Abstract

New particle formation (NPF) and subsequent particle growth are important sources of condensation nuclei (CN) and cloud condensation nuclei (CCN). While many observations have shown positive contributions of NPF to CCN at low supersaturation, negative NPF contributions were often simulated in polluted environment. Using the observations in a typical coastal city of Qingdao, we thoroughly evaluate the simulated number concentrations of CN and CCN using a NPF-explicit parameterization embedded in WRF-Chem model. In terms of CN, the initial simulation shows large biases of particle number concentrations at 10–40 nm (CN_{10-40}) and 40–100 nm (CN_{40-100}). By adjusting the process of gas-particle partitioning, including mass accommodation coefficient of sulfuric acid, the phase changes of primary organic aerosol emissions and the condensational amount of nitric acid, the concomitant improvement of the particle growth process yields a substantial reduction of overestimates of CN_{10-40} and CN_{40-100} . Regarding CCN, SOA formed from the oxidation of semi-volatile and intermediate volatility organic vapors (SI-SOA) yield is an important contributor. In the original WRF-Chem model with 20 size bins setting, the yield of SI-SOA is too high without considering the differences in oxidation rates of the precursors. Lowering the SI-SOA yield results in much improved simulations of the observed CCN concentrations. On the basis of the bias-corrected model, we find substantial positive contributions of NPF to CCN at low supersaturation ($\sim 0.2\%$) in Qingdao and over the broad areas of China, primarily due to the competing effects of increasing particle hygroscopicity surpassing that of particle size decrease. This study highlights the potentially much larger NPF contributions to CCN on a regional and even global basis.

66 **1. Introduction**

67 New particle formation (NPF) is a process in which gaseous vapors nucleate and
68 form critical molecular clusters, followed by subsequent growth to larger sizes
69 through condensation and coagulation (Kulmala et al., 2004; Kulmala et al., 2013;
70 Lee et al., 2019). Newly formed particles could effectively grow into the size of cloud
71 condensation nuclei (CCN) under certain supersaturation (SS), which exerts an impact
72 on the cloud microphysical process and global radiation balance (Merikanto et al.,
73 2009; Gordon et al., 2017; Kerminen et al., 2018; Ren et al., 2021). In addition, the
74 efficient nucleation and explosive growth of particles may contribute to the formation
75 of haze (Guo et al., 2014), affecting air quality and human health (Yuan et al., 2015;
76 Chu et al., 2019; Kulmala et al., 2021).

77 The overestimate of condensation nuclei (CN) in numerical models are
78 commonly seen, despite the attempt to rectify the bias (Matsui et al., 2013; Arghavani
79 et al., 2022). It is a common way to reduce the nucleation rate which may reduce the
80 particle number concentration in proportion (Matsui et al., 2013). For instance, in the
81 study of NPF in East Asia in the spring of 2009, even after lowering the nucleation
82 rate in a regional model of WRF-Chem applied in their study, the reduced number
83 concentration of particles at 10–130 nm remained to be overestimated (Matsui et al.,
84 2013). Using the same regional model and a similar method to reduce the nucleation
85 rate, Arghavani et al. (2022) found particle number concentration at 10–100 nm was
86 still overestimated by nearly one order of magnitude, despite the effectiveness to
87 reduce the overestimates for the smaller particles such as 2.5–10 nm. In addition to the
88 rate of NPF, the growth process of particles also has a crucial effect on particle
89 number concentration and size distribution. In this process, the condensation of some
90 chemical species such as sulfuric acid, nitrate and organic gases on particles plays a
91 major role in particle growth (Yao et al., 2018; Lee et al., 2019; Li et al., 2022), and
92 the uncertainty of their condensation amount may lead to the bias of CN simulation.

93 In addition to CN, there are large discrepancies in the predicted CCN between
94 the numerical models and observational results. Furthermore, as an important source
95 of CCN (Merikanto et al., 2009), the contribution of nucleation to CCN quantified by

96 numerical models is also highly uncertain. For example, in terms of predicting CCN,
97 Fanourgakis et al. (2019) evaluated the CCN concentrations simulated by 16 global
98 aerosol–climate and chemistry transport models with observations at 9 sites in Europe
99 and Japan from 2011 to 2015, and found that all models underestimated CCN
100 concentrations with a mean normalized mean bias of -36% at low supersaturation
101 ($SS=0.2\%$). WRF-Chem models also tend to underestimate the contribution of NPF
102 on CCN, especially at low supersaturation. The continuous observation of CCN
103 concentrations throughout the year (July 2008–June 2009) carried out in Hyytiälä,
104 Finland, showed that under low SS, nucleation enhanced the CCN by 106% and 110%
105 at $SS=0.1\%$ and 0.2% respectively (Sihto et al., 2011). Observations acquired in
106 Beijing from July 12 to September 25, 2008, also suggested that nucleation
107 significantly increases CCN at all supersaturations, even when supersaturation is low
108 (i.e., 0.07% and 0.26%). Thus, the occurrence of NPF enhanced CCN by a factor of
109 1.7 and 2.2, respectively (Yue et al., 2011).

110 However, previous numerical experiments behave oppositely. For instance,
111 Matsui et al. (2011) quantified the contribution of nucleation to CCN using WRF-
112 chem in Beijing in August and September 2006 and found reduced CCN under low SS,
113 e.g., when $SS=0.02\%$, the concentration of CCN is reduced by up to $\sim 50\%$. They
114 attributed this to the fact that the small particles produced by nucleation may inhibit
115 the growth of the preexisting particles (Matsui et al., 2011). Similarly, Dong et al.
116 (2019) conducted NPF simulations with the WRF-Chem for the summer of 2008
117 focusing on the Midwest of the United States, and found that the nucleation resulted
118 in decreased CCN at low supersaturation ($SS=0.1\%$). Besides, a study carried out for
119 East Asia in 2009 also indicated that at low supersaturation (e.g. $SS=0.1\%$),
120 nucleation has little impact on CCN (Matsui et al., 2013). The contrasting effects of
121 nucleation on CCN at low supersaturations in model and observations is not explained
122 in these previous studies.

123 At the stage of particle growth, secondary organic aerosol (SOA) formed by
124 atmospheric oxidation of organic vapors is a major contributor to particle growth to
125 CCN-related sizes (Liu and Matsui, 2022; Qiao et al., 2021). SOA formed by multi-

126 generational gas-phase oxidation of semi-volatile and intermediate volatility organic
127 compounds (S/IVOC) is called SI-SOA (Jimenez et al., 2009; Zhang et al., 2007).
128 Zhao et al. (2016) made a comprehensive assessment of the roles of various SOA
129 precursors in SOA formation in real atmosphere in China in 2010, and the results
130 demonstrated that evaporated POA and IVOC (i.e. S/IVOC) made a significant
131 contribution to SOA, contributing up to 82% to the average SOA concentration in
132 eastern China. However, the effect of SI-SOA on CCN has not been fully studied.

133 In this paper, WRF-Chem was applied to simulate the effect of the NPF on CCN
134 in Qingdao in February 2017. The simulated results from the WRF-Chem model are
135 firstly compared with observations in Qingdao, exhibiting large biases in CN. This is
136 followed by an improvement through a few processes. At the end, the impact of SI-
137 SOA yield and nucleation on CCN is investigated.

