12 **Key Points:**

- 13 • A significantly smaller dCo inventory was observed in the Ross Sea during the  
14 2017/2018 austral summer compared to two expeditions in 2005/2006.
- 15 • The drawdown of the labile dCo fraction can be explained by higher rates of Co uptake  
16 by phytoplankton.
- 17 • This change may be due to the alleviation of Fe limitation through inputs from increased  
18 glacial melting and subsequent development of intermittent vitamin B<sub>12</sub> and/or Zn  
19 limitation, both of which would be expected to increase the demand for Co among  
20 plankton communities.

## 21 **Abstract**

22 Cobalt (Co) is a scarce but essential micronutrient for marine plankton in the Southern Ocean and  
23 coastal Antarctic seas where dissolved cobalt (dCo) concentrations can be extremely low. This  
24 study presents total dCo and labile dCo distributions measured via shipboard voltammetry in the  
25 Amundsen Sea, Ross Sea and Terra Nova Bay during the CICLOPS (Cobalamin and Iron Co-  
26 Limitation of Phytoplankton Species) expedition. A significantly smaller dCo inventory was  
27 observed during the 2017/2018 CICLOPS expedition compared to two 2005/2006 expeditions to  
28 the Ross Sea conducted over a decade earlier. The dCo inventory loss (~10–20 pM) was present  
29 in both the surface and deep ocean and was attributed to the loss of labile dCo, resulting in the  
30 near-complete complexation of dCo by strong ligands in the photic zone. A changing dCo  
31 inventory in Antarctic coastal seas could be driven by the alleviation of iron (Fe) limitation in  
32 coastal areas where the flux of Fe-rich sediments from melting ice shelves and deep sediment  
33 resuspension may have shifted the region towards vitamin B<sub>12</sub> and/or zinc (Zn) limitation, both of  
34 which are likely to increase the demand for Co among marine plankton. High demand for Zn by  
35 phytoplankton can result in increased Co and cadmium (Cd) uptake because these metals often  
36 share the same metal uptake transporters. This study compared the magnitudes and ratios of Zn,  
37 Cd and Co uptake ( $\rho$ ) across upper ocean profiles and observed order of magnitude uptake trends  
38 ( $\rho\text{Zn} > \rho\text{Cd} > \rho\text{Co}$ ) that paralleled the trace metal concentrations in seawater. High rates of Co and  
39 Zn uptake were observed throughout the region, and the speciation of available Co and Zn  
40 appeared to influence trends in dissolved metal : phosphate stoichiometry and uptake rates over  
41 depth. Multi-year loss of the dCo inventory throughout the water column may be explained by an  
42 increase in Co uptake into particulate organic matter and subsequently increased flux of Co into  
43 sediments via sinking and burial. This perturbation of the Southern Ocean Co biogeochemical  
44 cycle could signal changes in the nutrient limitation regimes, phytoplankton bloom composition,  
45 and carbon sequestration sink of the Southern Ocean.

## 46 **Plain Language Summary**

47 Cobalt is an important micronutrient for plankton, yet is often scarce throughout the oceans. A  
48 2017/2018 expedition to coastal Antarctica, including regions of the Amundsen Sea and the Ross  
49 Sea, discovered lower concentrations of cobalt compared to two past expeditions in 2005 and 2006.  
50 In particular, this expedition observed lower concentrations of deep-ocean labile cobalt, or “free”  
51 cobalt unbound to strong organic molecules, the type of cobalt preferred by phytoplankton for  
52 uptake as a micronutrient. It is possible that a shifting nutrient landscape due to changing inputs  
53 of other micronutrients like dissolved iron is causing the lower dissolved cobalt concentrations,  
54 and may also be affecting the demand for micronutrients like dissolved zinc and vitamin B<sub>12</sub>, which  
55 contains a cobalt atom. We have modeled how increased cobalt uptake by plankton can result in  
56 the lower deep cobalt concentrations over a time period of 12 years.

## 57 **1 Introduction**

58 Coastal Antarctic seas are highly productive environments for phytoplankton blooms and  
59 are characterized by high nutrient, low chlorophyll (HNLC) surface waters that tend to be growth  
60 limited by iron (Fe) and other trace metal micronutrients (Martin et al., 1990; Arrigo et al., 2008,  
61 2012). During the spring and summer months, katabatic winds and fragmenting sea ice form open  
62 coastal polynyas in the Amundsen and Ross Seas that host high phytoplankton productivity and  
63 act as significant global carbon sinks (Arrigo et al., 2012). In the winter, ice cover supports the

