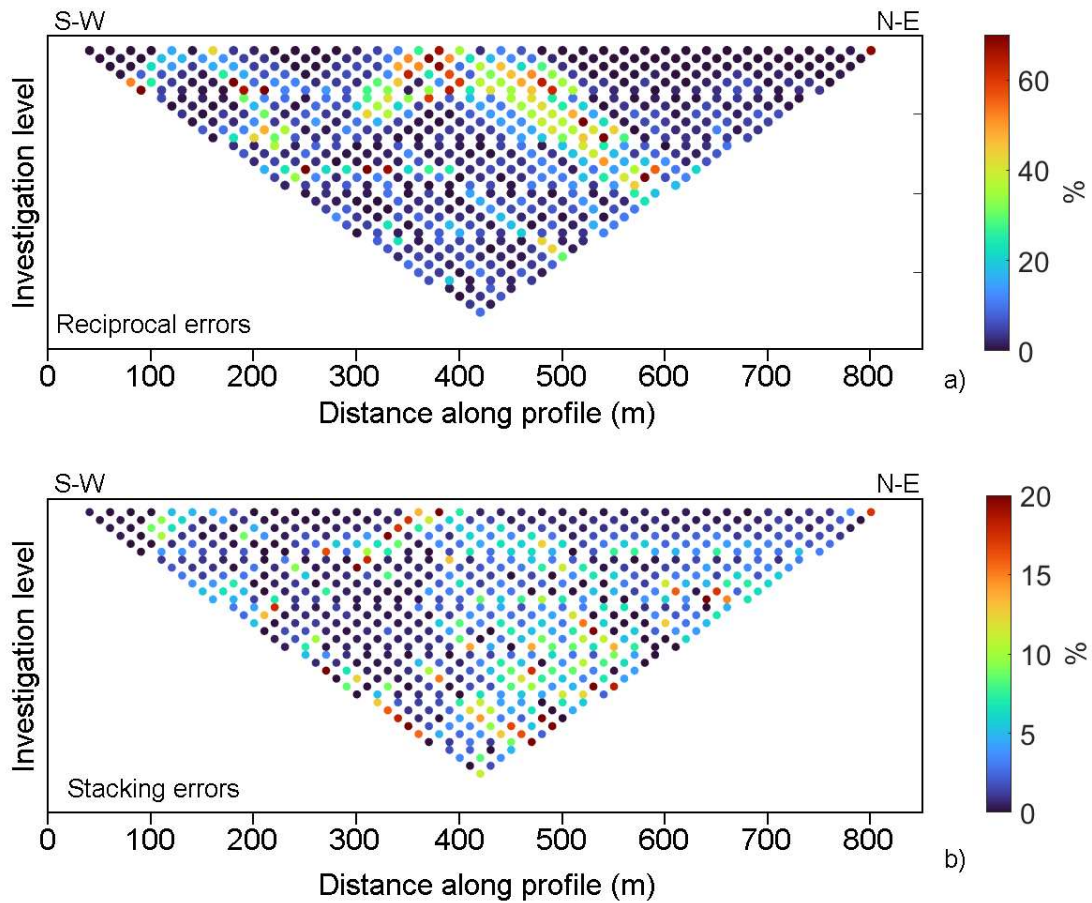

Figure 2: Panel a): distribution of the reciprocal percentage errors. Panel b): distribution of the percentage stacking errors calculated on DD direct measurements. The error magnitude is given by the colour scale placed on the right side of each panel. Note that the limits of the two-colour scales are different.

Finally, topographical information was included into the dataset which was inverted with RES2DINV program (Geotomo Software, Loke & Barker, 1996). The resistivity models presented in what follows were obtained by using a L2 norm and directly inverting the apparent resistivity values that better converged.

The two models presented in figure 3 show the inversion results obtained including in the inversion procedure both the reciprocal errors (fig. 3, panel a) and the stacking errors (fig. 3, panel b). The use of reciprocal errors in the inversion procedure leads to a model with a low RMS value (4.8%) and with resistivity contrasts smoother than those visible in the model with the stacking errors which, being smaller than the reciprocal ones, also influenced the final RMS errors (9.9%). Generally, the models show a similar pattern of resistivity distribution within the subsoil where:

- the SW part of the section is more resistive than the NE one

- a highly conductive surficial anomaly placed between 300 and 400 meters (horizontal distance) in the area less constrained by the data due to filtering operations
- a shallow highly conductive zone below the mud volcanoes, which is characterized by a lateral variability
- an intermediate relatively resistive layer, which appears to be more continuous in the model obtained by integrating the stacking errors
- two deep conductive zones placed on the SW and NE bottoms of the sections