138 **2. Data and methods**

139 **2.1 Observations**

140 The measurements used in this study were carried out over the sampling site
141 from February 5 to 24, 2017 at the campus of Ocean University of China (36°09'37"N,
142 120°29'44"E) in Qingdao, which is surrounded by residential buildings and is
143 situated about 10 km away from the city center. A fast mobility particle sizer (FMPS,
144 TSI Model 3091) was applied to measure the aerosol particle size distribution for the
145 size range of 5.6 nm to 560 nm (Liu et al., 2014b). The bulk CCN concentration is
146 measured by a cloud condensation nuclei counter at three different supersaturations
147 (0.2%, 0.4% and 0.6%) and each supersaturation lasts for 20 minutes. More
148 information about the CCN measurement can be found in Li et al. (2015). The urban
149 site in Beijing is located on the roof of the building of the Chinese Academy of
150 Meteorological Sciences (CAMS, 39°95'N, 116°33'E) in the campus of the China
151 Meteorological Administration, close to the main road with heavy traffic. The rural
152 site is Gucheng (GC, 39°08'N, 115°40'E), located in Hebei Province, surrounded by
153 farmland, and is a representative station of the severity of air pollution in Beijing
154 Tianjin Hebei region. The particle number size distribution of these two sites in the
155 range of 4–850 nm is measured by a Tandem Scanning Mobility Particle Sizer

156 (TSMPS), and more information about the instruments can be found in Shen et al.
 157 (2018).

158 **2.2 Model configurations**

159 WRF-Chem version 3.9 is used to simulate NPF events, with the main physical
 160 and chemical parameterization settings summarized in Table 1. The spatial resolution
 161 is 36 km by 36 km with 35 vertical layers and a model top at 50 hPa. The regional
 162 model simulations at a higher spatial resolution may be desirable in future when urban
 163 pollution is focused. A continuous run from February 1 to 25, 2017, was conducted,
 164 with the first five-day results as the spin-up and discarded in the analysis.

165 Table 1 WRF-Chem model configurations used in this work

Model configuration	
Microphysics	Morrison 2-moment microphysics scheme (Morrison et al., 2009)
Planetary Boundary Layer (PBL)	YSU boundary layer scheme (Hong et al., 2006)
Longwave and Shortwave Radiation	RRTMG longwave and shortwave radiation (Iacono et al., 2008)
Land model	Unified Noah Land Surface scheme (Chen and Dudhia, 2000; Tewari et al., 2016)
Cumulus	Grell-3D cumulus parameterization scheme (Grell, 1993)
Aerosol module	MOSAIC module (Zaveri et al., 2008; Matsui et al., 2011)
Gas-phase Chemistry	SAPRC-99 gas-phase chemistry scheme (Carter, 2000)

166
 167 The meteorological initial and boundary conditions are driven by Climate
 168 Forecast System model version 2 (CFSv2; (Saha et al., 2014)) reanalysis developed
 169 by National Centre for Environmental Prediction (NCEP). The initial and boundary
 170 chemical conditions of WRF-Chem are provided by Community Atmosphere Model
 171 with Chemistry (CAM-Chem; (Buchholz et al., 2019)). Anthropogenic emissions for
 172 the year of 2017 are obtained from the Multiresolution Emission Inventory for China

173 (MEIC, <http://www.meicmodel.org/>) emission dataset (Li et al., 2017; Zheng et al.,
174 2018).

175 The Model for Simulating Aerosol Interactions and Chemistry (MOSAIC) was
176 used to delineate dynamic gas-particle mass transfer to represent the condensation
177 growth of aerosol (Zaveri et al., 2008). The gas-particle partitioning of gas species on
178 particles is regulated by the mass transfer rate, which is related to mass
179 accommodation coefficient (α), a parameter involved in the model representing the
180 probability of gas molecules entering the bulk liquid phase (Pöschl et al., 1998). The
181 original setting of α for all condensing species for all size bins a in MOSAIC is 0.1
182 (Zaveri et al., 2008). In the default release of WRF-Chem, MOSAIC was
183 implemented in the sectional framework with aerosol size distributions divided into 4
184 or 8 size bins spanning 39 nm to 10 μm in diameter. To explicitly express the
185 nucleation and the growth of newly formed particles, the aerosol size range in the
186 MOSAIC module was extended from 1 nm to 10 μm , with the number of aerosol size
187 bins increased to 20 (Matsui et al., 2011; Matsui et al., 2013; Lupascu et al., 2015; Lai
188 et al., 2022). The calculation method of CCN concentration in the WRF-chem model
189 is referred to the study of Matsui et al. (2011). Based on Köhler theory, CCN
190 concentrations under the three given supersaturations of 0.2%, 0.4% and 0.6% were
191 calculated. The critical supersaturation (S_c) of each size bin in the WRF-chem model
192 was calculated by the following formula:

$$S_c = \sqrt{\frac{4 \times a^3}{27 \times r^3 \times \kappa}} \#(1)$$

$$a = \frac{2 \times \sigma}{R_v \times T \times \rho_w} \#(2)$$

193 Where α (m) is the coefficient of the Kelvin effect, κ is the volume-averaged
194 hygroscopicity, calculated using these values in Table 1, r (m) is the dry diameter, σ is
195 droplet surface tension over water (0.076 N m⁻¹), R_v is the gas constant for water
196 vapor (461.6 J K⁻¹kg⁻¹), T (K) is the air temperature, and ρ_w is the density of water
197 (1000 kg m⁻³).

198

Table 2 Hygroscopicity Parameters (κ) in the WRF-Chem Model

Species	Hygroscopicity (κ)
Sulfate	0.5
Ammonium	0.5
Nitrate	0.5
Black carbon	10^{-6}
Primary organic aerosol	0.14
Other inorganics	0.14
Sodium	1.16
Chloride	1.16

199

200 The chemical aging process of organic aerosols (OA) is modeled by the volatility
 201 basis set (VBS) approach, which was widely used in air quality models to represent
 202 complex mixtures of thousands of organic species (Donahue et al., 2006; Shrivastava
 203 et al., 2011; Chrit et al., 2018). The VBS method classifies compounds according to
 204 the effective saturation concentration (c^*), which represents the proportion of the
 205 component in the gas phase to the particle phase (Donahue et al., 2006), and species
 206 with higher c^* values are more volatile. The oxidation of highly volatile precursors to
 207 form relatively low volatile components represents the aging process of OA. OA
 208 consists of directly emitted primary organic aerosols and photochemically produced
 209 secondary organic aerosols (SOA) (Shrivastava et al., 2011). In this study, the
 210 simplified 2-species VBS mechanism was applied to the simulation of SOA, during
 211 which primary organic aerosol was represented by two species based on volatility
 212 with effective saturation concentration c^* values (at 298 K and 1 atm) of 10^{-2} and 10^5
 213 $\mu\text{g m}^{-3}$ (Shrivastava et al., 2011). Primary organic aerosols with c^* of $10^5 \mu\text{g m}^{-3}$
 214 refers to S/IVOC, which is in the gas phase under most atmospheric conditions due to
 215 its high volatility, while for those primary organic matters with c^* of $10^{-2} \mu\text{g m}^{-3}$, is
 216 treated as gas phase as well in the original model. The SOA formed by photochemical
 217 oxidation of S/IVOC precursors is called SI-SOA and the SOA formed by oxidation
 218 of VOC precursors is named V-SOA. In the simplified 2-species VBS mechanism, SI-

219 SOA (c^* of $10^{-2}\mu\text{g m}^{-3}$) is formed by the oxidation reaction of S/IVOC precursors (c^*
220 of $10^5\mu\text{g m}^{-3}$) and OH with an oxidation rate constant of $4 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$. The
221 equations for controlling the oxidation of S/IVOC precursors are as follows:

222 where POA(g) denotes primary organic aerosols with c^* of $10^5 \mu\text{g m}^{-3}$, which reacts
223 with OH to form SI-SOA(g) with c^* of $10^{-2} \mu\text{g m}^{-3}$. Subscripts c and o represent the
224 non-oxygen and oxygen parts respectively of given species and e is either the biomass
225 or anthropogenic emission sector. In addition, SVOC and IVOC emissions
226 corresponding to both anthropogenic and biomass burning emissions are derived
227 based on constant emission ratio of S/IVOC to POA (Shrivastava et al., 2011). A
228 detailed description of 2-species VBS mechanism can be found in Shrivastava et al.
229 (2011).

