Figure S1. Daily average daytime (8-17 UTC) observed CO₂ concentrations from 2016 to 2021 at seven in situ stations within Paris and its surrounding areas, together with their respective heights above ground level of the air intake inlet.

5 Figure S2. Monthly average daytime (8-17 UTC) observed CO₂ concentrations at seven in situ stations. The black dash line indicates the simulated background CO₂ concentration over Paris by WRF-Chem driven by the CAMS global atmospheric CO₂ dataset.

Text S1. Origins.earth fossil fuel CO₂ emission inventory

The Origins.earth inventory compilation method is mainly based on methodologies developed by Pôle National des Inventaires Territoriaux (PCIT, 2019), the body tasked by the French government to establish national guidelines for computing GHG emission inventories for local authorities. The near real-time high-resolution CO₂ emission maps are generated through the following two-step process. The first step involves the construction of gridded annual CO₂ emission datasets for different sectors for the base year 2018, which consists in spatializing geographically the intensity of annual emissions of the IdF region reported by the French climate agency (ROSE, <https://www.roseidf.org/>). Sector-specific spatial proxies (i.e., high spatial resolution French population census, CORINE Land Cover, locations of the thermal power stations, incinerators, and main emitting industries) are applied to allocate emissions to spatially resolved grids. The second step combines the annual sectorial emission maps with respective generic and/or measure-based (real activity data) temporal profiles. It combines the annual sectorial emission maps with respective generic and/or measure-based (real activity data) temporal profiles. For example, the on-road traffic emissions in the city of Paris are scaled using the real-time traffic count data from more than 3000 traffic measurement points. For the on-road traffic outside the Paris city, the temporal variations are assumed to follow the mean changes of the ones in the city. The temporal evolution of the residential emissions is estimated using the domestic gas consumption data from the SmartGRT database (<https://smart.grtgaz.com/en/consommation>). This proxy discards the specific temporal variations of other energy sources for the residential sector (e.g., petroleum, wood, coal), which may introduce additional uncertainties. Emissions from the tertiary, industry and energy are downscaled to hourly values based on the industrial gas consumption without SFM (Sites Fortement Modulés). Note that developing the near real-time CO₂ gridded emissions by sector at high-resolution is a relatively new endeavor. We continue to revise the methodology to further improve data quality.