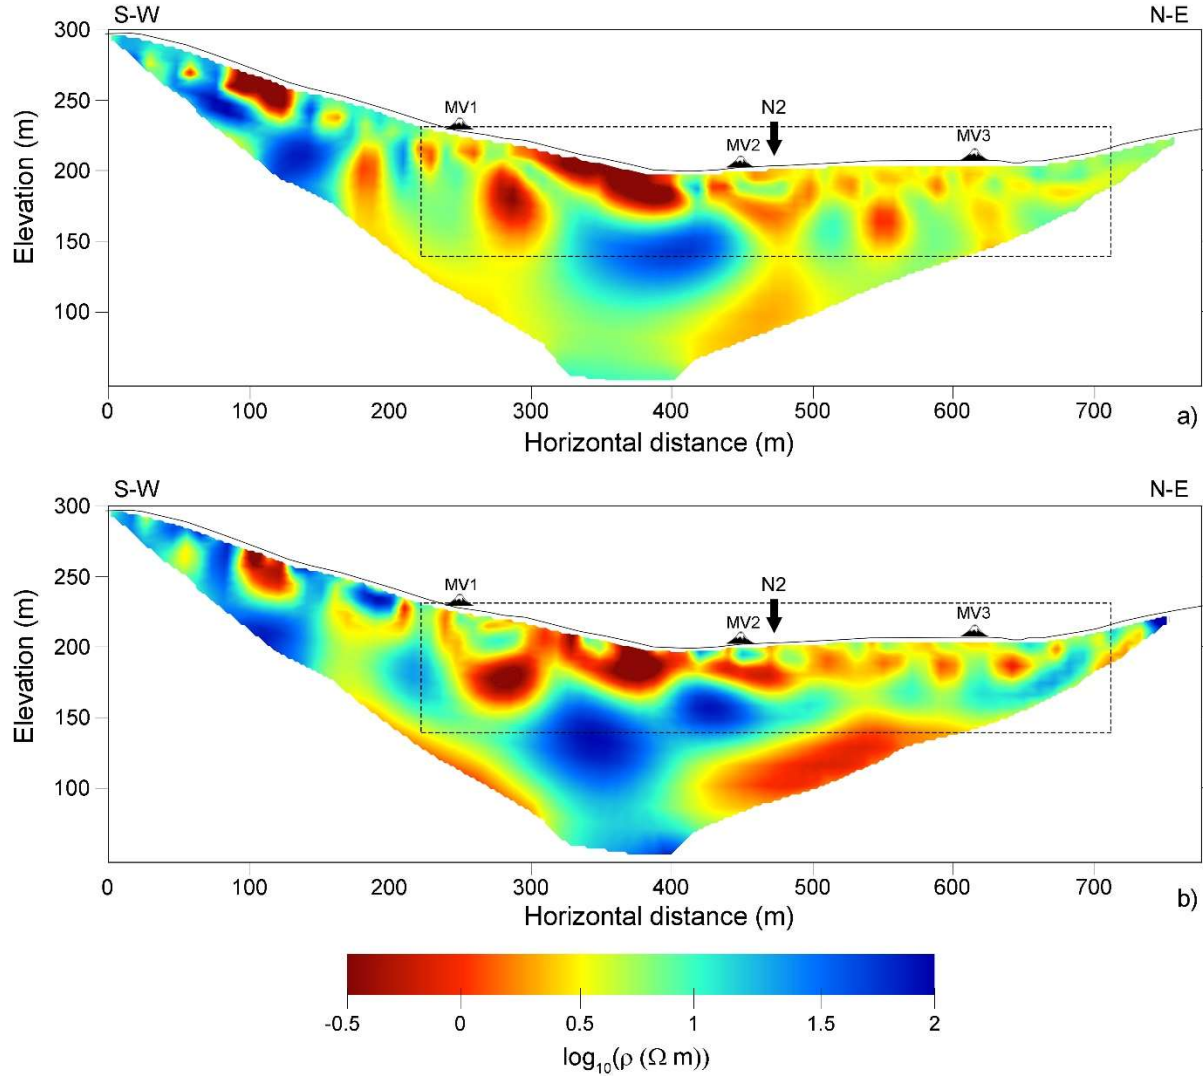

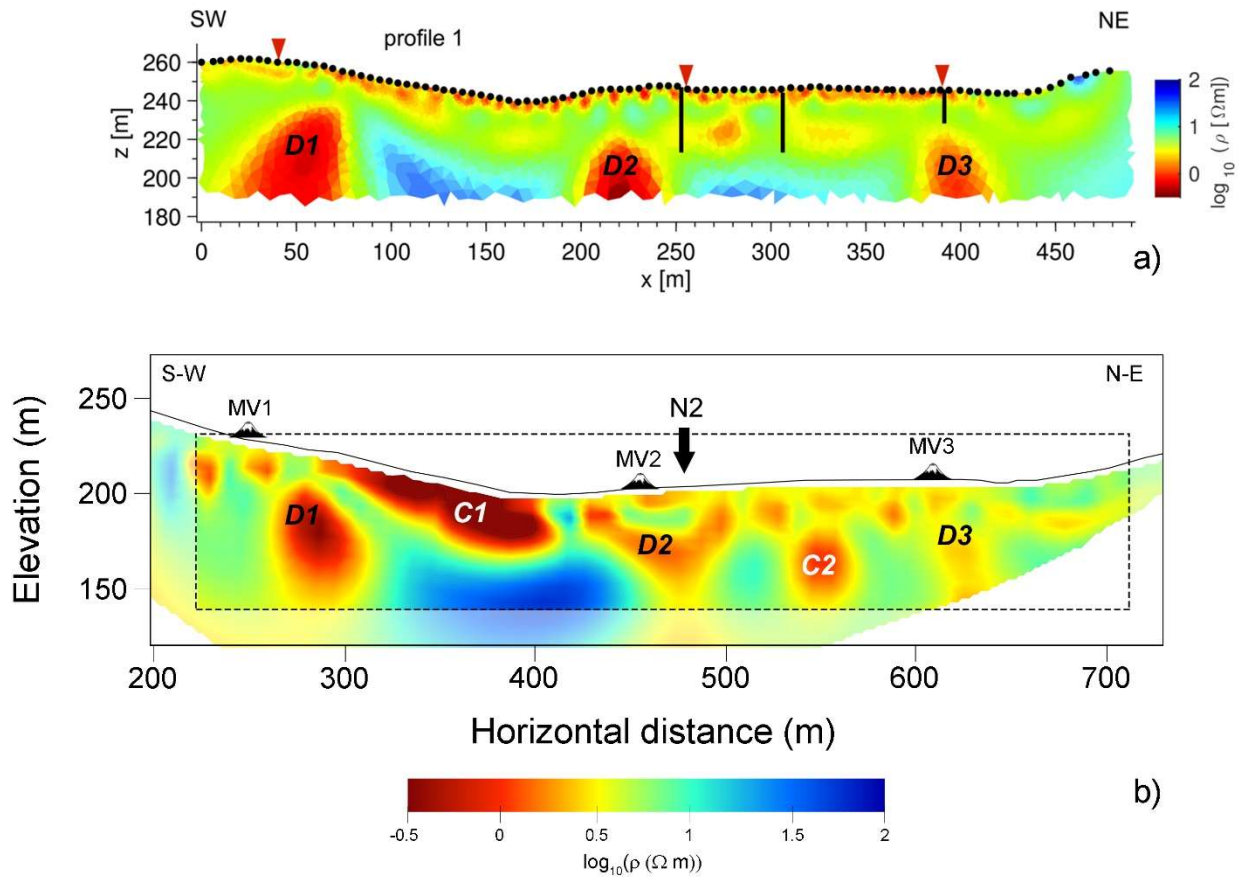

Figure 3: Resistivity models obtained integrating error estimates: panel a) reciprocal errors; panel b) stacking errors. The two model are presented with the same colour scale. In the sections, it is also reported the location of the mud volcanoes (MV1, MV2 and

275 **MV3), the crossing point between the ERT_N1 geoelectrical profile and the ERT_N2 ones (black arrow with the N2 label) and the**
280 **subsoil portion investigated by Lupi et al. (2016) (identified by a black dashed line).**

Considering the similarity between the two models and assuming a higher reliability level for the one obtained by integrating
the reciprocal errors, a comparison with Lupi et al. (2016) results is presented in figure 4. The colour scales adopted are similar
280 although not the same; the differences, in any case, are not relevant for the sake of a visual comparison of the tomographic
results. Furthermore, the elevation information in Lupi et al. (2016) ERT is not correct because it is upward shifted of about
30 m. Generally, the two resistivity distributions can be considered consistent in the limits of their different spatial resolution,
of their investigation depth, and of the time span intercurrent between the two datasets acquisition (November 2012 for Lupi et
al., 2016, dataset, February 2022 for the dataset here presented). The presence of the “conductive domes” in Lupi et al., (2016)
285 section, marked with the capital letter “D1-3” in figure 4, is here confirmed as well as the existence of more resistive areas
between them. The main differences are related to the conductive areas placed respectively a) in the shallow portion (20 m
from the surface) of the resistivity image between mud volcanoes 1 and 2 (marked with the capital letter “C1”) and b) in the
elevation range 150-180 m a.s.l. between volcanoes 2 and 3 (marked with the capital letter “C2”). The first one (C1) may be
an artifact of the inversion procedure and not a real feature of the subsoil. As already discussed in presenting figures 2 and 3,