230 **2.3 Model sensitivity formulations**

231 Three sets of sensitivity tests are designed and listed in Table3. The purposes of
232 the three sets of experiments are as follows: (1) Adjust the condensation growth
233 process of ultrafine particles in WRF-Chem model (Base, MAC, POA, NOCD,
234 RACD, with details in Table 3).; (2) Explore the effect of SI-SOA yield on CCN
235 (Low-Yield and High_Yield); (3) Study the effect of nucleation process on CCN
236 under the change of SI-SOA yield (Low-Yield and High_Yield and their
237 corresponding cases without nucleation parameterization, i.e., Low_nucoeff and
238 High_nucoeff). Each scenario will be explained in conjunctions with the results.

246
247
248
249

Table 3 The sensitivity tests involved in this study

Purposes	Simulation scenarios	Description
Adjust the condensation growth process of ultrafine particles	Base	Simulation with the default setting with nucleation coefficient set as $2 \times 10^{-6} \text{ s}^{-1}$, the same as Lai et al. (2022)
	Mass accommodation coefficient (MAC)	It is the same as Base except that the mass adjustment coefficient (α) of gaseous sulfuric acid is adjusted from 0.1 to 0.65.
	POA emission phase (PEP)	It is the same as MAC except that the phase of POA is changed from gas phase to particle phase.
	No condensation (NOCD)	It is the same as PEP except that no NH_4NO_3 condenses on particles below 40 nm.
Explore the effect of SI-SOA yield on CCN (Explore the effect of nucleation process on CCN under the change of SI-SOA yield)	Ratio method for condensation (RACD)	It is the same as PEP except that the condensation of NH_4NO_3 on particles below 40 nm is reduced according to the ratio of acid particles to total particles reported in Wang et al. (2014).
	High_Yield	Simulation with high oxidation rate of SI-SOA formation with reaction rate constant of $5 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$
	Low-Yield	Simulation with low oxidation rate of SI-SOA formation with reaction rate constant of $2 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$

Explore the effect of nucleation process on CCN under the change of SI-SOA yield	High_NUCOFF Low_ NUCOFF	Simulations without nucleation parameterizations based on High_Yield Simulations without nucleation parameterizations based on Low-Yield

251

252 **3. Results**

253 **3.1 Observational analysis**

254 Based on the criteria (Dal Maso et al., 2005; Kulmala et al., 2012), NPF is
 255 defined as an event with the emergence of a nucleation mode with particle diameters
 256 smaller than 25 nm, lasting for 2 hours or more, followed in general by a continuous
 257 particle growth. Six NPF events were identified in February 2017 in Qingdao, on the
 258 days of 6, 9, 10, 17, 20 and 23 (Fig. 1a), yielding a frequency of ~30% and displaying
 259 a typical banana-shaped growth of particles in the particle number size distribution.
 260 Compared to a few other studies on NPF frequency in Qingdao, the results in this
 261 study are to a large extent consistent with that in the fall of 2012–2013 (30%; (Zhu et
 262 al., 2019)), slightly higher than that in summer 2016 (22%; (Zhu et al., 2019)) and
 263 lower than that in spring of 2010 (41%; (Liu et al., 2014c)). The higher frequency in
 264 spring in Qingdao is consistent with the observational results at different stations in
 265 the Northern Hemisphere in Nieminen et al. (2018).

266

267 Fig. 1. Distribution of particle number concentration. (a) Temporal evolution of
 268 particle size distributions (colored shading) and geometric median diameter (GMD;
 269 dots in black) in Qingdao on February 5-24, 2017. (b) The mean diurnal variation of
 270 CN_{10-40} (blue), CN_{40-100} (orange) and $CN_{100-1000}$ (green) composited during the NPF
 271 (solid lines) and non-NPF (dashed lines) days on February 5-24, 2017. All times are
 272 local times (LT)

273

274 During the six NPF events identified in February in Qingdao, the mean diurnal
 275 cycle of CN_{10-40} (10–40 nm) particles exhibits triple peaks (solid blue in Fig. 1b), in
 276 the morning (8:00 LT), noon (12:00–14:00 LT) and evening (19:00 LT), respectively.
 277 A comparable three-peak feature was also observed in earlier years during 2016-2018
 278 in Qingdao (Zhu et al., 2021). The morning and evening peaks of CN_{10-40} , with values
 279 of $\sim 5300 \text{ cm}^{-3}$ and $\sim 12000 \text{ cm}^{-3}$, respectively, are likely caused by the primary
 280 emissions from traffic and cooking activities (Wu et al., 2021a; Wang et al., 2022; Cai
 281 et al., 2020). The occurrence of NPF starts approximately at 9:00 am LT, accompanied
 282 by a substantial increase in CN_{10-40} compared with non-NPF days (solid vs. dashed

283 lines, in blue), yielding a peak around noon (20000 cm^{-3} during 12:00–14:00 LT). In
284 addition, larger particles (e.g., CN_{40-100} and $\text{CN}_{100-1000}$) displayed a slow or no increase
285 in the afternoon.

286

287 **3.2 Model improvement in particle number concentration simulations**

288 Particle number concentrations, primarily in two ranges of 10–40 nm and 40–100
289 nm, are commonly simulated with large biases. In the smaller size range (10–40 nm),
290 the particle number concentration is associated with NPF and particle growth. During
291 NPF, despite differences among the formation mechanisms, H_2SO_4 is considered the
292 common species (Yu, 2005; Lovejoy et al., 2004), which often suffer large biases (Cai
293 et al., 2016; Matsui et al., 2011). In the size range of 40–100 nm, the particle number
294 concentration is primarily affected by the condensation growth of particles below 40
295 nm, which is closely related to chemical components such as SOA and nitrate. Prior to
296 the evaluation of particle number concentration, we first evaluate the compositions of
297 $\text{PM}_{2.5}$ and criteria air pollutants including $\text{PM}_{2.5}$, PM_{10} , O_3 , SO_2 , CO , and NO_2 ,
298 showing relatively low biases compared to observations (section S1 and Fig. S1 and
299 Fig. S2 of the supporting information).