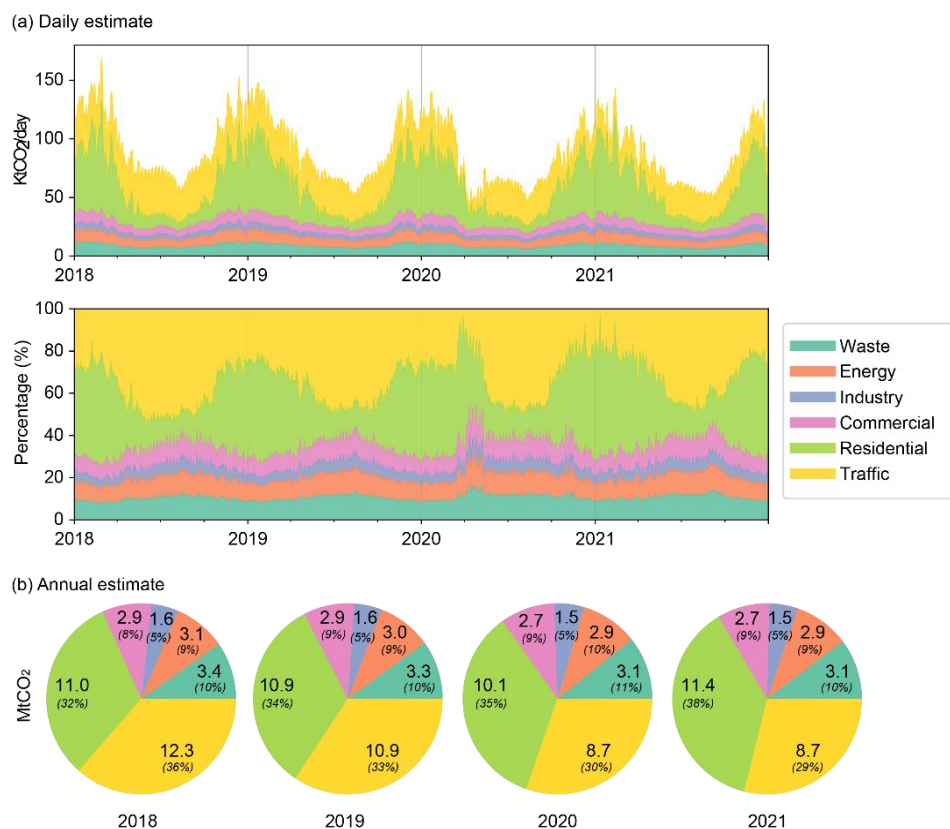

Figure S3. (a) Daily and (b) annual sectorial fossil fuel CO₂ emission estimates and their respective proportions from 2018 to 2021 according to the Origins.earth inventory.

Text S2. Evaluation of the observed and modeled ABL heights

In this study, we assume systematic differences between the thermodynamic and aerosol-based layer detection are negligible or in fact that the aerosol-based results provide a more suitable description for the dilution of near-surface CO₂ emissions, but it should be noted that these issues are subject to current research (Kotthaus et al. 2023).

Figure S4. Comparison of the observed and modeled hourly ABL heights at Sirta station, both for the (a) afternoon (12-17 UTC) and (b) morning (8-11 UTC) period.

Text S3. Inversion configuration

The configuration of the atmospheric inversion system in this study are described in detail in Lian et al. (2022). It comprises the setup of the control vectors, the selection of the assimilated CO₂ observation gradients, the assignments of the observation error and the prior flux uncertainties. Only two minor modifications were made in this study in order to assess the impacts of morning CO₂ concentrations on the retrieved emissions: 1) Regarding the fossil fuel emissions, we assume a 60% relative uncertainty in the prior estimates of individual 6 h emission budgets. 2) We assign no temporal correlation of prior uncertainties between the different 6h time windows.

The data selection criteria of the assimilated CO₂ observations and the assignments of the prior flux uncertainties of the reference inversion are shown in Table S1. Similar as Lian et al. (2022), we also conducted a series of sensitivity tests to investigate how the inverse estimates respond to changes in various setups of the inversion system.

Table S1. Summary of inversion configurations used in this study, both for the reference inversion setup and for the sensitivity tests with changing one configuration at a time compared to the reference.

Category	Description	Reference inversion	Sensitivity test
Data selection criteria	Time period of the assimilated data	Daytime (8-17 UTC)	Morning (8-11 UTC) / Afternoon (12-17 UTC)
	Wind bias outlier based on an interquartile range (IQR) method	0.5	
	Minimum wind speed	3m/s	
	Wind direction transects	30°	20°
	Station-to-station minimum distance	10km	
	Station-to-station preference distance	32 km	20km / 40 km
Prior flux uncertainty	Day-to-day temporal correlation	1 day	4 days
	Uncertainty for 6h fossil fuel flux	60%	40% / 80%
	Uncertainty for daily biogenic flux	60%	40% / 100%