290 data involved in the inversion procedure that led to the conductive anomalies are those characterized by the largest
experimental errors, both reciprocal and stacking. The same it is not true for the second conductive anomaly (C2) which can
be considered representative of a real condition of the subsoil that was probably not existing in 2012 when Lupi et al., (2016)
surveys were performed.

295 **Figure 4: comparison between Lupi et al. (2016) resistivity model (panel a) and the corresponding portion of the ERT_N1 DD resistivity model (black dotted line in panel b). The elevation information as well as mud volcano positions slightly differ in the two models. The meaning of the capital letters D1-3 and C1-2 is described in the text.**

3.2.1.2 Wenner-Schlumberger and Pole-Dipole data inversion.

300 As previously specified, for these datasets only stacking errors are available. The integration of the stacking errors in the inversion procedure, the lower noise level which usually characterize these geoelectrical array data, and the comparison with the DD inversion results are deemed to be sufficient to evaluate the reliability of the resistivity models.

As for DD data, the inversion procedure was preceded by the analysis of the contact resistances (Fig. 5, panels a and c) and of the stacking error spatial distributions (Fig. 5, panels b and d). The WS dataset is characterized (Fig. 5 a and c) by low contact resistances and low stacking error values almost uniformly distributed along the profile and in depth (differently from what observed for the DD dataset). The P-DD dataset had an electrode with a bad contact resistance (as highlighted by the two “red bands” in fig. 5 panels b and d). The P-DD data were acquired soon after the WS data which show no evidence of bad

305

resistivity contact. Thus, the observed worsening of the contact resistance is probably due to a tourist in the area who unplugged one of the electrodes. The stacking errors amplitude distribution agrees with the measuring conditions. Negative data were also removed from the maps in figure 5.