300

301 **3.2.1 Bias correction of particle number concentration at 10–40 nm**

302 In this study, as shown in Fig. 2, comparisons of CN_{10-40} between simulations
303 (red line in Fig. 2a) and observations (black line in Fig. 2a) results of the six NPF
304 events mentioned in the previous section in Qingdao in February 2017 indicate that
305 model overestimates CN_{10-40} with mean fractional bias of 48%. As one of the major
306 processes affecting the particle number concentration of 10–40 nm, nucleation is
307 governed by the particle nucleation rate of 1 nm particles ($\text{cm}^{-3} \text{ s}^{-1}$), which is closely
308 associated with the concentration of H_2SO_4 . For instance, in a commonly applied
309 activation mechanism, the nucleation rate calculated by $J^* = K_{\text{ACT}} \times [\text{H}_2\text{SO}_4]$. Note
310 that K_{ACT} is the nucleation coefficient considering the physical properties and
311 chemical species of nucleation process under different environments, indicating that a
312 lumped chemical species are included in the scheme reflected primarily in the

313 nucleation coefficient k , set as $2 \times 10^{-6} \text{ s}^{-1}$ based on previous studies (Sihto et al.,
 314 2006; Riipinen et al., 2007). Dong et al. (2019) simulated NPF occurring in the
 315 summer of 2008 in the United States using the NPF-explicit WRF-Chem based on the
 316 activation mechanism, which overestimated the particle number concentration at 10–
 317 63 nm by nearly doubled, even when the K_{ACT} decreased by one order of magnitude
 318 (set at a very low value of 10^{-7} s^{-1}). Therefore, it is likely that the overestimation of
 319 particle number concentration in the smaller particle size segment is probably due to
 320 the bias of simulated sulfuric acid.

321
 322 Fig. 2. Time series of (a) CN_{10-40} on NPF days, where red and blue represent Base and
 323 MAC simulation results respectively, and black represents observation results, and (b)
 324 sulfuric acid gas concentration obtained by simulation and by proxies (dark grey: Eq.
 325 5; green: Eq. 6; purple: Eq. 7; brown: Eq. 8; pink: Eq. 9; yellow: Eq. 10). All times are
 326 in local times.

327
 328 Measurement of sulfuric acid gases in the lower troposphere is challenging due
 329 to the generally low ambient concentration of sulfuric acid (10^6 – 10^7 molecule cm^{-3}).
 330 Different methods have been proposed to estimate ambient sulfuric acid
 331 concentrations based on observations such as SO_2 (Petäjä et al., 2009; Lu et al., 2019;
 332 Mikkonen et al., 2011). For instance, Petäjä et al. (2009) proposed a linear method to
 333 approximate observed H_2SO_4 concentration in Hyytiälä, southern Finland. Moreover,
 334 a recent study by Lu et al. (2019) proposed a nonlinear method to construct a number

335 of proxies for gaseous sulfuric acid concentration (Eq. 5–9), indicating that compared
 336 to the linear method in Petäjä et al. (2009), the nonlinear relationship can provide
 337 more accurate H₂SO₄ concentration in Beijing during February–March 2018 period.
 338 In addition, we also used another sulfuric acid nonlinear proxy (Eq. 10) based on
 339 long-term observations in Germany, Finland, the United States, etc. (Mikkonen et al.,
 340 2011). In this study, we adopt the above six nonlinear proxy methods (referred as
 341 proxy5 to proxy10) to estimate H₂SO₄ in Qingdao.

$$[H_2SO_4] = 515.74 \times [SO_2]^{0.38} \times \text{Radiation}^{0.14} \times CS^{0.03} \#(5)$$

$$[H_2SO_4] = 280.05 \cdot \text{Radiation}^{0.14} [SO_2]^{0.40} \#(6)$$

$$[H_2SO_4] = 9.95 \times [SO_2]^{0.39} \times \text{Radiation}^{0.13} \times CS^{-0.01} \times [O_3]^{0.14} \#(7)$$

$$[H_2SO_4] = 14.38 \times [SO_2]^{0.38} \times \text{Radiation}^{0.13} \times [O_3]^{0.14} \#(8)$$

$$[H_2SO_4] = 0.0013 \times [SO_2]^{0.38} \times \text{Radiation}^{0.13} \times CS^{-0.17} \times ([O_3]^{0.14} + [NO_x]^{0.41}) \#(9)$$

$$[H_2SO_4] = 8.21 \times 10^{-3} \times [SO_2]^{0.62} \times \text{Radiation} \times (CS \times RH)^{-0.13} \#(10)$$

342 where [SO₂], [O₃] and [NO_x] (molecule cm⁻³) represents concentration of
 343 observed SO₂, O₃ and NO_x, respectively. “Radiation” (W m⁻²) is global radiation. RH
 344 (%) is the relative humidity, and CS (s⁻¹) is the condensation sink, which is calculated
 345 based on observed particle distribution.

346 The simulated H₂SO₄ concentration from the Base simulation (dots in Fig. 2b) is
 347 compared with observations obtained by proxies (see Fig. 2b), indicating that Base
 348 simulations apparently overestimate by one order of magnitude compared to the
 349 H₂SO₄ estimated by proxies. The overestimation has been frequently reported
 350 previously, i.e., over Beijing (Matsui et al., 2011), which ascribes the bias to the
 351 overestimation of the SO₂ concentration. In a more recent study, the sensitivity of
 352 H₂SO₄ to SO₂ is tested, and the result shows that even when SO₂ is reduced to an
 353 unrealistically low level, the simulated H₂SO₄ is still more than one order of
 354 magnitude higher than the observed value (Lai et al., 2022), suggesting that the SO₂
 355 concentration cannot fully explain the overestimates.

356 In addition to the precursor of H₂SO₄, the mass accommodation coefficient (α),
 357 representing the probability of impaction of a gaseous molecule on a liquid surface

358 and entering the bulk liquid phase, is another important factor affecting the
359 concentration of sulfuric acid gas. In the public release of WRF-Chem, mass
360 accommodation coefficient is typically set to a low value of 0.1 for all gas species
361 under different volatility during the condensation process, including H_2SO_4
362 (Davidovits et al., 2004; Zaveri et al., 2008). Recent studies indicate that the low mass
363 accommodation coefficient value may not be applicable to the low volatile gases,
364 which tend to have a mean mass accommodation coefficient value of 0.7 and close to
365 the unity (Krechmer et al., 2017). In fact, an earlier study has indicated based on
366 experimental determination, the mass accommodation coefficient of H_2SO_4 vapor in
367 sulfuric acid aqueous solution was measured, and the best fit value was 0.65 (Pöschl
368 et al., 1998). Accordingly, a sensitivity simulation was conducted by adjusting the
369 mass accommodation coefficient of H_2SO_4 from 0.1 to 0.65, referred to as MAC.

370 This simulation brought the H_2SO_4 concentration (see Fig. 2b) much closer to the
371 calculated results from proxies, and the corresponding biases reduced by
372 approximately an order of magnitude. Notably, the MAC simulation decreases the
373 overestimate of sulfuric acid gas concentration, resulting in a lower particle formation
374 rate. The MAC simulation also significantly reduces overestimate of CN_{10-40} (Fig. 2a),
375 and mean fractional bias compared to observations decreases from 48% to 1%.

376

377 **3.2.2 Improvement of particle number concentration simulations at 40–100 nm**

378 The number concentration of particles in the 40–100 nm range is mainly affected
379 by the coagulation and condensation processes. While the coagulation process tends
380 to largely affect ultrafine particles below 10 nm than those with larger sizes (Wu et al.,
381 2011), the condensation growth of particles during gas-particle partitioning at sizes of
382 10–40 nm, to a large extent, governs the variations in number concentration of 40–
383 100 nm particles. The condensation process is primarily controlled by gas-particle
384 partitioning of chemical species, which may change the chemical composition of
385 particles, such as organic compounds and inorganics including sulfate, nitrate and
386 ammonium.