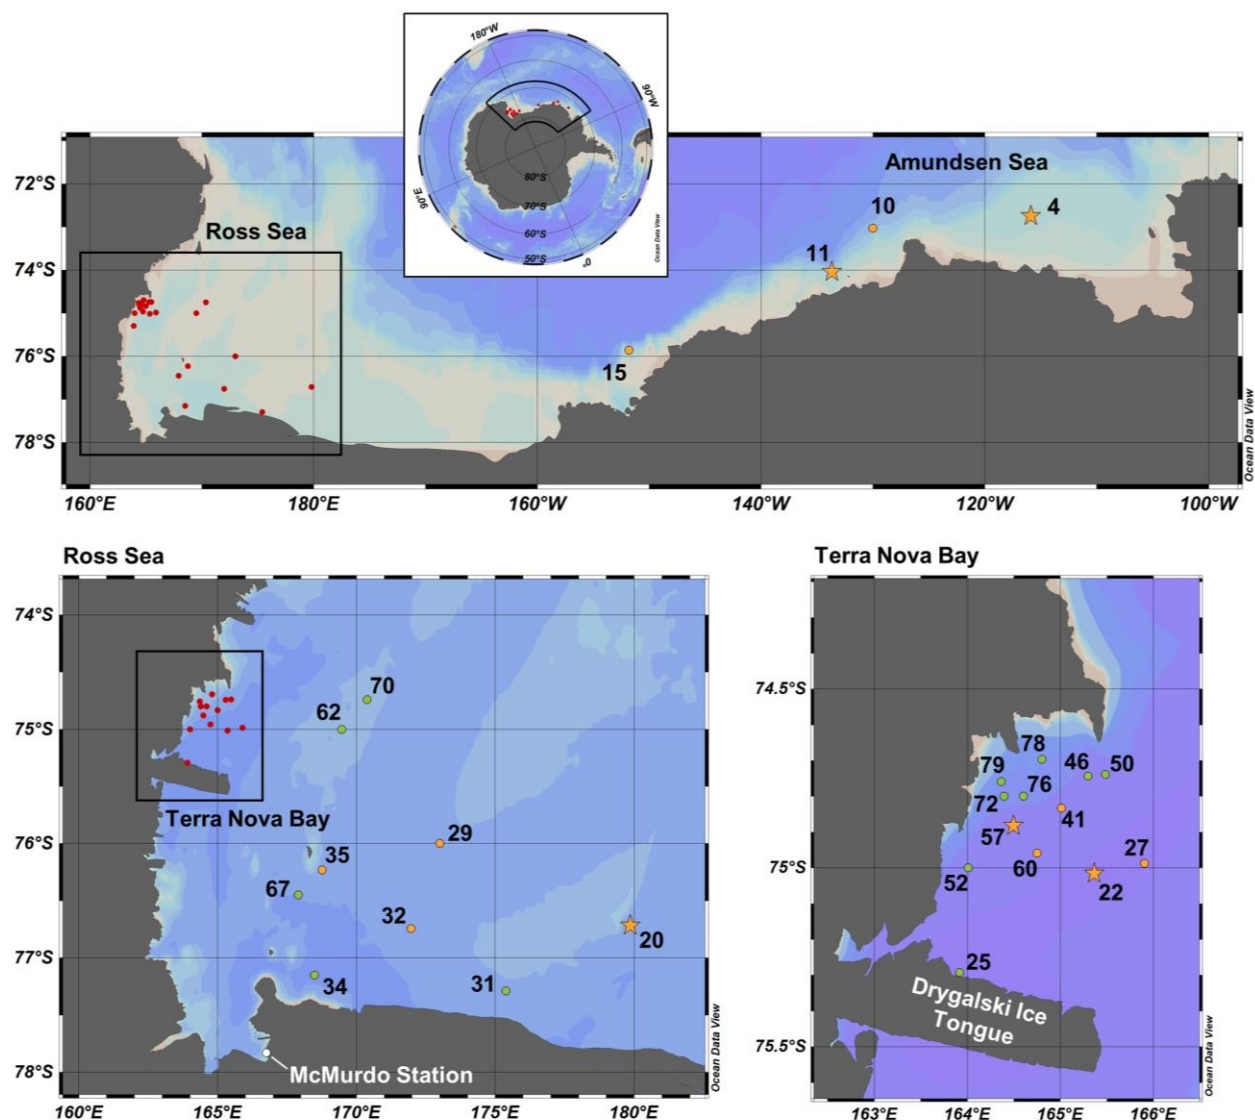

64 turnover of deep waters that allow trace metals like Fe to be redistributed to the upper ocean  
65 (Sedwick and DiTullio, 1997; Sedwick et al., 2011). Phytoplankton blooms in coastal Antarctic  
66 polynyas are dominated by eukaryotes such as diatoms and the haptophyte *Phaeocystis antarctica*  
67 (Arrigo et al., 1999; DiTullio et al., 2003), while cyanobacteria like *Prochlorococcus* and  
68 *Synechococcus*, which are highly abundant in the adjacent South Pacific and South Atlantic gyres,  
69 are near-absent from the phytoplankton community in the Southern Ocean (DiTullio et al., 2003;  
70 Bertrand et al., 2011; Chandler et al., 2016).

71 Cobalt (Co) is an essential trace metal nutrient for many marine plankton and is relatively  
72 scarce in the marine environment, often present in the dissolved phase (dCo) in picomolar  
73 concentrations ( $10^{-12}$  mol L<sup>-1</sup>). Co acts as a cofactor for metalloenzymes like carbonic anhydrase,  
74 a crucial enzyme in the carbon concentrating mechanism of photosynthetic phytoplankton (Sunda  
75 and Huntsman, 1995; Roberts et al., 1997; Kellogg et al., 2020), and vitamin B<sub>12</sub> (cobalamin),  
76 which can be used for the biosynthesis of methionine but is only produced by some bacteria and  
77 archaea (Warren et al., 2002; Bertrand et al., 2013). In the Ross Sea, vitamin B<sub>12</sub> availability has  
78 been observed to co-limit phytoplankton growth with iron (Fe) when bacterial abundance is low  
79 (Bertrand et al., 2007). Some phytoplankton exhibit flexible vitamin B<sub>12</sub> metabolisms and can  
80 express a vitamin B<sub>12</sub>-independent methionine synthase pathway (*metE* gene) instead of the  
81 vitamin B<sub>12</sub>-dependent pathway (*metH* gene), allowing these organisms to thrive in vitamin-  
82 depleted environments (Rodionov et al., 2003; Bertrand et al., 2013; Helliwell, 2017). Recently,  
83 *P. antarctica* was discovered to contain both *metH* and a putative *metE* gene, displaying a  
84 metabolism that is flexible to vitamin B<sub>12</sub> availability (Rao et al., [In review]). Additionally, recent  
85 observations of Zn co-limitation with Fe have been documented in the Ross Sea (Kellogg et al.,  
86 [Submitted]), suggesting a complex landscape of trace metal and vitamin stress interactions in the  
87 otherwise macronutrient-rich waters of coastal Antarctica.

88 Dissolved Co is present as two primary species in the marine environment: a “free” labile  
89 Co(II) species with weakly bound ligands and a Co(III) species that is strongly bound to organic  
90 ligands ( $K_s > 10^{16.8}$ ) (Saito et al., 2005). Labile dCo is considered to be more bioavailable to marine  
91 microbes than strongly-bound dCo, although there is evidence that phytoplankton communities  
92 can access Co in strongly-bound organic ligand complexes (Saito and Moffett 2001) and that  
93 microbial communities may produce extracellular Co ligands that stabilize dCo and prevent its  
94 loss via scavenging to manganese (Mn)-oxide particles (Saito et al., 2005; Bown et al., 2012).  
95 Previous dCo sampling expeditions to the Ross Sea, including two 2005/2006 Controls of Ross  
96 Sea Algal Community Structure (CORSACS) expeditions (Saito et al., 2010) and fieldwork in  
97 2009 that sampled the water column below early spring sea ice in the McMurdo Sound (Noble et  
98 al., 2013), reported relatively high concentrations of labile dCo in the surface Ross Sea when  
99 compared to the tropical and subtropical global oceans, suggesting that labile dCo was fairly  
100 replete and bioavailable to phytoplankton at the time (Saito et al., 2010).

101 This study examines the biogeochemical cycle of Co in the Amundsen and Ross Seas  
102 during the 2017/2018 austral summer as part of the Cobalamin and Iron Co-Limitation of  
103 Phytoplankton Species (CICLOPS) expedition. Here, we present profiles of dCo speciation that  
104 revealed a lower dCo inventory during the 2017/2018 summer bloom compared to that observed  
105 during the 2005/2006 CORSACS expeditions, as well as mostly undetectable concentrations of  
106 labile dCo in the surface ocean. Additional datasets of dissolved zinc (dZn) and cadmium (dCd),  
107 as well as profiles of Co, Zn and Cd uptake rates measured by isotope tracer incubation  
108 experiments suggest that regions of vitamin B<sub>12</sub> and Zn stress within phytoplankton blooms could

109 be driving high demand for bioavailable Co in the surface ocean. The results presented by this  
 110 study reveal a substantial perturbation of the Co cycle, a shift towards vitamin B<sub>12</sub> and/or Zn  
 111 limitation, and possible, but unconfirmed, perturbations to the dissolved iron (dFe) cycle in coastal  
 112 Antarctic waters impacted by high rates of glacial ice melt and a warming climate.  
 113

114 **Figure 1.** Map of CICLOPS stations in coastal Antarctic waters, including insets of stations within  
 115 the Ross Sea and Terra Nova Bay. Dissolved Co, dZn and dCd were analyzed at stations marked  
 116 in yellow, and stations marked in green were analyzed for dZn and dCd, but electrochemical dCo  
 117 measurements were not conducted. At stations marked with a star, Co, Zn and Cd uptake profiles  
 118 are presented in this study. Stations marked in red are shown in more detail in an inset. Note that  
 119 the grey coastline marks both terrestrial coastline and areas of consistent ice, including ice shelves  
 120 and glaciers; this includes the Drygalski Ice Tongue, a glacier to the south of Terra Nova Bay.  
 121

122

## 123 2 Methods

### 124 2.1 Study area and trace metal sampling

125 Samples were collected along the coastal Antarctic shelf from the Amundsen Sea, Ross  
126 Sea, and Terra Nova Bay (Fig. 1) during the CICLOPS expedition on the RVIB *Nathanial B.*  
127 *Palmer* (NBP-1801; December 16, 2017 – March 3, 2018). The expedition track first mapped a  
128 transect from the Amundsen Sea, through the Ross Sea, and ending in Terra Nova Bay (Stations  
129 4–22) over 10 days from December 31, 2017 to January 9, 2018, and then sampled at stations  
130 between Terra Nova Bay and the western Ross Sea for the remainder of the expedition.