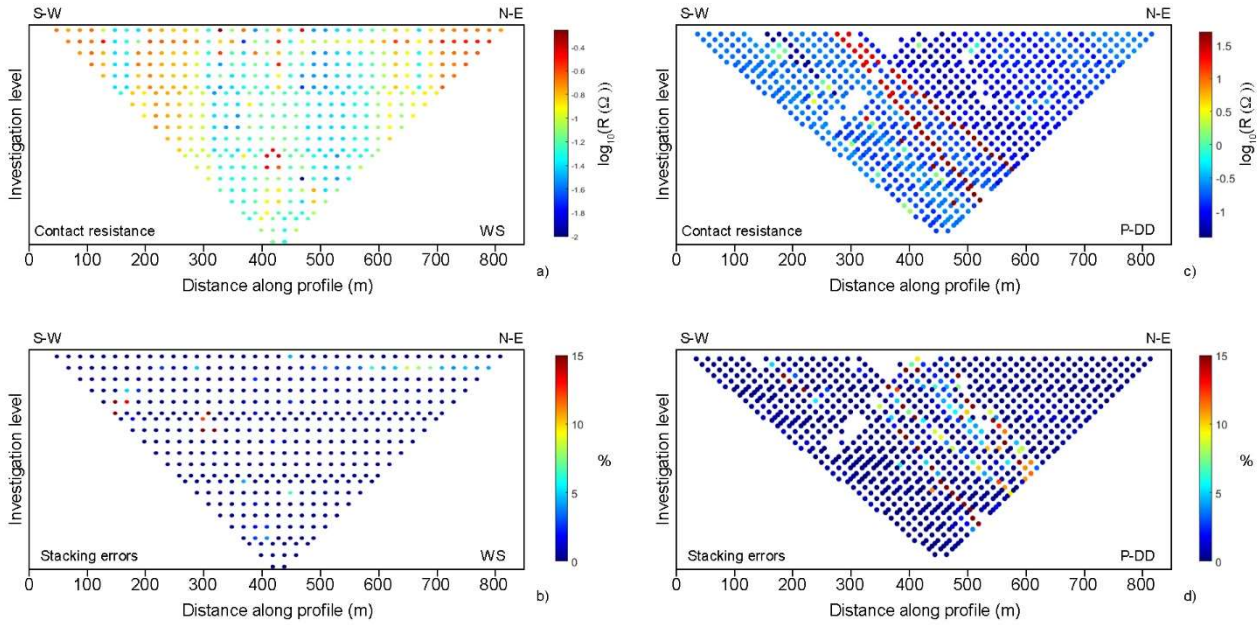

Figure 5: Panel a): distribution of the contact resistances related to the WS dataset. Panel b): stacking errors distribution of the WS dataset. Panel c): distribution of the contact resistances related to the P-DD dataset. Panel d): stacking errors distribution of the P-DD dataset. The contact resistances and error magnitude can be read on the colour scale placed on the right side of each panel. Note that, for the contact resistances, the limits of WS and P-DD colour scales are different. In the P-DD panels, the lack of dots in some area of the distribution is due to the presence of negative resistivity data which were filtered out from the dataset used for creating the figure.

The datasets were then filtered by eliminating data associated with a percentage stacking error higher than 5%. This procedure removed less than 5% of the data for the WS dataset and less than 7% of the data for the P-DD dataset. The inversion results are shown in figure 6 along with the DD model previously shown in figure 3 (upper panel).

Considering the differences in terms of sensitivity and vertical/horizontal resolution of the three adopted electrodic configurations, the resistivity models (Fig. 6) show a general agreement both in terms of resistivity contrast and spatial distribution of the electrical properties in the subsurface with an investigation depth which, in the P-DD model, goes down to -50 m b.s.l..

For distances along the profile < 300m and >400m, the P-DD and the DD model images a similar resistivity distribution within the subsoil. In this ranges, differences can be noticed between P-DD and DD models and the WS one. We retain that these differences can be ascribed to:

- 330 - the different sensitivity of the arrays to lateral resistivity variation (much higher in the P-DD and DD than in the WS) and the substantial difference in data spatial coverage (DD and P-DD have a higher data coverage than WS, see figure 5). This, for example, may explain what imaged by the datasets just below MV1 (figure 6). Here, the WS model depicts the presence of a unique conductive body while P-DD and DD (with reciprocal errors) show the presence of two smaller conductive nucleus.
- 335 - Different investigation depth. The P-DD has an investigation depth which is almost two times the one of the WS. Thus, resistivity anomalies recovered at the bottom of the WS model are less reliable due to the lack of data in the deeper portion of the section. For example, the resistive nucleus depicted in the WS at about 180m along profile extends up to the lower limit of the sections. In the P-DD model, the same resistivity anomaly is confined at shallower depth and overlays a conductive area (not imaged by the WS due to the lack of deeper data).
- 340 DD and P-DD are differs in the area between 300 and 400 meters (horizontal distance) (magenta dashed rectangle in Fig. 6). Here, the conductive surficial layer in the DD ERT is replaced both in the P-DD and in the WS by a less extended and less conductive area whereas the deeper resistive area visible in the DD is divided in two by a conductive anomaly (more continuous in the P-DD image). WS, as emerged by the analysis of the stacking error distribution, is the only dataset which does not show any error value increase in this area. This condition ensures reliability of the resistivity distribution imaged in this area by the
- 345 WS model and, by similarity, also by the P-DD model.