387 Among the species contributing to the condensation growth of particles at 10–40

388 nm, the organic compounds with c^* of $10^{-2} \mu\text{g m}^{-3}$ play the dominant role (Pierce et
389 al., 2011). In the current model setting, the low volatile organic matter of $10^{-2} \mu\text{g m}^{-3}$
390 comes from two gas-phase sources, including the direct emission of primary organic
391 aerosol (POA) and SOA formed from S/IVOC (SI-SOA), conducive to condensation
392 on particles. While the condensation of gaseous SOA is in general reasonable, the gas
393 phase emissions of POA may be problematic. For instance, previous studies suggested
394 that POA is in gas phase close to the emissions source. However, with rapid dilution
395 and cooling in the atmosphere away from the source, most POA condenses to particle-
396 phase (Roldin et al., 2011b; Roldin et al., 2011a; Shrivastava et al., 2008). Therefore,
397 away from the emissions source POA, being in the particle phase, will not be involved
398 in the growth of newly formed particles. Therefore, POA may not contribute to
399 particle growth away from the emission sources, which caused different size
400 distributions of POA compared to when it was emitted in the gas-phase (Fig. S3a vs.
401 Fig. S3b). Emitting low volatility POA in the particle phase eliminates the
402 unreasonable quasi-banana shape pattern exhibiting concomitant growth of newly
403 formed particles with increasing mass concentration of POA.

404 The composition analysis (Fig. S3c) in the 10–40 nm particles mass from the
405 model results indicates that organic compounds mentioned above only account for
406 21% of total mass (sulfates, nitrates, ammonium salts and organics) in this size range
407 and the dominant species is nitrate which accounts for 51% of total mass, exhibiting
408 inconsistencies with the previous studies which in general indicates a much smaller
409 contribution of nitrate. For instance, Liu et al. (2014a) suggested that over North
410 China Plain in summer 2009, organic matter accounted for 77% of particles around 30
411 nm, while the sum of SO_4^{2-} , NO_3^- and NH_4^+ only accounted for 18%. Another study
412 showed that nitrate accounted for 7–8% at urban sites and 17% at rural sites for
413 particles mass in 7–30 nm in the United States in 2007 (Bzdek et al., 2012). Therefore,
414 the potentially too high modeled nitrate fraction in 10–40 nm in this study is tightly
415 associated with the condensation process, with the specific reasons explained below.

416 The condensation of nitric acid on particles is highly constrained by the particle
417 acidity. The acidity in smaller particles (i.e., 10–40 nm) tends to be higher than that in

418 large particles, primarily due to the larger condensation of H₂SO₄ (Lu et al., 2022),
419 and particles with sizes greater than 40 nm have a much weaker acidity or are nearly
420 neutral. For example, observed evidence has shown that acidic ultrafine particles
421 account for a large proportion of ultrafine particles from 22 December 2010 to 15
422 January 2011 in Hong Kong, e.g., 65% for particles within 5.5–30 nm (Wang et al.,
423 2014).

424 In the model, a particle is determined to be in solid phase when the ambient
425 relative humidity is lower than the mutual deliquescence relative humidity of the
426 particles (Zaveri et al., 2005; Zaveri et al., 2008), which is in general suitable for
427 particles dominated by inorganics. In the study area, the results indicate that at most
428 conditions relative humidity are relatively low and the particles are in solid phase, in
429 which the condensation process is not affected by particle acidity and the
430 condensation of nitric acid on particles is directly calculated based on the gas-particle
431 equilibrium concentration (Zaveri et al., 2008). However, for particles below 40 nm,
432 the main compositions are likely to be organic matter (Zhu et al., 2014; Ehn et al.,
433 2014), which tends to be in liquid phase (Virtanen et al., 2011; Cheng et al., 2015),
434 under which the condensation of nitric acid is strongly constrained by acidity.
435 Therefore, the phase misrepresentation ignores the weakening effect of acidity on
436 nitric acid condensation, resulting in too high nitrate therein.

437 To overcome this issue, we propose a ratio method for condensation (RACD) to
438 partition the condensation of nitric acid on particles under 40 nm, by applying a ratio
439 of the number concentration of non-acidic particles to ultrafine particles. The method
440 is based on two assumptions, including: 1) little condensation of nitric acid on
441 particles with strong acidity (Lu et al., 2022); 2) the condensation of nitric acid on
442 particles is proportional to the ratio of the number concentration of non-acidic
443 ultrafine particles to the total particles, despite the existence of uncertainties. Fig. S4
444 depicts the average particle number concentration and acid particle in the 1 to 40 nm
445 range, calculated based on Wang et al. (2014). The ratio of non-acidic particles is 8%
446 for particles below 10 nm, 18% for particles at 10–15.8 nm, 30% for particles at 15.8–
447 25.1nm, and 55% for particles at 25.1–39.8 nm (Fig. S4). Note that the ratio is based

448 on measurements acquired at a single site in Hong Kong, therefore more
449 observational studies are needed to warrant the robustness of the method.
450 Alternatively, the condensation of nitric acid on particles in bins from 1 nm to 40 nm is
451 completely suppressed, referred to as NOCD.

452 The simulation results based on the two methods (RACD and NOCD) are shown
453 in Fig. 3. Compared to MAC, RACD simulations reduce previously noted
454 overestimation of particle number concentration in the 40–100 nm size range (Fig. 3b),
455 with the mean fractional bias decreases from 83% to 63%. In addition to the amount
456 of nitrate condensation during particle growth mentioned above, the overestimation of
457 particle number concentrations in the 40–100 nm range may be attributed to
458 nucleation process. More specifically, in the $\text{H}_2\text{SO}_4\text{-H}_2\text{O}$ binary nucleation
459 mechanism used in this study, when the concentration of sulfuric acid gas is reduced
460 (Section 3.2.1), the resulting decrease in nucleation rate leads to a slight decrease in
461 particle number concentration at 40–100 nm relative to Base (mean fractional bias
462 from 98% to 83%). Apart from that, it may also be related to the choice of nucleation
463 parameterization scheme. For example, using a global chemical transport model
464 GEOS-Chem with a nucleation mechanism in which formation rate is a function of
465 the concentrations of sulfuric acid and low-volatility organics, Yu et al. (2015)
466 overestimated the concentration of particles in the 10–100 nm range by 161% at nine
467 sites in the summer in North America. A possible explanation for this overestimation
468 was given by the uncertainty of the predicted concentration of organic compounds
469 involved in organics-mediated nucleation parameterization. After they switched to
470 another scheme of the ion-mediated nucleation mechanism without organic matter, the
471 number becomes 27% lower than the observations (Yu et al., 2015). The test based on
472 different schemes is beyond the scope of the study, which is therefore not investigated.

473 Moreover, the overestimation of particles over 100 nm ($\text{CN}_{100-1000}$; Fig. 3c), which
474 have a strong influence on CCN, also decrease in the RACD simulation. Thus, the
475 mean fractional bias decreases from 25% (MAC) to 1%. Note that the slight increase
476 of CN_{10-40} through the application of RACD, can be linked to the decrease of nitrate
477 condensation, and leads to weakened particle growth and enhanced particle number

478 concentration at 10–40 nm (Fig. 3a). The alternative method by completely removing
 479 the nitrate condensation (NOCD) yields even better performance in particle number
 480 concentration of 40–100 nm (mean fractional bias of 34%), indicating the feasibility
 481 by reducing the nitrate condensation. The proportion of nitrate simulated by RACD is
 482 23%, closer to values reported in past observations (Bzdek et al., 2011; Bzdek et al.,
 483 2012), while the nitrate (1%) in the scenario of NOCD seems to be too low.
 484 Considering the limited observational information obtained based on previous studies,
 485 RACD is applied in this study.