131 Dissolved seawater was collected from full-depth station profiles using a trace metal clean  
132 sampling rosette deployed on a conducting synthetic line supplied by the U.S. Antarctic Program  
133 (USAP) and equipped with twelve 8 L X-Niskin bottles (Ocean Test Equipment) supplied by the  
134 Saito laboratory (Woods Hole Oceanographic Institution; Woods Hole, MA, USA). Real-time  
135 trace metal rosette operations allowed for the careful collection of seawater from 10 and 20 m  
136 above the ocean floor to study sediment-water interactions within a potential nepheloid layer. After  
137 deployment, the X-Niskin bottles were transported to a trace metal clean-air van and pressurized  
138 with high-purity (99.999 %) N<sub>2</sub> gas. Seawater samples for macronutrients, dCo and trace metal  
139 analysis were then filtered through acid-washed 0.2 µM Supor polyethersulfone membrane filters  
140 (Pall Corporation, 142 mm diameter) within 3 hours of rosette recovery.

141 To minimize metal contamination of samples, all sample bottles were prepared using trace  
142 metal clean procedures prior to the expedition. The cleaning procedure for dCo sample bottles  
143 entailed soaking sample bottles for ~1 week in Citranox, an acidic detergent, rinsing with Milli-Q  
144 water (Millipore), soaking sample bottles for ~2 weeks in 10% trace metal grade HCl (Optima,  
145 Fisher Scientific), and rinsing with lightly acidic Milli-Q water (< 0.1% HCl). Macronutrient  
146 sample bottles were rinsed with Milli-Q water and soaked overnight in 10% HCl. The procedure  
147 for total dissolved metal sample bottles (dZn and dCd) was identical to that used for dCo bottles  
148 except the Citranox soak step was omitted.

149 Samples for dCo analysis were collected in 60 mL low-density polyethylene (LDPE)  
150 bottles and stored at 4°C until analysis. Duplicate dCo samples were collected: one for at-sea  
151 analysis of labile dCo and total dCo, and another for preservation and total dCo analysis in the  
152 laboratory after the expedition. Preserved total dCo samples were stored with oxygen-absorbing  
153 satchels (Mitsubishi Gas Chemical, model RP-3K), which preserve the sample for long-term  
154 storage and future analysis (Noble et al., 2017; Bundy et al., 2020). Preserved dCo samples were  
155 stored in groups of 6 within an open (unsealed) plastic bag, which was then placed into a gas-  
156 impermeable plastic bag (Ampac) with one oxygen-absorbing satchel per 60 mL dCo sample. The  
157 outer bag was then heat-sealed and stored at 4°C until analysis. Total dCo concentrations for  
158 stations 57 and 60 were analyzed in the laboratory, while all other total dCo and labile dCo  
159 concentrations were analyzed at sea.

160 Samples for total dissolved metal analysis (dZn and dCd) were collected in 250 mL LDPE  
161 bottles and stored double-bagged at room temperature. After ~7 months, the total dissolved metals  
162 samples were acidified to a pH of 1.7 with trace metal grade HCl (Optima, Fisher Scientific), and  
163 were stored acidified for more than one year before instrumental analysis.

### 164 2.2 Dissolved Co and labile dCo analysis

165 Total dCo – the combined fractions of labile and ligand-bound dCo, hereafter simply dCo  
166 – and labile dCo concentrations were analyzed via cathodic stripping voltammetry (CSV) as  
167 described by Saito and Moffett (2001) and modified by Saito et al. (2010) and Hawco et al. (2016).  
168 CSV analysis was conducted using a Metrohm 663 VA and  $\mu$ AutolabIII systems equipped with a  
169 hanging mercury drop working electrode. All reagents were prepared as described in Chmiel et al.  
170 (2022). Most samples were analyzed at sea within 3 weeks of sample collection, and stations 57  
171 and 60 were analyzed for labile dCo at sea and their duplicate preserved samples were analyzed  
172 for total dCo in November 2019 in the laboratory.

173 To measure total dCo concentrations, filtered seawater samples were first UV-irradiated in  
174 quartz tubes for one hour in a Metrohm 705 UV Digester to destroy natural ligand-bound Co  
175 complexes. 11 mL of sample was then added to a 15 mL trace metal clean polypropylene vial, and  
176 100  $\mu$ L of 0.1 M dimethylglyoxime (DMG; Sigma Aldrich) ligand and 130  $\mu$ L of 0.5 M N-(2-  
177 hydroxyethyl)piperazine-N-(3-propanesulfonic acid) (EPPS, Sigma Aldrich) buffer was added to  
178 each sample vial. A Metrohm 858 Sample Processor then loaded 8.5 mL of each sample into the  
179 electrode's Teflon cup and added 1.5 mL of 1.5 M  $\text{NaNO}_2$  reagent (Merck). The mercury electrode  
180 performed a fast linear sweep from -1.4 V to -0.6 V at a rate of  $5 \text{ V s}^{-1}$  and produced a cobalt  
181 reduction peak at -1.15 V, the voltage at which the  $\text{Co(DMG)}_2$  complex is reduced from Co(II) to  
182 Co(0) (Saito and Moffett, 2001). The height of the Co reduction peak is linearly proportional to  
183 the amount of total dCo present in the sample. Peak heights were determined by NOVA 1.10  
184 software. A standard curve was created with 4 additions of 25 pM dCo to each sample, and a type-  
185 I linear regression of the standard addition curve performed by the LINEST function in Microsoft  
186 Excel allowed for the calculation of the initial amount of Co present in the sample.

187 When analyzing labile dCo concentrations, samples were not UV-irradiated so as to only  
188 quantify the free or weakly bound dCo not bound to strong organic ligands. 11 mL of labile  
189 samples were instead allowed to equilibrate with the DMG ligand and EPPS reagent overnight (~8  
190 hours) before analysis to allow time for the labile dCo present in the sample to bind to the DMG  
191 ligand via competitive ligand exchange ( $K > 10^{16.8}$ ). Labile dCo samples were then loaded onto  
192 the Sample Processor and analyzed electrochemically using identical methods as described above  
193 for total dCo samples.

### 194 2.3 Dissolved Co standards and blanks

195 During the CICLOPS expedition, an internal standard consisting of filtered, UV-irradiated  
196 seawater was analyzed for dCo every few days while samples were being analyzed ( $39 \pm 4 \text{ pM}$ ,  $n$   
197 = 9). While additional preserved dCo samples were analyzed in the laboratory in November 2019,  
198 triplicate GSC2 GEOTRACES community intercalibration standards were carefully neutralized to  
199 a pH of ~8 using negligible volumes of ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) and analyzed for dCo.  
200 This is the same intercalibration batch originally reported in Table 1 of Chmiel et al. (2022), as  
201 analysis for both expeditions overlapped temporally. The GSC2 standard was determined to have  
202 a dCo concentration of  $80.2 \pm 6.2$  ( $n = 3$ ), a value that is very similar to the one reported by Hawco  
203 et al., (2016) ( $77.7 \pm 2.4$ ). Currently, no official community consensus for dCo in the GSC2  
204 intercalibration standard exists.