For this reason, the geological and structural interpretation of the geoelectrical model will be performed on the P-DD one.

- Before proceeding with the geological interpretation of the model, an additional test was performed to check if the use of an amplified stacking error, with an amplification factor of 2.4 (see section 3.2.1.1), could produce relevant modifications of the inversion results. Keeping unchanged the filtering procedure and considering the staking error distribution (figure 5), the
- 350 inverted WS dataset (with amplified errors) was composed by the same measuring points of the one used to obtain the model of figure 6 (central panel). Thus, no additional data were filtered out. The inversion produced a “new” WS resistivity model (not shown here) that has lower rms compared to the model shown in figure 6 (central panel) but which is really similar to it with no relevant changes observable. As regard the P-DD datasets, by amplifying the stacking errors and keeping unchanged the filtering rules, a larger number of data was filtered out especially in the central and shallow part of the section. The “new”
 - 355 resistivity model (not shown here) is hence almost equal to the one shown in figure 6 (lower panel) except for the shallow part between 300m and 400m along the profile. In this area, the conductor is more pushed toward the surface. Also in this case, like for the WS, the main features of the model do not vary significantly. We can hence conclude that, at least in this case, the stacking errors amplification does not modify in a relevant way the inversion results provided that the inverted dataset is unchanged. If the staking error amplification produces, like happened for the P-DD dataset, a dataset reduction (due to the

360 adoption of filtering rules), modifications are observed. In this case, the more data are discarded the greater the inversion result difference will be.

365 **Figure 6: profile ERT_N1: resistivity models obtained by inverting the DD dataset (upper panel), the WS dataset (middle panel) and the P-DD dataset (lower panel). All models are presented by using the same colour scale. The position of the mud volcanoes (MV1, MV2 and MV3) along the profile is marked on top of each section along with the indication (vertical black arrow) of the crossing point between the section ERT_N1 and the section ERT_N2. The magenta dashed rectangles indicate the area of higher dissimilitude between the tomographic results. The dotted and dashed lines reported on the P-DD section represent the subsurface area investigated by the WS and DD sections, respectively.**

3.2.2 ERT_N2 profile

For the ERT_N2 profile, it was adopted the same approach used for ERT_N1 profile except for the comparison with previous/independent geophysical data. In Lupi et al. (2016), in fact, several profiles oriented as ERT_N2 are presented but they have a higher spatial resolution and lower investigation depth with respect to ours, to be used as a reference point for a fruitful comparison. For the DD dataset, the mean percentage reciprocal error is 8.3% while the mean percentage stacking error is 4.4%. By integrating the two different error types in the inversion procedure, similar results, in terms of resistivity distributions, came out (not shown here). The reliability of the resistivity models is also ensured by the similarities between DD models and WS and P-DD ones (Fig. 7). All models show the presence of strong resistivity contrasts from 300 m (horizontal distance) till the end of the profile. In all models and in their central portion, a uniformly high resistive area is visible which, as it emerges from the DD and from the P-DD sections, is confined in depth down to ~100 m a.s.l.. As before discussed for the ERT_N1 profile, DD and P-DD are more sensitive to horizontal resistivity variations and, hence, depict a more detailed resistivity distribution. For this reason, the geological and structural interpretation of the geoelectrical model will be performed on the P-DD one.

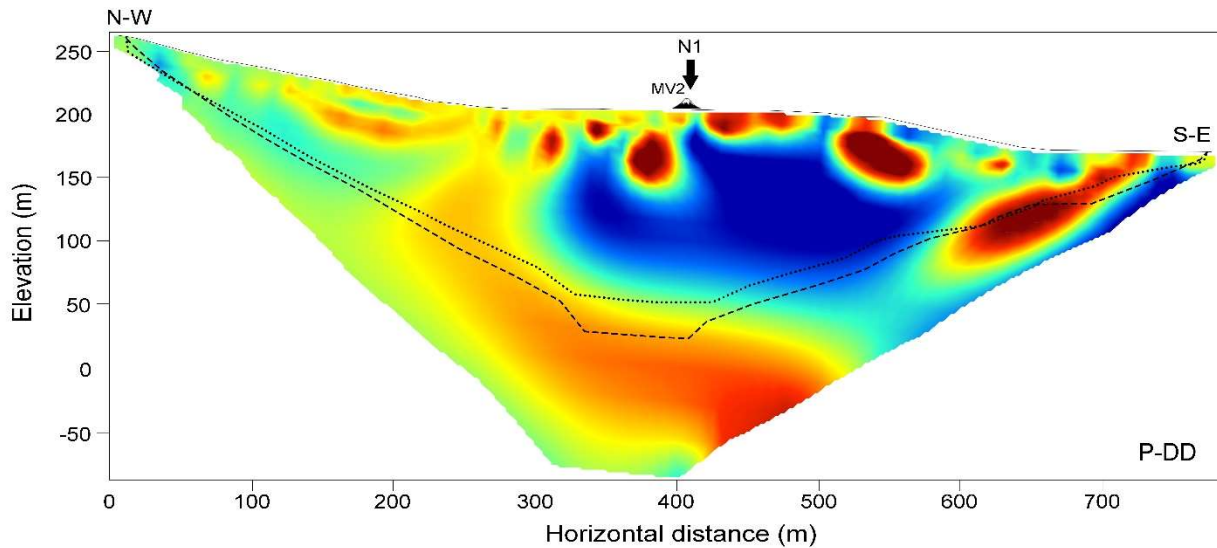

Figure 7: profile ERT_N2: resistivity models obtained by inverting the DD dataset (upper panel), the WS dataset (middle panel) and the P-DD dataset (lower panel). All models are presented by using the same colour scale. The position of the mud volcano MV1, placed off profile at about 20 m from the ERT_N2 trace, is marked on top of each section along with the indication (vertical black arrow) of the crossing point between the section N2 and the section N1. The dotted and dashed lines reported on the P-DD section represent the subsurface area investigated by the WS and DD sections, respectively.