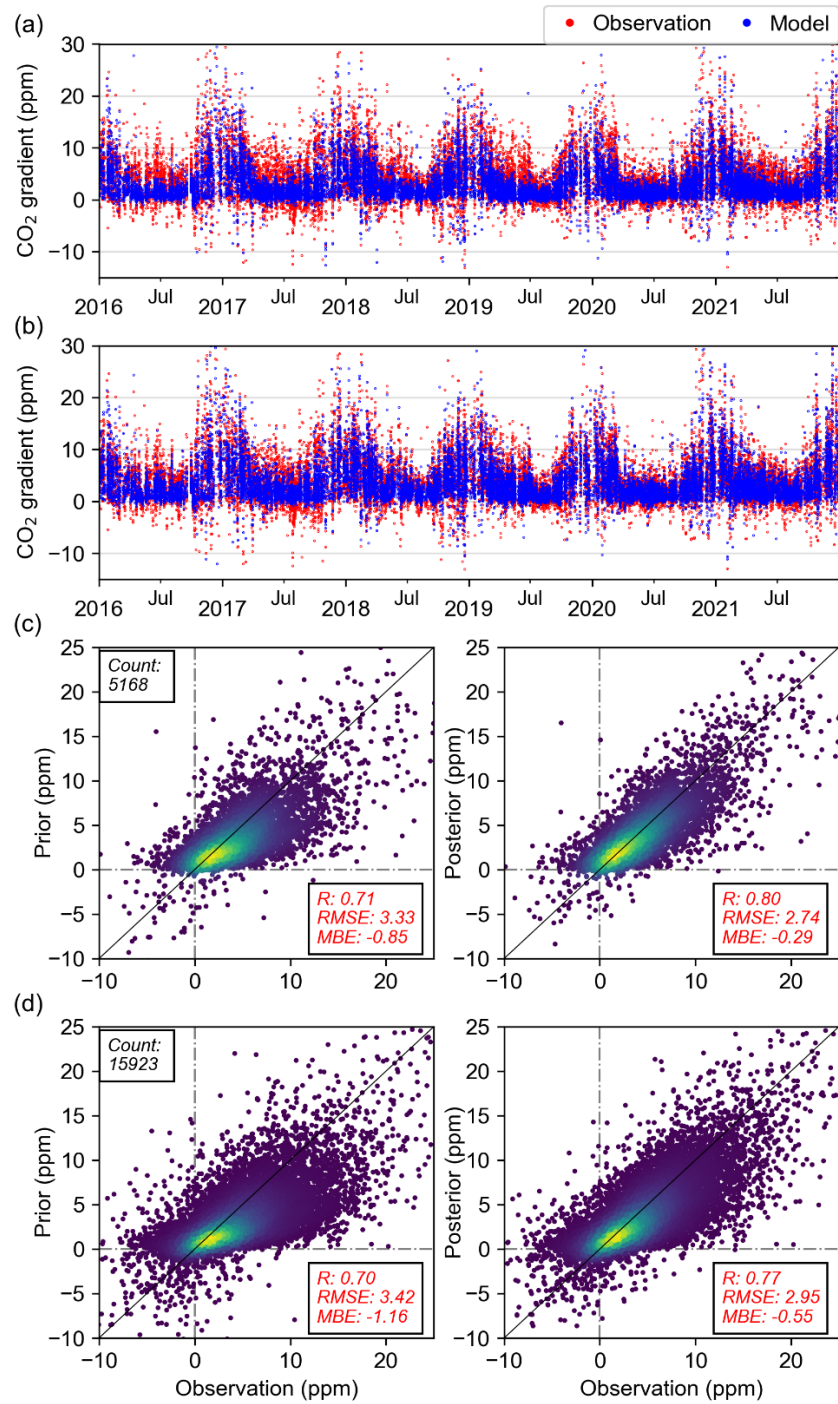

Figure S5. The assimilated hourly daytime CO₂ concentration gradients with (a) prior fluxes and (b) posterior fluxes against the observations from 2016 to 2021. Scatter plot of the assimilated observations and the corresponding simulated CO₂ concentration gradients using the prior fluxes and the posterior fluxes for the (c) morning 8-11 UTC and (d) afternoon 12-17 UTC period, respectively. The statistics of the coefficient correlation (R), root mean square error (RMSE) and mean bias error (MBE) of prior model-data misfit and posterior model-data misfit for the inversion are also provided in the figure.