205 Analytical blank measurements for each reagent batch (a unique combination of DMG,  
206 EPPS, and  $\text{NaNO}_2$  reagent batches) were measured to determine any Co contamination due to  
207 reagent impurities. Blanks were prepared in triplicate with UV-irradiated surface seawater passed  
208 through a column with Chelex 100 resin beads (Bio-Rad) to remove metal contaminants, then UV-

209 irradiated again. Chelex beads were prepared as described in Price et al. (2013) to remove organic  
 210 impurities from leaching into the eluent. For the 5 batches of reagents used on this expedition, the  
 211 analytical blanks were found to be 2.3 pM, 4.0 pM, 10.1 pM, 15.6 pM, and 8.6 pM dCo, with an  
 212 average of 8.1 pM Co. The analytical blank detected for the laboratory-run total dCo samples was  
 213 1.0 pM. It should be noted that blank values above 10 pM are considered high for this method.  
 214 Analytical blank values were subtracted from the measured Co values determined with the  
 215 respective reagent batch. The average standard deviation within each triplicate batch of blanks (1.3  
 216 pM) was used to estimate the analytical limit of detection ( $3 \times$  blank standard deviation) of 4 pM.  
 217 When detectable dCo concentrations were found below the 4 pM detection limit, their values were  
 218 preserved in the dataset and flagged as below the detection limit (<DL). In cases where no dCo or  
 219 labile dCo were detected (i.e., when no peak was measurable and/or the dCo value predicted was  
 220 < 0 pM), values of 0 pM were assigned for the purposes of plotting and selecting statistical analysis  
 221 and were flagged as not detected (n.d.) as well as <DL in the dataset; although these concentrations  
 222 were not detectable with our methodology, we believe the incredibly low concentrations of dCo  
 223 and labile dCo observed on this expedition were meaningful, and that removing these values from  
 224 our analysis misrepresents the data and would skew the results to appear higher than was observed.

225 **Table 1.** Mean dCo and labile dCo values measured in the surface ocean (10 m) and the deep  
 226 ocean (> 100 m) in the three regions sampled. One dCo sample and numerous labile dCo samples  
 227 were determined to be below the analytical detection limit (<DL) of 4 pM. Only using the values  
 228 measured above the detection limit would artificially inflate the calculation of the mean value;  
 229 instead, samples measured between 0 and the DL were left unaltered as their originally measured  
 230 value and samples with no detected concentrations of dCo or labile dCo (n.d.) were adjusted to 0  
 231 pM. The number of samples included in the mean calculation that are <DL is indicated by  $n_{<DL}$ .  
 232

Surface (10 m)					
Region	n	dCo <sub>mean</sub> [pM]	dCo $n_{<DL}$	Labile dCo <sub>mean</sub> [pM]	Labile dCo $n_{<DL}$
Amundsen Sea	4	28 ± 7	0	5 ± 6	2
Ross Sea	4	28 ± 12	0	1 ± 2 <sup>a</sup>	4
Terra Nova Bay	5	11 ± 7	1	UD <sup>b</sup>	5
Deep (> 100 m)					
Region	n	dCo <sub>mean</sub> [pM]	dCo $n_{<DL}$	Labile dCo <sub>mean</sub> [pM]	Labile dCo $n_{<DL}$
Amundsen Sea	30	41 ± 5	0	4 ± 4	14
Ross Sea	32	46 ± 8	0	9 ± 7	9
Terra Nova Bay	34	39 ± 18	0	6 ± 8	18

233  
 234 <sup>a</sup> Of the 4 surface samples analyzed for labile dCo in the Ross Sea, 3 were n.d. and the fourth  
 235 contained 3.5 pM labile dCo.

236 <sup>b</sup> All surface samples in Terra Nova Bay were n.d. for labile dCo.

#### 237 2.4 Dissolved Zn and Cd analyzed by ICP-MS

238 Total dissolved trace metal samples were analyzed for dZn and dCd using isotope dilution  
 239 and inductively coupled plasma mass spectrometry (ICP-MS) as described in Kellogg et al.  
 240 (Submitted) based on methodology described in Cohen et al. (2021). Briefly, 15 mL of acidified

241 filtered seawater samples were spiked with an acidified mixture of stable isotopes including  $^{67}\text{Zn}$ ,  
242 and  $^{110}\text{Cd}$ , among other metal stable isotopes, and pre-concentrated via a solid phase extraction  
243 system seaFAST-pico (Elemental Scientific) to an elution volume of 500  $\mu\text{L}$ . The samples were  
244 then analyzed using an iCAP-Q ICP-MS (Thermo Scientific) and concentrations were determined  
245 using a multi-elemental standard curve (SPEX CertiPrep).

## 246 2.5 Co, Zn and Cd uptake rates via isotope incubations

247 Co, Zn and Cd uptake rates were quantified using incubations of collected marine microbial  
248 communities spiked with stable or radioisotopes to trace the conversion of dissolved trace metal  
249 into the particulate phase. Briefly, unfiltered seawater used for the incubation uptake experiments  
250 was collected from the trace metal rosette, and the Co, Zn and Cd uptake incubations were spiked  
251 with 0.1 pM  $^{57}\text{CoCl}_2$ , 2 nM  $^{67}\text{ZnO}$  and 300 pM  $^{110}\text{CdO}$ , respectively. All incubation bottles were  
252 then sealed and placed in a flow-through shipboard incubator on the deck that exposed the  
253 incubations to a natural day/night cycle and surface-temperature seawater for 24 hours. The  
254 incubator was shielded by black mesh screening to allow 20% ambient light penetration.  
255 Incubation biomass was collected by vacuum filtration onto acid-rinsed 3  $\mu\text{m}$  Versapor filters  
256 (Pall). The  $^{57}\text{Co}$  incubation filters were stored at room temperature in Petri dishes prior to  
257 radiochemical gamma-ray counting both at sea and in the laboratory, and the  $^{67}\text{Zn}$  and  $^{110}\text{Cd}$   
258 incubation filters were stored at  $-80\text{ }^\circ\text{C}$  in acid-rinsed cryovials until ICP-MS analysis in the  
259 laboratory. See Kellogg et al. (Submitted), Rao 2020 and Kellogg (2022) for full methodology and  
260 instrumental analysis.

## 261 2.6 Pigment and phosphate analysis

262 Phytoplankton pigment samples were collected from a non-trace metal rosette deployed  
263 separately from the trace metal rosette, and were filtered and analyzed for select pigments by high-  
264 performance liquid chromatography (HPLC) as described in DiTullio and Geesey (2003).  
265 Macronutrient samples were collected from the trace metal rosette alongside dCo samples and  
266 were filtered using the same methodology as dCo and total metal samples (see above). Samples  
267 were collected in 60 mL high-density polyethylene (HDPE) bottles and were stored frozen until  
268 analysis. Dissolved  $\text{PO}_4$  concentrations were determined by Joe Jennings at Oregon State  
269 University via the molybdenum blue method (Bernhardt and Wilhelms, 1967) using a Technicon  
270 AutoAnalyzer II attached to an Alpkem autosampler.

## 271 2.7 Historical dCo and pigment data

272 In this study, dCo profiles from the CICLOPS expedition are compared to those from  
273 previous fieldwork in the Ross Sea, including the Controls of Ross Sea Algal Community Structure  
274 (CORSACS) expeditions: CORSACS-1 (NBP-0601; December 27, 2005 – January 23, 2006) and  
275 CORSACS-2 (NBP-0608; November 8, 2006 – December 3, 2006), reported in Saito et al. (2010),  
276 and fieldwork sampling the water column under the sea ice of the McMurdo Sound (November 9  
277 – 23, 2009), reported in Noble et al. (2013). The locations of stations used in this study from the  
278 CORSACS-1 expedition, CORSACS-2 expedition, and McMurdo Sound fieldwork are given with  
279 respect to CICLOPS stations in Fig. A1. Dissolved cobalt and pigment data from these three  
280 fieldwork expeditions were sampled and analyzed with comparable methodologies as those used  
281 on the CICLOPS expedition, and the CORSACS data are accessible online at [https://www.bco-](https://www.bco-dmo.org/dataset/3367)  
282 [dmo.org/dataset/3367](https://www.bco-dmo.org/dataset/3367).