3.2.3 3D visualization of the ERT profiles

The spatial continuity of the two tomographic results and a clearer image of the resistivity distribution within the subsoil can be obtained by simultaneously plotting ERT_N1 and ERT_N2 (fig. 8). This operation shows a good match between N1 and N2 with a quite good consistency between the two resistivity distributions in the common investigated portion of subsoil. Figure 8 also reveals how the Northern sector of the Nirano Salse area strongly differs, in term of resistivity distribution, from the southern one. To the North, the subsoil is more homogeneous and generally conductive ($\rho < 10 \Omega\text{m}$). To the South, strong resistivity contrasts (both lateral and vertical) characterize the resistivity sections. Mud volcanoes are generally located over conductive anomalies.

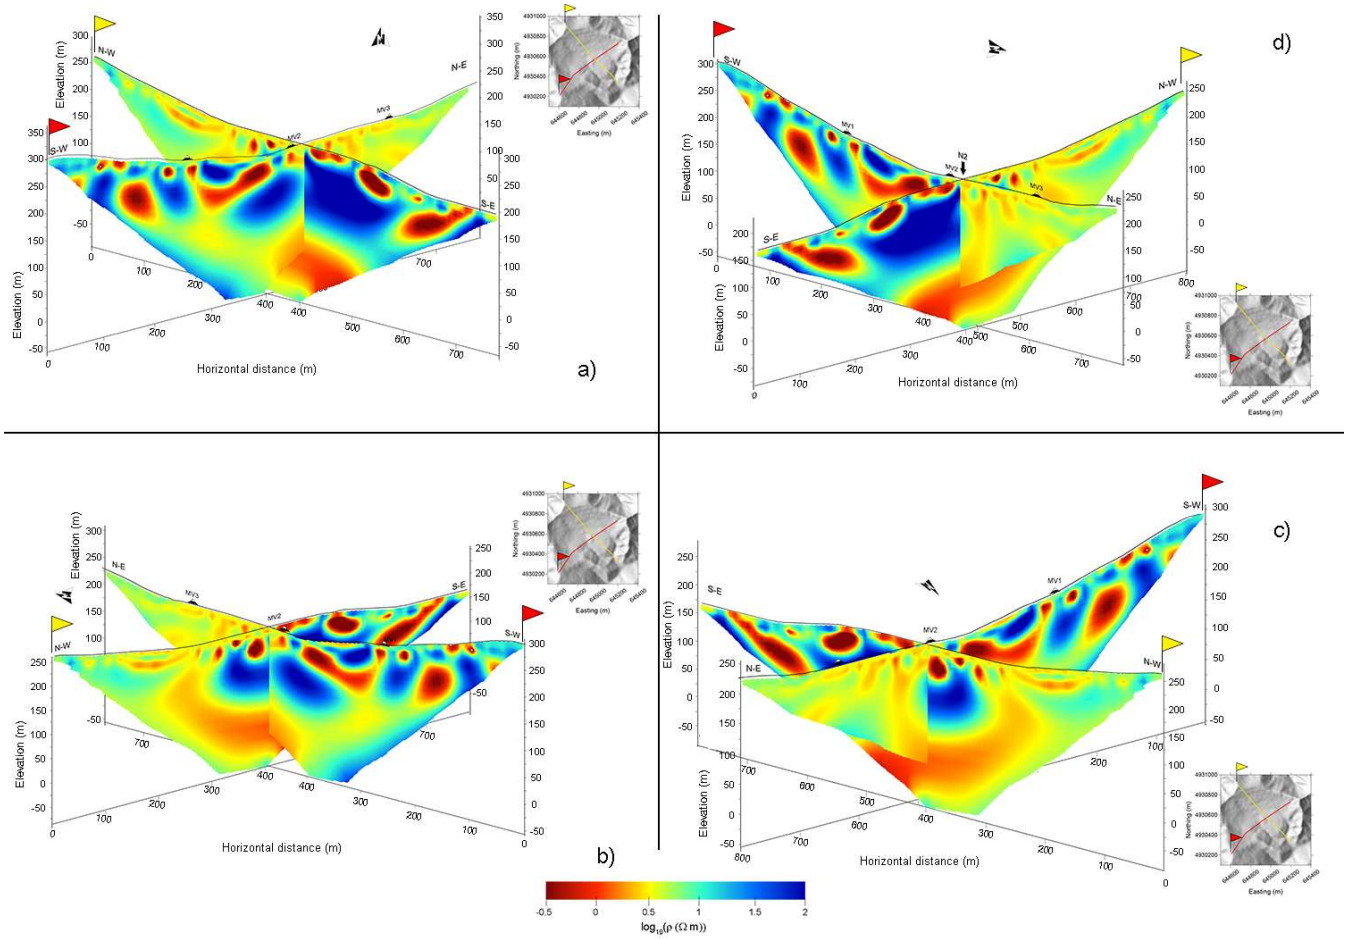

Figure 8: 3D arrangements of the tomographic results. Starting from panel a) a counter clockwise rotation of the tomographic result is performed. The yellow and red flags on top of each section indicate the starting point of the geoelectrical surveys. The inset in each panel shows the location of the survey.