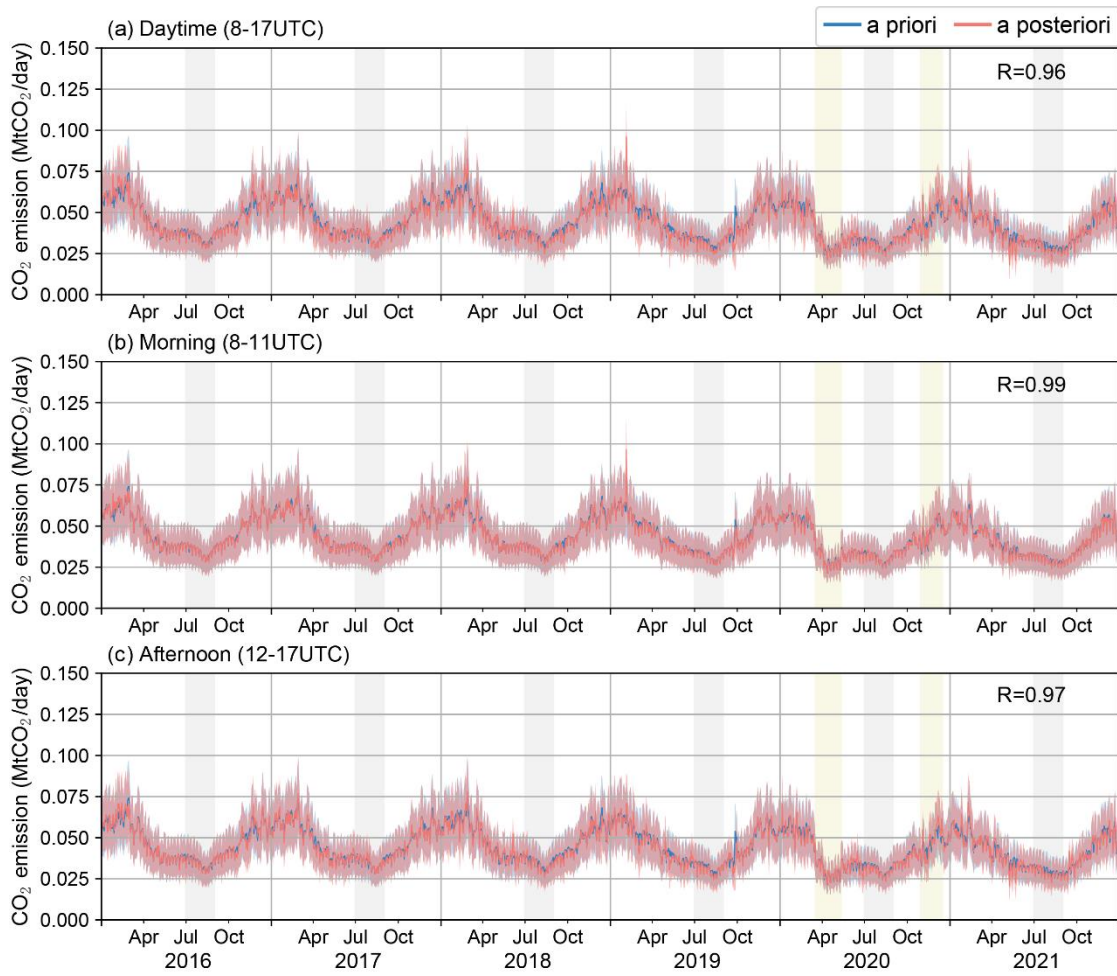

Figure S6. Daily estimates of fossil fuel CO₂ emissions over the rest of IdF region when assimilating (a) daytime (8-17UTC), (b) morning (8-11UTC) and (c) afternoon (12-17UTC) CO₂ concentration observations. The blue line and shading show the prior flux according to the Origins.earth inventory together with its assumed uncertainty. The pink and shading show the posterior estimates with their uncertainty ranges. The yellow shaded areas are the two COVID-19 lockdown periods in France. The grey shaded areas are the summer holidays of July and August.