## 283 2.8 Statistical Analysis

284 The linear regressions presented in this study are two-way (type-II) linear regressions, with  
285 the exception of the standard addition curves used to calculate dCo concentrations (Sect. 2.2).  
286 Two-way regressions are ideal for stoichiometric ratios because they allow for error in both the x  
287 and y parameters and do not assume dependence between the x and y axes. The two-way regression  
288 function used in this study was rewritten to Python from a MATLAB file (lsqfitma.m) originally  
289 written by Ed Pelzer circa 1995 (Chmiel et al., 2022) and is available at [https://github.com/rebecca-  
290 chmiel/GP15](https://github.com/rebecca-chmiel/GP15).

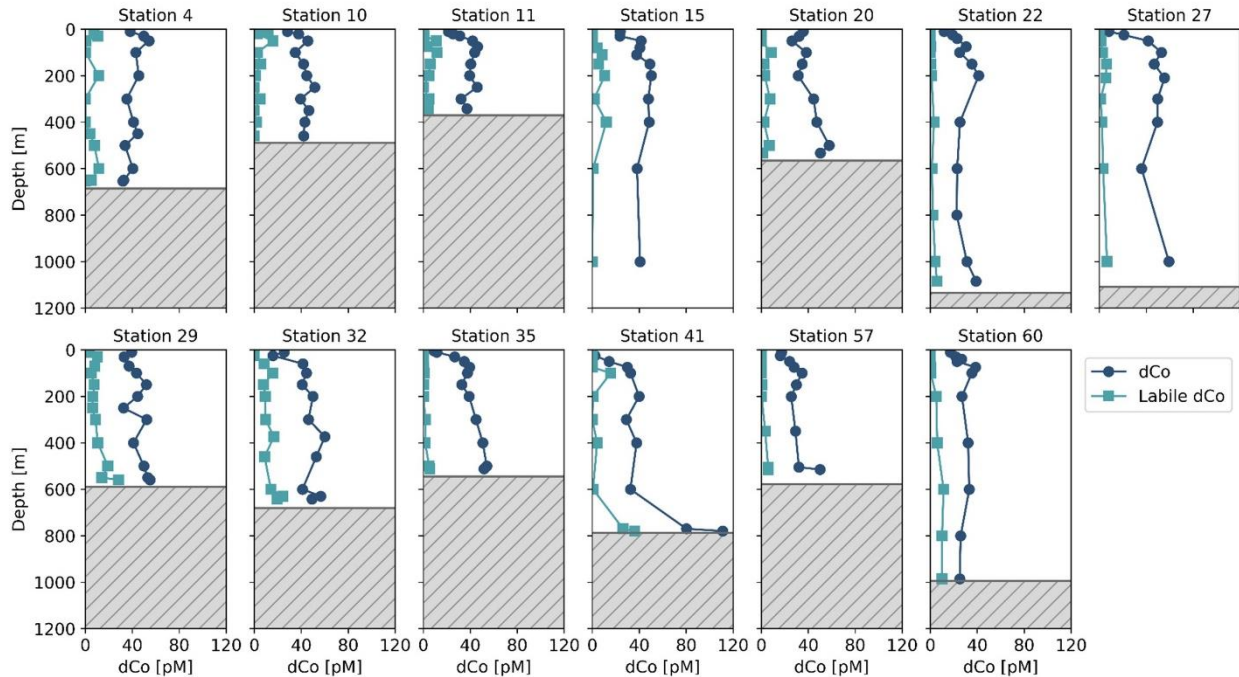

291 Independent t-tests were performed using the `stats.ttest_ind` function within statistical  
292 function module of the SciPy Python library.

## 293 3 Results

### 294 3.1 Dissolved Co distribution and speciation

295 During the CICLOPS expedition, full-depth profiles of dCo and labile dCo samples were  
296 analyzed from 13 stations in the Amundsen Sea (Stations 4, 10, 11, 15), the Ross Sea (Stations 20,  
297 29, 32, 35) and Terra Nova Bay (Stations 22, 27, 41, 57, 60; Fig. 1). The resulting dCo profiles  
298 (Fig. 2) show depletion in the surface ocean consistent with a nutrient-type profile; at 10 m depth,  
299 dCo concentrations were found to be  $28 \pm 7$  pM in the Amundsen Sea ( $n = 4$ ),  $28 \pm 12$  pM in the  
300 Ross Sea ( $n = 4$ ), and only  $11 \pm 7$  pM in Terra Nova Bay ( $n = 5$ ; Table 1). Labile dCo distributions  
301 generally followed those of dCo, and also showed strong depletion in the surface ocean. In the  
302 Amundsen and Ross Seas, surface ( $\sim 10$  m) labile dCo concentrations ranged between 12 pM at  
303 station 10 and undetected (n.d.) concentrations at stations 15, 20, 32 and 35. In Terra Nova Bay,  
304 no surface labile dCo concentrations were detected at any of the 5 stations sampled, indicating that  
305 the dCo inventory was dominated by the strongly ligand-bound dCo fraction.

306 In the deep ocean ( $\geq 100$  m depth), dCo distributions were relatively consistent throughout  
307 the water column, with the exception of elevated concentrations of dCo at near-bottom depths. The  
308 Amundsen Sea, Ross Sea, and Terra Nova Bay all displayed similar deep dCo concentrations of  
309  $41 \pm 5$  pM ( $n = 30$ ),  $46 \pm 8$  pM ( $n = 32$ ), and  $39 \pm 18$  pM ( $n = 34$ ), respectively (Table 1). The high  
310 standard deviation of deep dCo in Terra Nova Bay is partially driven by the elevated near-seafloor  
311 signal at Station 41 (770 m and 780 m); when the two deepest points at Station 41 are omitted, the  
312 average deep dCo in Terra Nova Bay was  $36 \pm 10$  pM. The CICLOPS expedition included regular  
313 near-bottom sampling as allowed by the altimeter aboard the trace metal rosette. As a result, many  
314 of the deepest profile samples contained elevated concentrations of dCo and labile dCo along the  
315 seafloor, including stations 20, 22, 27, 29, 32, 41 and 57. This deep dCo signal was particularly  
316 observable in stations where two near-seafloor samples were taken: one  $\sim 10$  m above the seafloor  
317 and a second  $\sim 20$  m above the seafloor. At stations 41 and 57, the elevated near-seafloor dCo  
318 signal was pronounced (Fig. 2); the samples  $\sim 10$  m above the seafloor contained 111 pM and 50  
319 pM dCo, respectively, which represents a 31 pM and 18 pM increase, respectively, from the  
320 samples collected  $\sim 20$  m above the seafloor. This finding indicates that dCo was elevated in a  
321 narrow band close to the seafloor, and it is likely that dCo concentrations continued to increase in  
322 the 10 m between the deepest samples and the seafloor.

323  
 324 **Figure 2.** Dissolved Co and labile dCo full-depth profiles from the CICLOPS expedition to the  
 325 Amundsen Sea (Stations 4, 10, 11, 15), Ross Sea (Stations 20, 29, 32, 35) and Terra Nova Bay  
 326 (Stations 22, 27, 41, 57, 60). The top of the grey box marks the location of the seafloor.