486 In addition to Qingdao, we evaluate the model performance over a few other sites,
 487 including one site over urban Beijing and the other one over the rural area of Gucheng,
 488 yielding consistent improvements in model simulations (Section S2; Fig. S6-S8).
 489 Moreover, we select another empirical scheme, e.g., kinetics, and one classical
 490 nucleation scheme, indicating the empirical scheme of activation scheme is in general
 491 a good option in this study (Section S2; Fig. S9-S11; Table S1-3).

492 Fig. 3. The time series of (a) CN_{10-40} , (b) CN_{40-100} and (c) $CN_{100-1000}$ on NPF days in
 493 Qingdao on February 5-24 simulated from MAC (marked in red), NOCD (marked in
 494 blue) and RACD (marked in green) as well as from observations (OBS) (marked in
 495 black). All times are local time.

497

498 3.3 Substantial contributions of SI-SOA to CCN

499 Compared with the original model setting, after adjusting the growth process of
500 ultrafine particles (RACD), the number concentration of particles tend to decrease,
501 especially for particles above 40 nm. Ultrafine particles above 40 nm are important
502 sources of CCN (Dusek et al., 2006), in this way, the number concentration of CCN
503 also tends to decline. In addition, in the Base case, we found that the model
504 overestimated $CCN_{0.4\%}$ and $CCN_{0.6\%}$, with mean fractional bias being 64% and 87%,
505 respectively. After adjusting the condensation growth process of ultrafine particles,
506 under high supersaturation (i.e., $CCN_{0.4\%}$ and $CCN_{0.6\%}$), the capability of the model in
507 reproducing the CCN is improved. RACD reduces the overestimation of $CCN_{0.4\%}$ and
508 $CCN_{0.6\%}$, with mean fractional bias reduced to 30% and 56%, respectively, although
509 the overestimates still exist (Figs. S5b, c). However, for low supersaturation (i.e.,
510 $CCN_{0.2\%}$), the decrease of number concentration of CCN is too large, and mean
511 fractional bias decreases from 7% to -45% (Fig. S5a), therefore the bias will be
512 further adjusted later.

513 In addition to the growth process, the remaining overestimate of CCN under high
514 SS and underestimate of CCN over low SS is likely to be influenced by the chemical
515 compositions involved in the activation of ultrafine particles into CCN. Specifically,
516 ultrafine particles can grow up to CCN size under certain SS (Pierce and Adams,
517 2007). This process is influenced by both particle size and hygroscopicity, and
518 hygroscopicity is closely related to the chemical composition of particles (Petters and
519 Kreidenweis, 2007). In particular, inorganic compounds generally increase particle
520 hygroscopicity, increasing CCN. SOA has dual effects on CCN since it decreases
521 particle hygroscopicity but also promotes growth of particles, and these two effects
522 are competitive with each other (Wu et al., 2015; Zaveri et al., 2021). Ultrafine
523 particles must grow to a critical size to be activated into CCN (Dusek et al., 2006).
524 SOA act as a major contributor in promoting the condensational growth of ultrafine
525 particles to the critical size, facilitating particles activation into CCN. In contrast,
526 SOA tends to reduce the hygroscopicity of particles, leading to a diminished ability of
527 activation to CCN (Wu et al., 2015). These two competing effects work together and
528 modulate the number of CCN. Moreover, considering that SI-SOA is the main SOA

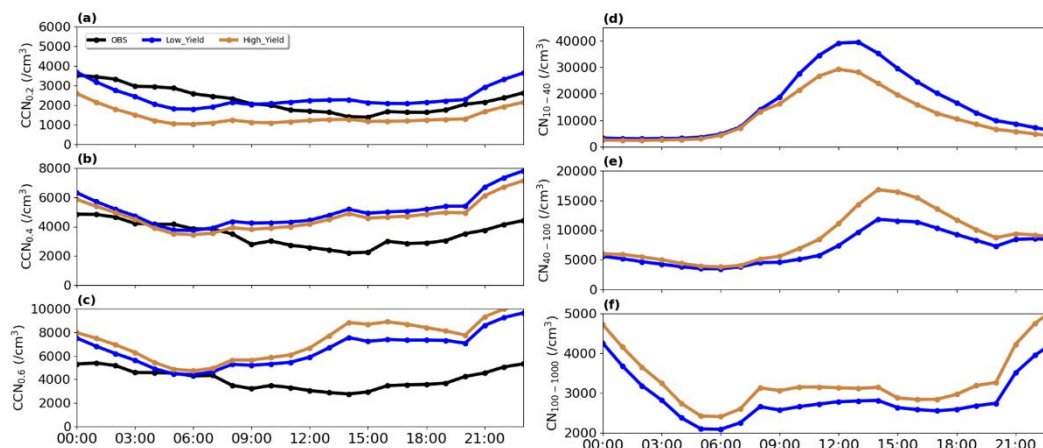

529 component on ultrafine particles (Fig. S5d), the effect of SI-SOA on CCN is therefore
530 explored in this study.

531 Considering SI-SOA is a product of S/IVOC oxidation, the oxidation rate of
532 S/IVOC is tightly associated with CCN, which likely affects the bias of CCN. In the
533 original model setup, the oxidation rate is set to be a constant of $4 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1}$
534 s^{-1} for all S/IVOC. However, a recent study (Wu et al., 2021b) proposed that the
535 oxidation rate can be as high as $5 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ such as for polycyclic
536 aromatic hydrocarbons (PAHs), close to the original model value, but can be as low as
537 half (i.e., $2 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$) of the original modeling setting for S/IVOC
538 species except PAHs (O-S/IVOCs). It is noteworthy that the oxidation rates of 5×10^{-11}
539 $\text{cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ and $2 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ in general represent the upper and lower bounds (Zhao et al., 2016;
540 Wu et al., 2021b).

541 To delve into how oxidation rates affect CCN, we set up a few numerical
542 experiments (Table 2) to investigate the response of CCN to the oxidation rate of
543 S/IVOC at three supersaturations (0.6%, 0.4%, 0.2%), including cases of High_Yield
544 and Low_Yield. As it is shown in Fig. 4, decreasing the oxidation rate (Low_Yield)
545 leads to a reduction of $\sim 10\%$ of CCN at high supersaturation (i.e., CCN_{0.6%}) as
546 compared to the High_Yield simulation. This behaviour is a consequence of the
547 decrease of particle number concentrations associated with Low_Yield, particular of
548 the particles close to the critical diameter (40–100 nm). In this case, the effect of
549 particle size dominates the hygroscopicity. In contrast, at a lower supersaturation
550 (CCN_{0.2%}), CCN increases by 42% when the oxidation rate is switched from a high to
551 a low value, which is due to the smaller fraction of SI-SOA contributing to particulate
552 mass when the oxidation rate is low. In this case, relative to SOA, a larger fraction of
553 other particle constituents such as inorganics, increase the volume weighted particle
554 hygroscopicity (Dusek et al., 2006) which causes the increase of CCN number. This
555 means that the effect of hygroscopicity on CCN surpasses the influence on particle
556 size at low supersaturations. This conclusion is consistent with the observation
557 conducted by Ma et al. (2016) in the North China Plain in 2013, which suggested that

558 along with the decrease of SS, the particles that can be activated to CCN is more
 559 sensitive to changes of particle hygroscopicity.