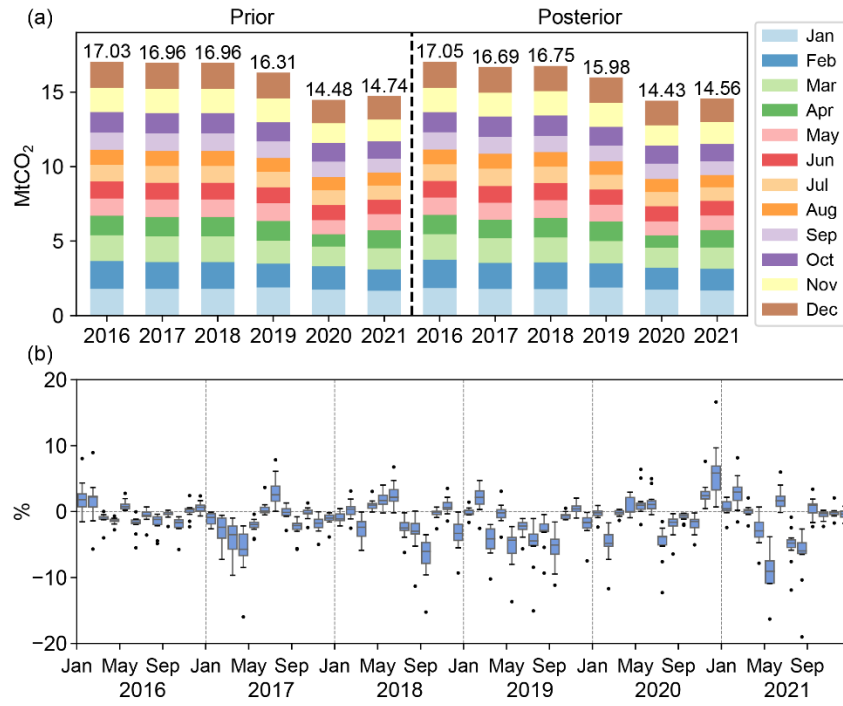

Figure S7. (a) Prior and posterior estimates of the monthly total fossil fuel CO₂ emission over the rest of IdF region. (b) the change of CO₂ emissions in percentage (posterior-prior)/prior. The boxplots are the posterior emissions from an ensemble of sensitivity tests of the inversion configuration.

Figure S8. Average diurnal cycle and the standard deviation of the observed and modeled wind speeds at 100m above the ground level at SAC station for four seasons from 2016 to 2021.

Text S4. Residential heating

Residential CO₂ emissions are typically determined by multiple energy consumption statistics accounting for fossil fuels and their corresponding emission factors. It usually includes petroleum, bottle gas, city gas, wood, and coal. Note that the electricity and urban network energy sources are included in the energy sector in the Origins.earth inventory and are therefore not accounted for here. The calculation of fossil fuel CO₂ emissions for the residential sector in the Origins.earth inventory follows two steps: (1) estimating the spatialized annual emissions from different energy consumption sources. (2) downscaling annual emission to the hourly time scale based on the domestic gas consumption data from the SmartGRT database (<https://smart.grtgaz.com/en/consommation>). This assumption of the evolution of emissions with time ignores the temporal variations of other energy sources for the residential sector (e.g., petroleum, wood, coal). We thus calculate the proportions of annual residential fossil fuel CO₂ emissions from different energy types (Figure S9). These shares indicate that the temporal variation of residential CO₂ emissions from petroleum and wood burning might be an important missing source in the Origins.earth inventory, especially in suburban areas.

Figure S9. The proportions of annual residential fossil fuel CO₂ emissions from different energy types (in percentage) over Île-de-France, Greater Paris and Paris city respectively.

Text S5. Biogenic flux

5

The VPRM modeled biogenic fluxes (net ecosystem exchange, NEE) are compared with the eddy flux measurements at two stations within the IdF region (Figure S10). The Fontainebleau forest site (48.4763°N; 2.7801°E) is located southeast of Paris center. Deciduous broadleaf trees (oak (*Quercus petraea* and *Quercus robur*), beech (*Fagus sylvatica*), and hornbeam (*Carpinus betulus*)) are the dominant species in the vicinity of the flux tower. The Grignon site (48.8442°N, 1.9519°E) is located at around 40 km west of Paris. The crop is a maize, winter-wheat, oilseed rape, winter-wheat rotation.