### 327 3.2 Phytoplankton communities in the Amundsen Sea, Ross Sea and Terra Nova Bay

328 Stations 11, 15, 22 and 27 exhibited high surface chlorophyll-a (Chl-a) fluorescence (17–  
 329 42 mg m<sup>-3</sup> at 10 m), characteristic of phytoplankton blooms. The Amundsen Sea stations displayed  
 330 high concentrations of 19'-hexanolyoxyfucoxanthin (19'-Hex), a pigment commonly used as a  
 331 proxy for haptophyte biomass. In the coastal Southern Ocean, 19'-Hex is often correlated with  
 332 *Phaeocystis antarctica* (DiTullio and Smith, 1996; DiTullio et al., 2003), and it is typical to find  
 333 concentrated blooms of *P. antarctica* in these regions, particularly during the highly productive  
 334 spring blooms of the Antarctic polynyas (Arrigo et al., 1999; DiTullio et al., 2000). The pigment  
 335 fucoxanthin (Fuco) is commonly used as a proxy for diatom biomass, although it can also be  
 336 produced by haptophytes like *P. antarctica* growing under Fe-replete conditions (DiTullio et al.,  
 337 2003; DiTullio et al., 2007); Fuco was observed at stations throughout the expedition and tended  
 338 to be relatively consistent throughout the CICLOPS stations, particularly in comparison to 19'-  
 339 Hex, which displayed very high concentrations at some stations and much lower concentrations at  
 340 others. In general, higher concentrations of Fuco were observed within Terra Nova Bay as well as  
 341 at stations sampled later in the summer season. This is consistent with past observations of summer  
 342 diatom blooms, which tend to occur after the annual spring bloom where and when dFe is available  
 343 (Sedwick et al., 2000; Peloquin and Smith, 2007; Saito et al., 2010).

344 The upper ocean inventories of three pigments, 19'-Hex, Fuco and Chl-a, a proxy for  
 345 general phytoplankton biomass in the Southern Ocean, were estimated via trapezoidal integration  
 346 of their profiles between 5 and 50 m depth and compared to the 2005/2006 summer bloom  
 347 observed on the CORSACS-1 expedition (Fig. 3). In the Ross Sea and Terra Nova Bay, CICLOPS  
 348 stations contained smaller inventories of Chl-a and 19'-Hex compared to the Amundsen Sea, likely  
 349 reflecting the end of the spring bloom and transition to a summer phytoplankton assemblage in

350 these regions. One noticeable difference between the overlapping 2006 and 2018 January seasons  
 351 is the larger Fuco inventory in 2006 in both the Ross Sea and Terra Nova Bay compared to the  
 352 2018 season, indicating a larger presence of diatom biomass during the CORSACS-1 expedition  
 353 compared to the CICLOPS expedition despite relatively similar Chl-a inventories.

354 **Figure 3.** Upper ocean inventories of Chlorophyll-a (Chl-a), 19'-hexanolyoxyfucoxanthin (19'-  
 355 Hex) and fucoxanthin (Fuco) plotted over the austral summer season for both the 2005/2006  
 356 CORSACS-1 and 2017/2018 CICLOPS expeditions. Inventories were estimated via trapezoidal  
 357 integration of the pigment depth profiles between 5 and 50 m depth. Note that the dates along the  
 358 x-axis are not continuous between plots of each region, and the y-axis scales differ among the 3  
 359 pigments.  
 360

### 361 3.3 dZn, dCd and trace metal uptake rates

362 Dissolved Cd and Zn profiles, as well as trace metal uptake rate ( $\rho$ M) profiles for Co, Zn  
 363 and Cd from the CICLOPS expedition were originally presented in Rao (2020) and Kellogg  
 364 (2022). This study presents a comparison between dCo distribution and the distribution and uptake  
 365 of dZn and dCd, two trace metals linked with Co biogeochemical cycling since all three metals are  
 366 known to share similar uptake transporter pathways and can be interchangeably utilized as  
 367 cofactors within specific classes of the enzyme carbonic anhydrase (Sunda and Huntsman, 1995,  
 368 2000; Saito and Goepfert, 2008; Kellogg et al., 2020, 2022).

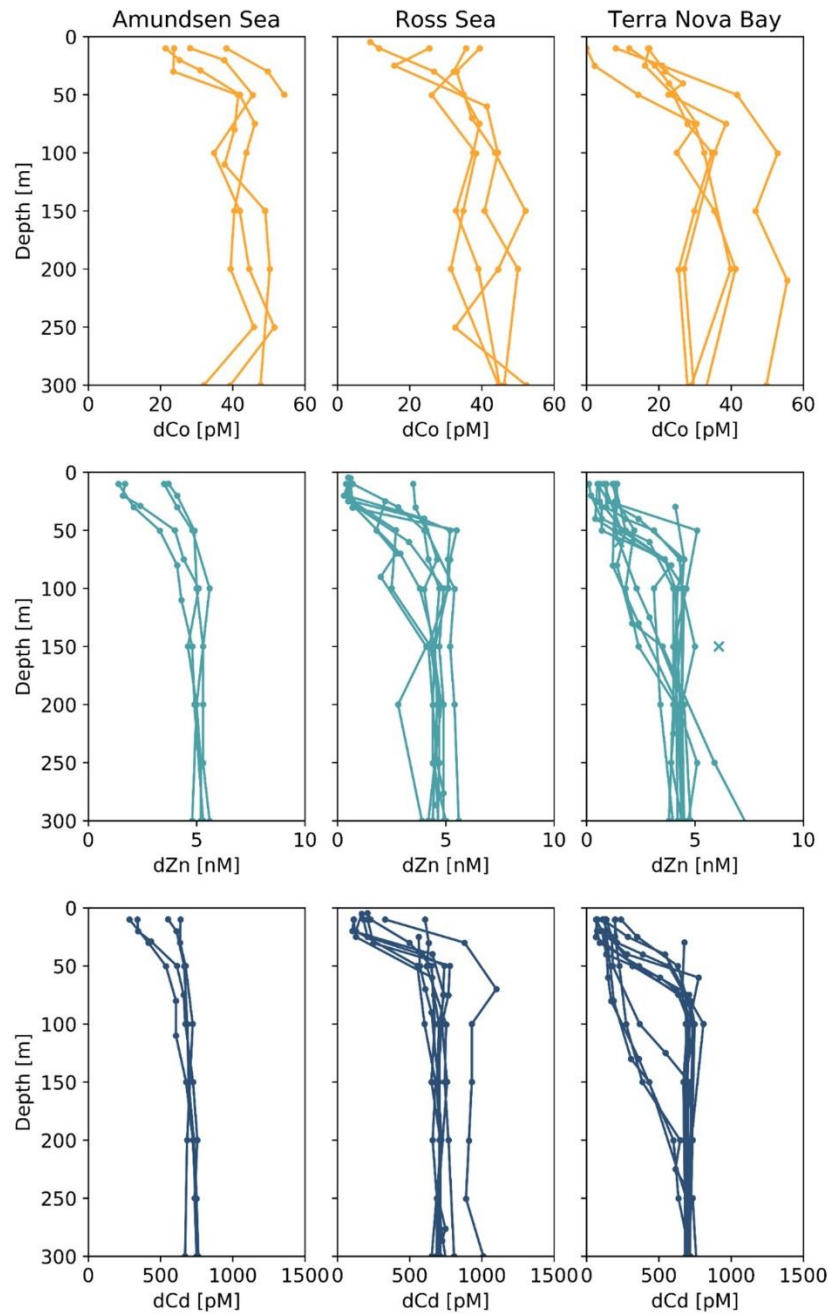

369 The dZn and dCd profiles observed on the CICLOPS expedition displayed nutrient-like  
 370 structure, with depleted concentrations near the surface (Fig. 4). In the deep ocean ( $\geq 100$  m), dZn  
 371 and dCd concentrations were relatively uniform, displaying average deep concentrations of  $4.6 \pm$   
 372  $1.1$  nM ( $n = 182$ ) and  $700 \pm 90$  pM, respectively (Table 2). Average dissolved metal concentrations  
 373 in the surface ocean (10 m depth) were higher in the Amundsen Sea ( $2.5 \pm 1.2$  nM dZn;  $450 \pm 170$   
 374 pM Cd) compared to the Ross Sea ( $1.1 \pm 1.2$  nM dZn;  $250 \pm 170$  pM dCd) and Terra Nova Bay  
 375 ( $0.87 \pm 0.42$  nM dZn;  $130 \pm 170$  pM dCd). This trend of decreasing surface dissolved metals from  
 376 the Amundsen to Terra Nova Bay was mirrored in the dCo distributions, and could be explained  
 377 by the seasonal drawdown of metal nutrients in the mixed layer over time, differences in the metal  
 378 uptake of phytoplankton in the different regions, or both phenomenon occurring simultaneously.