560

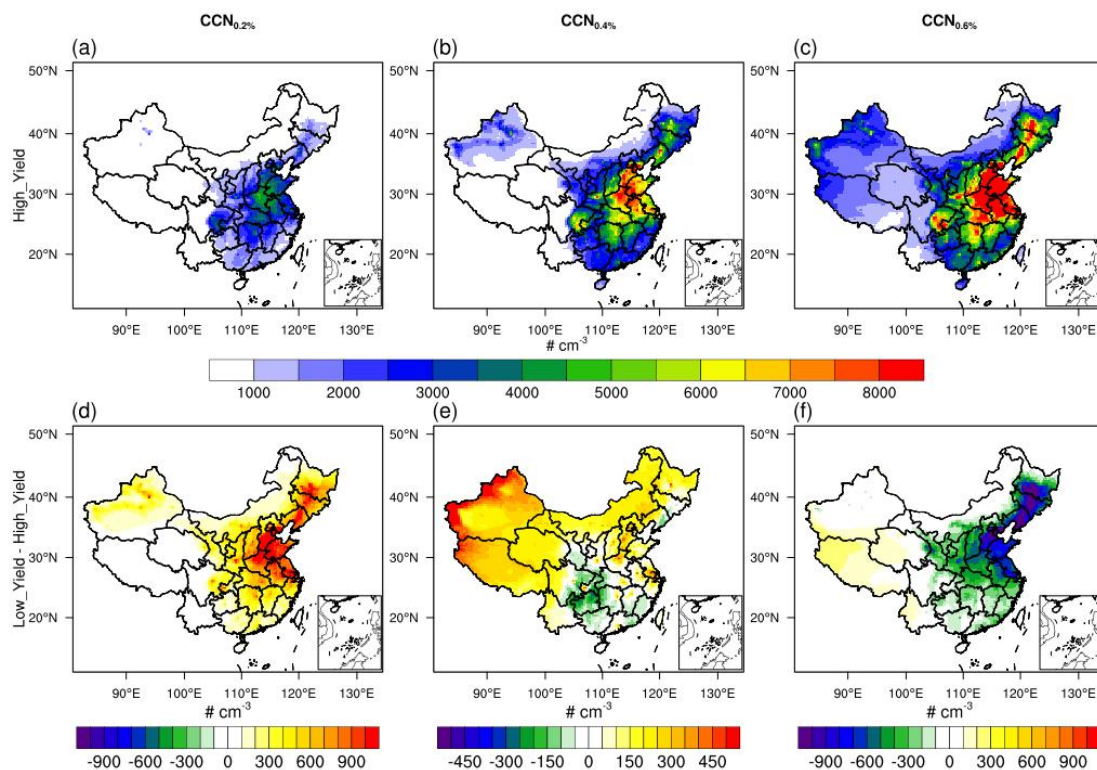

561

562 Fig. 4. Average diurnal variation of (a) $CCN_{0.2\%}$, (b) $CCN_{0.4\%}$ and (c) $CCN_{0.6\%}$ and (d)
 563 CN_{10-40} , (e) CN_{40-100} , (f) $CN_{100-1000}$ on NPF days in Qingdao on February 5-24, 2017,
 564 in Low_yield and High_yield simulations, shown as blue and brown lines, and black
 565 lines represent observation results.

566 Furthermore, compared to the high yield of SI-SOA, the low SI-SOA yield
 567 results in a high CCN concentration under low SS and low CCN concentration under
 568 high SS. Therefore, both the underestimates of $CCN_{0.2\%}$ (mean fractional bias of -45%)
 569 and overestimates of $CCN_{0.6\%}$ (mean fractional bias of 56%) mentioned above are
 570 improved, with mean fractional bias of $CCN_{0.2\%}$ and $CCN_{0.6\%}$ reaching 7% and 43%,
 571 respectively (Fig. 4a,c). This result suggests that the oxidation rate of S/IVOC is
 572 possibly closer to the low value, which is understandable based on Wu et al. (2021b),
 573 who found that the amount of O-S/IVOCs, which corresponds to a low oxidation rate,
 574 is in general much larger (i.e., 20 times) than that of PAHs with a high oxidation rate.

575 In addition to the single site of Qingdao, we further explore the impact of SI-
 576 SOA yield on CCN from a larger spatial coverage (Fig. 5). Consistent with the
 577 mechanism revealed over Qingdao, even from a larger spatial perspective, a lower
 578 oxidation rate of S/IVOC essentially enhances CCN at a lower SS (e.g., $CCN_{0.2\%}$; Fig.
 579 5a) with the highest increase over North China Plain area (Fig. 5a), and weakens CCN
 580 (i.e., by 10–20% over Beijing-Tianjin-Hebei) at a higher SS (Fig. 5c), particularly

581 over the dense emission area (Fig. S12). It is worth noting that in the 2-species VBS
 582 mechanism used in our study, all S/IVOC in the inventory is calculated based on a
 583 constant emission ratio of S/IVOC to POA from all source categories (Shrivastava et
 584 al., 2011), which may miss part of S/IVOC due to different emission ratios of POA
 585 from different source (Chang et al., 2022). In addition, the simplified VBS mechanism
 586 used in our study does not take into account the multi-step oxidation of organic
 587 species, which may introduce some uncertainties. To be more specific, in the 2-
 588 species VBS mechanism, SI-SOA with effective saturation concentrations (c^*) of 10^{-2}
 589 $\mu\text{g m}^{-3}$ is formed by the vapor phase oxidation of S/IVOC vapors with c^* of $10^5 \mu\text{g}$
 590 m^{-3} , reducing volatility by 7 orders of magnitude. The process of one-step oxidation
 591 does not mean to represent a physical process, but to parameterize the mean effect of
 592 a complex process of SOA formation (Shrivastava et al., 2011). However, in the real
 593 atmosphere, the gaseous VOCs often undergo multi-generational oxidation to form
 594 SOA (Garmash et al., 2020), during which the properties and composition of SOA
 595 change substantially.

596
 597 Fig. 5. Spatial distributions of CCN concentrations at different supersaturations (SS),
 598 (a) and (d) are $\text{CCN}_{0.2\%}$, (b) and (e) are $\text{CCN}_{0.4\%}$, and (c) and (f) are $\text{CCN}_{0.6\%}$. The top

599 panels exhibit the results from the High_Yield simulation, and the bottom panels
600 shows the difference between the Low_Yield and High_Yield simulations.