4 Geological model

The interpretation of the two geoelectric pole dipole profiles (Fig. s 9 and 10) presented in this study allows to shed some light on the structural setting of the Nirano area and propose a novel geological model that can account for the position of the vents, their activity, and the morphology of the area.

410 The resistivity features recovered by the presented models will be discussed in terms of i) geological boundaries, ii) mechanical conditions (in terms of fracture presences), iii) fluid presence, and iv) fluid compositions.

The Miocene marly rocks and the Argille Azzurre (Pliocene FAA), the most relevant geological units expected in the area, are characterized by a different electrical fingerprint with the former generally more resistive than the latter. Fluid presence can affect the measured resistivity in a more complex way. On a first approximation, a gas phase is expected to enhance resistivity whereas a liquid phase electrical signature depends on the liquid type; saline fluids lower the resistivity whereas hydrocarbons, for example, have the opposite effect.

4.1 SW-NE ERT1 section

The SW-NE ERT1 section is characterized by the presence of a shallow conductive layer (2-10 Ωm) that is associated to the Argille Azzurre outcrop (FAA). The SW portion of the model shows strong resistivity contrasts (ranging from 0.3 to 80 Ωm) down to about 50 m of elevation a.s.l. (from 0 to about 450 m of distance along profile); the alternating resistivity anomalies often assume a subvertical elongated shape. In contrast, the NE portion of the model is mostly conductive (ranging from 2 to 20 Ωm) with a layered structure. It is worth noting that the passage between these two different resistivity distribution domains occurs in correspondence of the axis of a monocline or of a fault (horizontal distance about 500 m, grey shaded rectangle in Fig. 9 labelled as “F”) that may be related at depth to the structural trap for fluid accumulation (Bonini, 2007).

We interpret the subvertical resistivity contrast present towards SW as faults that spatially well corresponds at faults inferred also by other authors (Bonini, 2008) (red arrows in Fig. 9). These faults slightly offset the base of the FAA represented with the thick dashed red line (Fig. 9).

The conductive layered structure toward NE is interpreted as the presence of multiple aquifers (low resistivity areas, indicated in figure 9 by blue dashed lines), that well agree with the presence of sandy turbidite deposits in the FAA (Castaldini et al., 2017; Giambastiani et al., 2022) and are locally interconnected between vents MV2 and MV3.

A shallow sub-horizontal connection also exists between vents MV1 and MV2 (labelled as “C”) in Fig. 9), although characterized by lower resistivity values. These very low resistivity values (as low as 0.3 Ωm) nearby MV1 and MV2, were also imaged by the shallow ERT model presented by Lupi et al. (2016) and were interpreted to reflect the presence of high-salinity fluids. This interpretation, however, is not supported by recent fluid conductivity measurements performed directly in situ at some vents (Giambastiani et al., 2022; Oppo, 2011; Oppo et al., 2013) with conductivity values ranging between 10 to 21 mS/cm (that correspond to a resistivity value ranging 0.5 to 1 Ωm) typical of brackish water.

To justify the observed low resistivity values at depth, it is hence required to add at least another conductivity phase (Glover & Hole, 2000). We explore two possibilities. The first one is clay content and surface conductivity phase. In saturated soil, electrical current flow by means of ions that are present in the saturating fluid (brine). If the grain size is very small, such as in clay, electrical current will easily flow through the pore fluid making it less resistive. Particle size distributions of mud samples collected in some of the gryphons (Giambastiani et al., 2022) support this the extra conduction phase as they indicate the presence of about 35% of clay, 56% of silt, and remanent of sand. The second possibility to be considered is the presence of iron sulphides (pyrite) due to precipitation of hydrogen sulphide (H_2S). Supporting this condition is the low amount of H_2S at surface both among the emitted gas and solutions since it can precipitate as iron sulphides due to the largely available iron

445 in the siliciclastic sedimentary units (Oppo, 2011; Oppo et al., 2013). Thus, we can interpret the very low resistivity anomaly
 “C” as very shallow reservoir hosting brackish water and where one of the above-mentioned conductivity phases is acting.
 The subvertical low (NE) (“F” in Fig. 9) and very low resistivity (SW) (“C” in Fig. 9) anomalies, here interpreted as favourable
 routes for fluid uprising, converge deeply (above 50 m elevation) towards a common deep conductor (“D” in Fig. 9). This
 common conductive zone may represent the Cigarello Fm clay unit (Gasperi et al., 2005).

450

Figure 9: interpreted ERT_N1 profile. The capital letter “C” shows the location of the conductive anomalies associated to favourable routes for fluids uprising. The capital letter “D” shows the location of the common conductive zone possibly representing the Cigarello Fm clay unit. The capital letter “F” indicates the area probably associated to a fault zone.