379 At Stations 4, 11, 20, 22 and 57, uptake rates of Co, Zn and Cd within seawater collected  
 380 from 0–200 m were determined via spiked-isotope incubations (Rao, 2020; Kellogg, 2022). The  
 381 relative ratios of the resulting uptake profiles from biomass collected onto 3  $\mu\text{m}$  filters provide  
 382 insight into the demand for Co, Zn and Cd of eukaryotic phytoplankton in coastal Antarctica (Fig.  
 383 5). Note that Co uptake within the bacterial size fraction (0.2–3  $\mu\text{m}$ ) was also analyzed and the  
 384 results are presented in Rao (2020), but here we present the results of the eukaryotic size fraction  
 385 ( $> 3$   $\mu\text{m}$ ) to best represent the eukaryotic phytoplankton community present and compare to the  
 386 Zn and Cd uptake experiments. It should be noted that uptake rates measured via tracer addition  
 387 and shipboard incubations represent potential uptake and may be overestimations of the  
 388 environmental nutrient uptake rates because the isotope tracer addition was labile – not at  
 389 equilibrium with the natural seawater ligands – and could have perturbed the natural  
 390 micronutrient inventories. The  $^{57}\text{CoCl}_2$  addition (0.1 pM) was likely a small enough addition that  
 391 the inventory was not significantly disturbed, but added concentrations of  $^{67}\text{ZnO}$  (2 nM) and  
 392  $^{110}\text{CdO}$  (300 pM) were not tracer-level additions and necessarily increased the existing trace metal  
 393 inventories, possibly leading to the overestimation of total metal uptake rates (Rao, 2020; Kellogg,  
 394 2022).

395 **Table 2.** Mean dZn and dCd values from the surface ocean (10 m) and the deep ocean ( $> 100$  m)  
 396 in the three regions sampled.

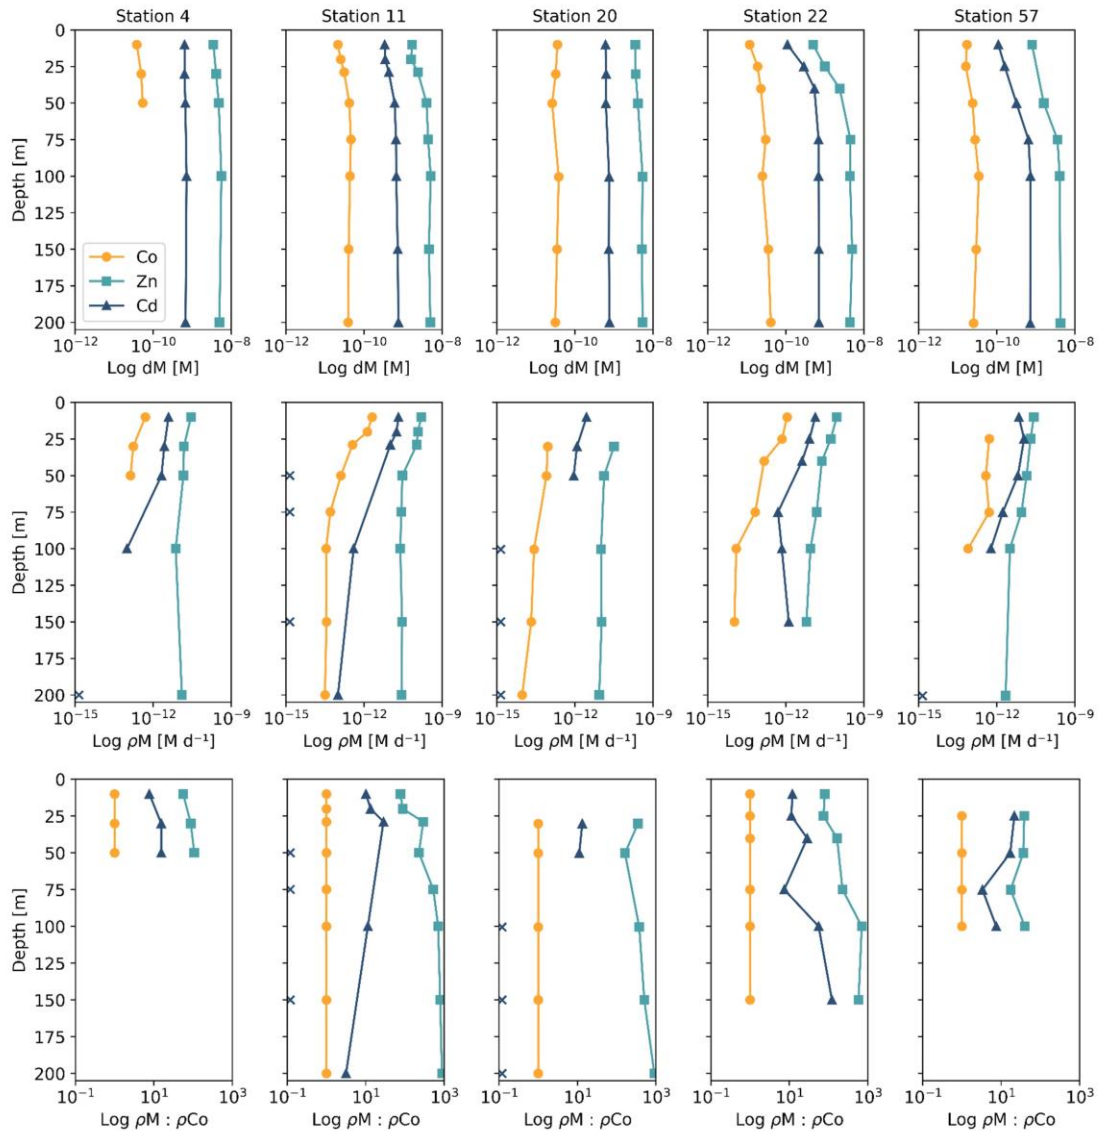

Region	Surface (10 m)			
	dZn <sub>mean</sub> [nM]	n <sub>dZn</sub>	dCd <sub>mean</sub> [pM]	n <sub>dCd</sub>
Amundsen Sea	$2.6 \pm 1.2$	4	$450 \pm 170$	4
Ross Sea	$1.1 \pm 1.2$	6	$250 \pm 170$	7
Terra Nova Bay	$0.87 \pm 0.42$	11	$130 \pm 60$	11
All	$1.3 \pm 1.0$	21	$230 \pm 170$	22
Region	Deep ( $> 100$ m)			
	dZn <sub>mean</sub> [nM]	n <sub>dZn</sub>	dCd <sub>mean</sub> [pM]	n <sub>dCd</sub>
Amundsen Sea	$5.4 \pm 0.6$	30	$730 \pm 40$	30
Ross Sea	$4.7 \pm 0.6$	65	$740 \pm 80$	65
Terra Nova Bay	$4.3 \pm 1.4$	87	$670 \pm 100$	90
All	$4.6 \pm 1.1$	182	$700 \pm 90$	185

397

398  
 399  
 400  
 401  
 402

**Figure 4.** Upper ocean trace metal depth profiles of dCo, dZn and dCd, by region (left panels, Amundsen Sea; middle panels, Ross Sea; right panels, Terra Nova Bay). Outliers are marked with an 'x'. Dissolved Zn and Cd profile data are further described in Kellogg (2022).