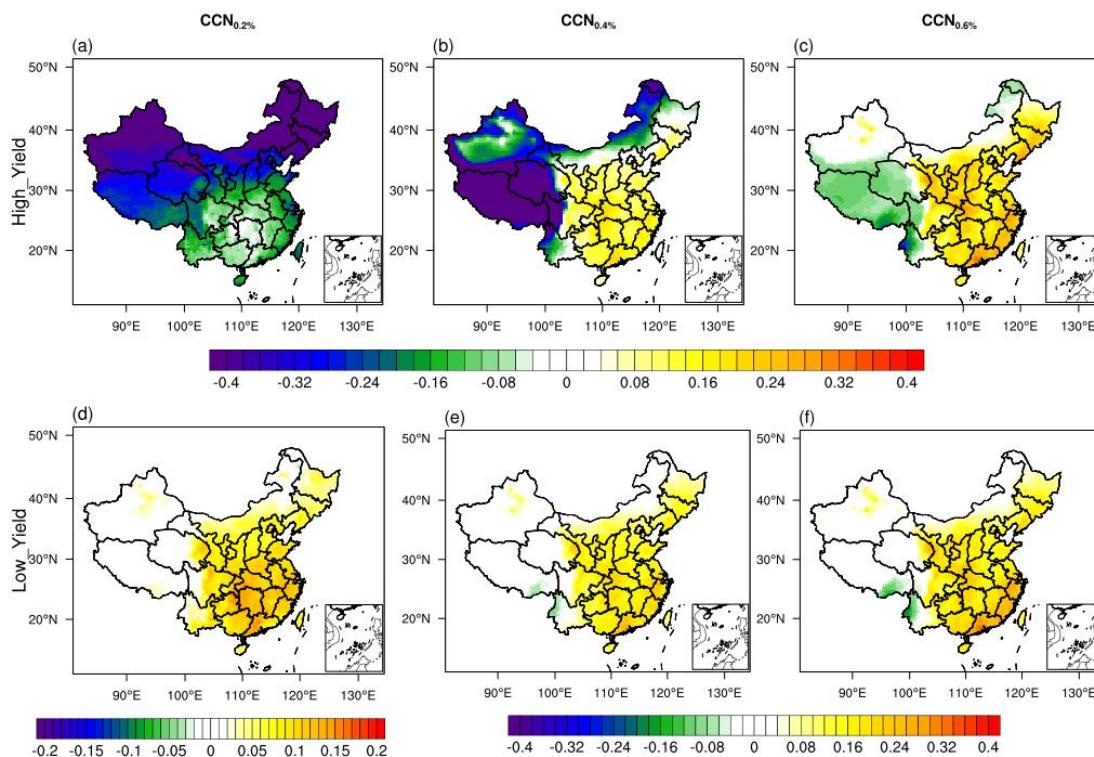

601

602 **3.4 Contribution of nucleation to CCN under different SI-SOA yields**

603 Considering the importance of nucleated particles on CCN (Yu et al., 2020;
604 Westervelt et al., 2013), we further investigate the influence of nucleation on CCN
605 under different SI-SOA yield conditions discussed above.

606 As shown in Fig. 6, in simulations close to the original model setting
607 (High_Yield), when SS is low (i.e., SS=0.2%), the nucleation process tends to reduce
608 the CCN by ~10–50%. In contrast, when the SS is high (0.6%), the nucleation results
609 in a significant increase in CCN in most regions of China. When the yield of SI-SOA
610 is adjusted to a lower level, the nucleation process has a positive contribution to CCN
611 under both low and high SS. Especially, when SS is low (0.2%), the sign reversal, i.e.,
612 from negative (Fig. 6a) to positive (Fig. 6d) contributions of NPF to CCN along with
613 the decrease of SI-SOA yield, i.e., the increase is concentrated in the eastern China
614 with an average of 10–20%. The primary mechanism lies in that along with the
615 decrease of SI-SOA yield, the smaller fraction of SI-SOA yields an increase in
616 hygroscopicity, which surpasses the suppression effect on particle growth due to
617 reduced SI-SOA formation. In the real atmosphere, when the supersaturation is
618 usually low, e.g. about ~0.1% in polluted areas (Kalkavouras et al., 2019; Hudson and
619 Noble, 2014), CCN will likely reduce with increasing oxidation rate of S/IVOC and
620 corresponding SI-SOA formation.

621

622

623 Fig. 6. Spatial distribution of contribution of nucleation to CCN calculated by the ratio
 624 of the difference between the parameterization with and without nucleation to the
 625 parameterization with nucleation under different SI-SOA yields in China in February
 626 2017. (a), (d) is $CCN_{0.2\%}$, (b), (e) is $CCN_{0.4\%}$, (c), (f) is $CCN_{0.6\%}$. The upper panel and
 627 lower panel represent High_Yield and Low_Yield simulation respectively

628

629 In addition to the linear- H_2SO_4 nucleation mechanism, one more empirical
 630 scheme of kinetics nucleation is selected, which assumes that the nucleation rate is
 631 proportional to the square of the concentration of sulfuric acid ($J = K[H_2SO_4]^2$), to
 632 investigate the effect of nucleation on CCN. Substantially positive contributions of
 633 nucleation to CCN is found when the low SI-SOA yield is applied, consistent with
 634 what was shown based on the linear- H_2SO_4 nucleation scheme (Fig. S13). However,
 635 nucleation contributes positively to CCN even when the SI-SOA yield is high in the
 636 quadratic- H_2SO_4 nucleation scheme (e.g., kinetics nucleation scheme). When more
 637 sulfuric acid molecules participate in nucleation under this scheme than the linear-
 638 H_2SO_4 nucleation scheme, the particles are more easily hygroscopically activated to
 639 CCN, which is equivalent to the effect of a reduction in organic components in the

640 linear-H₂SO₄ nucleation scheme (e.g., activation-type nucleation scheme). The results
641 from this study show the importance of assessing the simulated effects of the
642 nucleation scheme on not only the formation and growth process of particles but also
643 climate factors such as CCN using observations.

644

645 **Conclusions**

646 In this study, WRF-Chem explicit-NPF simulations are used to investigate the
647 observed wintertime NPF events and their contribution to CCN in China. Based on
648 observations in a typical coastal city of Qingdao, we identify high biases of the model
649 simulated CN and CCN concentrations. Therefore, we updated and improved the
650 parameterization setting on particle growth in the model, mainly including: (1)
651 adjusting the mass accommodation coefficient (α) to from the default value of 0.1 to
652 0.65, an important parameter for sulfuric acid condensation; (2) proportionally
653 reducing the condensation amount of nitric acid on particles below 40 nm, (3)
654 changing the emitted low-volatility POA from gas to particle. Through these
655 adjustments, the capability of the model in reproducing CN and CCN is substantially
656 improved, leading to better agreement with the observed results, which significantly
657 reduces the overestimation of CN₁₀₋₄₀ (mean fractional bias decreases from 48% to
658 1%) and CN₄₀₋₁₀₀ (mean fractional bias decreases from 98% to 63%).

659

660 For CCN, due to the crucial role of SI-SOA in promoting the growth of ultrafine
661 particles, on the basis of previous studies, we lower the oxidation rate of S/IVOC and
662 hence the production rate of SI-SOA, which weakens the growth of particles to reach
663 the critical size of CCN activation, but enhances particulate hygroscopicity favoring
664 the activation to CCN. When the yield of SI-SOA is adjusted to the lower bound of
665 literature value, CCN_{0.6%} is reduced by ~10% and is closer to observations. At low SS
666 (CCN_{0.2%}), the decrease of SI-SOA yield has greater effects on the increase of particle
667 hygroscopicity compared to the effect of the reduction of particle size due to the
668 decrease of condensation growth. It results in an increase of CCN (as large as ~42%)
669 in better agreement with observations. Under low SS conditions, common in the

670 atmosphere, a 2.5-fold reduction in SI-SOA yield results in a substantial increase of
671 CCN that switches from a negative contribution of new particle formation to CCN
672 from -50%~-10% to a positive contribution of 10~20%. The substantial contribution
673 of new particle formation to CCN under low SS and SI-SOA is applicable to other
674 mechanisms such as kinetics.