455

4.2 NW-SE ERT2

The NW-SE ERT2 section (fig. 10) is almost parallel to the axis of the anticline. In this section, we also observe a relevant heterogeneity in resistivity distribution. Like in the NE-SW ERT1, the NW portion of the section is regular and shows the presence of a sub-horizontal stratification, which may indicate the presence of several aquifers (blue dashed lines in fig. 10).
 460 The SE portion of the model shows more enhanced resistivity contrasts as the SW portion of the of ERT1 model, but with a less complex pattern. The transition between the more regular NW portion and the more heterogeneous SE is spatially

coincident with the presence of the fault zone (two central red arrows in fig. 10) also described in ERT1, which forms a small angle with this section. Indeed, down to 50 m of elevation, local shallow conductive zones are hosted in a resistive layer that is sharply interrupted in the S-Easternmost area, at about 650 m along profile, where we infer the presence of a fault (blue arrow) whose surface intersection is located near a dry gas seep (yellow arrow in fig. 10). This fault may be related a NE-SW trending faults that are strike-slip transfer structures reported by Gasperi et al.,(2005) in this area (blue arrow in fig. 10). Thus, we interpret the resistive layer as the Termina marls and Pantano Fm (Miocene) unit hosting local conductive anomalies associabile to very shallow fluid reservoirs. In the deeper part of the model, along the whole profile, a deep conductor gently dipping towards SE is imaged. This conductive zone spatially well coincides with the one recovered in ERT1, and thus is interpreted as the Cigarello Fm claystone (Gasperi et al., 2005).

Figure 10: interpreted ERT_N2 profile. The capital letter “C” shows the location of the conductive anomalies associated to favourable routs for fluids uprising.

Summing up, the resistivity features recovered by the two models well matche in the intersection area. Interestingly, an undisturbed layered system characterizes the norther sector (NW and NE) of the Nirano area in contrast to a more heterogeneous (SE) and even chaotic (SW) resistivity distribution in the southern sector. These major heterogeneities are located just where also the “bowl” morphology is irregular: in the SE corner a small creek cuts across the rim and two relatively NW-SE oriented steep ridges border the southwestern flank of the circular structure. It could be speculated that regional NW-

480 SE and NE-SW oriented faults interacting and interfering with each other contribute to the formation of the geomorphological
bowl. The tomographic images, in fact, suggest the presence of linear faults and fracture zones and not of circular structures
as previously speculated by Bonini (2011) and Sciarra et al. (2019). These are important observations, because they do not
support a gravitational collapse of the “bowl” area as previously assumed. On the other hand, the deepest parts of both models
485 (below 70 m elevation) share a common conductive feature, associated with a clayey horizon (Cigarello Fm) that may act as
an impermeable horizon for deep uprising fluids. These deep fluids can reach the surface only where the fault zone break this
sealing unit allowing for gas and mud venting at the surface.

5 Conclusions

The geophysical investigation performed in the Nirano Salse provided new information on their deep structure. The pole-
490 dipole geoelectric sections showed the existence of different structural conditions in the bowl-shaped morphology of the area.
The Northern sector of Nirano subsurface seems to be characterized by a regular vertical stratification which can be associated
to the presence of multilayer aquifers within the Argille Azzurre Fm. The Southern sector, on the contrary, is dominated by
the presence of subvertical discontinuities which can be associated with faults and fracture zones. In the geoelectrical sections,
conductive zones can be associated to fluid accumulation areas. Fluid presence, however, is not sufficient to justify the
495 extremely low resistivity values observed in both sections. We suggest that the low resistivity values may be associated with
i) clay content and surface conductivity phase and/or ii) presence of iron sulphides (pyrite) due to precipitation of hydrogen
sulphide.

Regardless of what the explanation for the observed resistivity values is, the areas containing fluids (gas and water) are in the
shallow portion (50-100 m) of the subsoil and in correspondence with the main mud volcanoes. It is therefore reasonable to
500 assume that these fluid accumulation zones constitute the surficial reservoirs of volcanoes. Larger scale of investigation
geophysical survey could disclose the existence of a deeper fluid storage and its relationship with these shallow, and localized
reservoirs. The shallow fluid reservoirs have a relatively small volume, and they are sparse in the sections clearly showing that
there is not a shallow fluid caldera below the Nirano Salse. This observation has important implications for the safety of the
site. The most hazardous area, in fact, are those closer to the mud vents where the shallow small reservoirs are located and not
505 the whole area of the “bowl”. This could help pinpoint the routes for tourists’ access and fence out areas of potential
liquefaction and mud eruption. This methodology for assessing local hazard could be extended to other mud volcanoes areas
around the world.

The geoelectrical sections also highlighted the presence of faults, which are linear features oriented as most of the structures
in this sector of the Apennines (NW-SE) and not circular collapse rim faults as previously thought. Likely, they provide
510 gas/fluid flow routes from deep sources to the shallow reservoirs and finally to the mud volcanoes. A relevant example can
be the major fault zone in the central portion of ERT_N1, which could be thought as the main pathway for the fluids and gas

to reach the surface from their deep reservoirs (located out of ERT investigation depth limit). This major fault zone also offsets down-to-the-NE the Argille Azzurre Fm (FAA) and it accommodates deformation along the monocline flexure, which is well exposed north of the Nirano Salse.