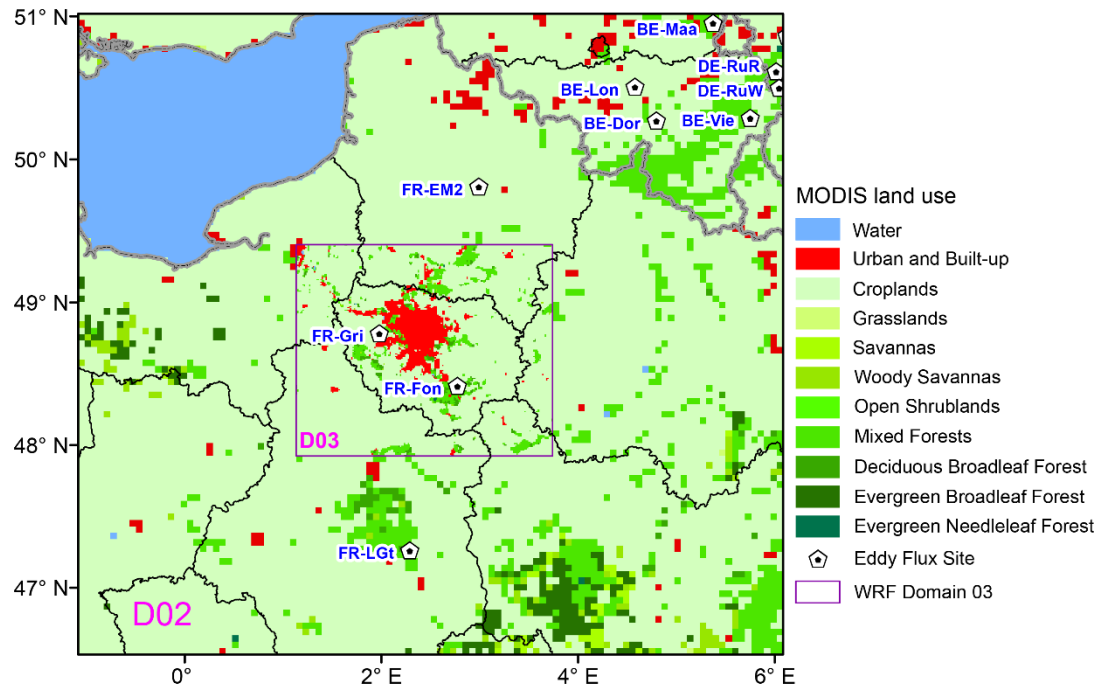

Figure S10. Locations of eddy flux stations within the inner two WRF domains (D02 and D03) together with the MODIS land use map.

10

Figure S11. Comparison of the WRF-VPRM simulated hourly biogenic flux (net ecosystem exchange, NEE) with the measured eddy flux data at the (a) Fontainebleau forest station and (b) Grignon cropland station from 2016 to 2020.

Figure S12. Differences in annual fossil fuel CO₂ emission between the Origins.earth and the TNO 1km inventory for the year 2018.

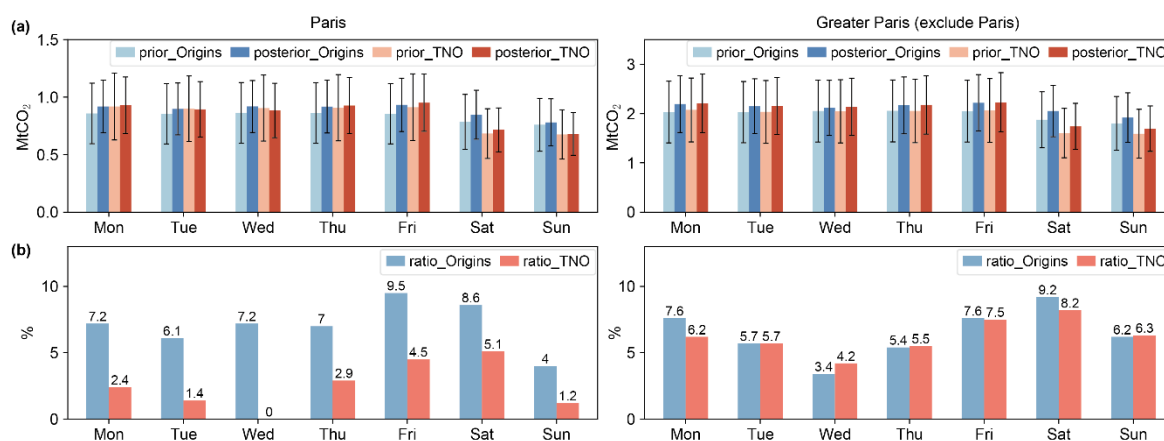

Figure S13. (a) Annual fossil fuel CO₂ emissions prior estimates by Origins.earth and TNO 1km inventory and the respective posterior estimates for the seven days of the week in 2018 over the city of Paris (left panel) and the rest of Greater Paris region (right panel) (cf. Figure S12) respectively. (b) the change of CO₂ emissions in percentage (posterior-prior)/prior.