403  
 404 **Figure 5.** Depth profiles of dissolved metals (dM; top), trace metal uptake rates ( $\rho M$ ; middle), and  
 405 trace metal uptake rates normalized to the uptake rate of dCo ( $\rho M : \rho Co$ ), plotted along a log scale.  
 406 Stations 4 and 11 are from the Amundsen Sea, Station 20 is from the Ross Sea, and Stations 22  
 407 and 57 are from Terra Nova Bay. Depths at which an uptake rate is below detection (specifically  
 408 for  $\rho Cd$ ) are marked with an 'x' along the y-axis. Co trace metal uptake data are further described  
 409 in Rao (2020) and Zn and Cd uptake data are further described in Kellogg (2022).

410 Of the five stations with uptake rate data from all three trace metals of interest, four  
 411 (Stations 4, 11, 20 and 22) were from a transect conducted from the Amundsen Sea to Terra Nova  
 412 Bay, and were sampled within a span of 10 days from December 31, 2017 to January 9, 2018,  
 413 while the last station (Station 57) was sampled later in the summer on February 6, 2018; this range  
 414 of stations allows us to assess the uptake stoichiometry along both spatial (location) and time  
 415 (bloom progression) dimensions. The  $\rho M$  profiles displayed an increase in metal uptake of Co, Zn  
 416 and Cd towards the surface, a shape which was mirrored in the lower dissolved trace metal  
 417 concentrations of the surface ocean, suggesting the influence of phytoplankton uptake on the

418 drawdown of micronutrients in the photic zone. The stoichiometry of  $\rho M$  among Co, Zn and Cd  
 419 tended to directly follow the metals' availability as dissolved species: Co, which is present at the  
 420 lowest concentrations of  $\sim 10^{-11}$  M, was taken up at rates ranging between  $10^{-13}$  and  $10^{-12}$  M d<sup>-1</sup>;  
 421 Cd, at concentrations of  $\sim 10^{-10}$  M, was taken up at rates of  $10^{-12}$  to  $10^{-11}$  M d<sup>-1</sup>; and Zn, present in  
 422 the highest concentration of  $\sim 10^{-9}$  M, was taken up at rates of  $10^{-12}$  to  $10^{-10}$  M d<sup>-1</sup>. This observation  
 423 reveals order-of-magnitude differences in biological uptake between the three metals, matching  
 424 patterns of metal availability in the water column.

## 425 **4 Discussion**

### 426 4.1 Biogeochemical Co cycle processes observed via dCo profiles and dCo : dPO<sub>4</sub><sup>3-</sup> stoichiometry

427 Low surface ocean dCo and labile dCo concentrations are attributable to uptake by  
 428 phytoplankton and bacteria in the Southern Ocean, giving the dCo and labile dCo vertical profiles  
 429 a distinct nutrient-like shape (Fig. 2). The labile dCo fraction was extremely low or below the limit  
 430 of detection in surface waters, particularly within Terra Nova Bay, indicating strong drawdown of  
 431 the labile fraction and near 100% complexation of dCo in the water column. Labile dCo is  
 432 considered to be more bioavailable than strongly-bound dCo and thus is likely preferentially taken  
 433 up by microbes when available. This labile dCo may then be rapidly cycled by phytoplankton in  
 434 the mixed layer and any labile dCo released via remineralization, cell lysis, or grazing would be  
 435 promptly taken up by other algae and microbes. A rapid turnover of labile dCo suggests a high  
 436 demand for bioavailable Co from the surface phytoplankton community.

437 Dissolved Co and PO<sub>4</sub> displayed a generally positive relationship in the upper ocean, which  
 438 is indicative of the co-cycling of both nutrients via phytoplankton uptake and remineralization  
 439 (Fig. 6a). The processes of biological uptake and remineralization, when observed along dCo vs.  
 440 dPO<sub>4</sub><sup>3-</sup> axes, can be represented by vectors with positive slopes and opposite directionality. Abiotic  
 441 dCo inputs and Co scavenging processes can be represented by vertical or near-vertical vectors  
 442 because they decouple the cycling of dCo and dPO<sub>4</sub><sup>3-</sup>. The positive dCo vs. dPO<sub>4</sub><sup>3-</sup> linear  
 443 relationship that is often observed within the ocean's mixed layer can exhibit a variety of slopes  
 444 that are dictated by the nutrient uptake and remineralization stoichiometry of the microbial  
 445 community (Saito et al., 2017). On CICLOPS, the dCo vs. dPO<sub>4</sub><sup>3-</sup> relationship displayed a  
 446 drawdown of both dCo and dPO<sub>4</sub><sup>3-</sup> in the upper ocean, and the labile dCo vs. dPO<sub>4</sub><sup>3-</sup> relationship  
 447 revealed the stark lack of labile dCo throughout the upper ocean (Fig. 6b,d). The dCo vs. dPO<sub>4</sub><sup>3-</sup>  
 448 slope in the upper ocean (0–100 m depth) was found to be distinct for each of the three regions  
 449 sampled on the expedition; the Ross Sea displayed the highest slope ( $74 \pm 18$   $\mu\text{mol} : \text{mol}$ ), followed  
 450 by the Amundsen Sea ( $47 \pm 9$   $\mu\text{mol} : \text{mol}$ ) and Terra Nova Bay, which displayed the lowest dCo  
 451 vs. dPO<sub>4</sub><sup>3-</sup> slope ( $26 \pm 4$   $\mu\text{mol} : \text{mol}$ ; Fig. 7; Table 3). These slopes reflect a relatively wide range  
 452 of dCo stoichiometries that vary by a factor of 2.8 between the lowest and highest slopes observed.  
 453 For comparison, the 2005/2006 CORSACS-1 and CORSACS-2 Ross Sea data points were pooled  
 454 and the dCo vs. dPO<sub>4</sub> slope was recalculated (originally reported as  $37.6$   $\mu\text{mol} : \text{mol}$  between 5–  
 455 500 m depth; Saito et al., 2010) to fall within the same depth window (0–100 m). The resulting  
 456 slope fell within the range of slopes observed on CICLOPS ( $49 \pm 4$   $\mu\text{mol} : \text{mol}$ ;  $R^2 = 0.57$ ;  $n =$   
 457 106).

458 The range of dCo vs. dPO<sub>4</sub><sup>3-</sup> slopes reflects the elasticity of cobalt uptake stoichiometry in  
 459 the upper ocean, which varies by microbial community and the availability of dCo and other  
 460 nutrients. Due to the number of factors that can affect the environmental stoichiometry of trace

461 metal nutrients, the dCo vs.  $dPO_4^{3-}$  slope must be interpreted alongside other information about  
 462 the marine environment, such as the available dCo inventory and the local nutrient limitation  
 463 regime, making global comparisons of dCo :  $dPO_4^{3-}$  stoichiometry complex. The lower  
 464 stoichiometric slope observed in Terra Nova Bay compared to the Ross and Amundsen Seas likely  
 465 indicates not a lack of demand for Co by phytoplankton, but the low availability of Co in the  
 466 surface ocean despite high demand for the metal. Terra Nova Bay was found to have the lowest  
 467 average surface dCo, dZn and dCd concentrations of the three regions studied, and both Terra  
 468 Nova Bay stations where  $\rho Co$  was measured (Stations 22 and 57) displayed higher surface Co  
 469 uptake rates (0.71 and 0.51  $pM d^{-1}$ , respectively, at 25 m depth) than Station 20 in the Ross Sea  
 470 (0.09  $pM d^{-1}$  at 30 m depth). It is likely that the lower dCo stoichiometry in Terra Nova Bay was  
 471 driven by nutrient draw-down and low availability of labile dCo in the region resulting from  
 472 productive phytoplankton blooms. Remineralization would also have played a role in setting the  
 473 dCo vs.  $dPO_4$  slope below the photic zone; a remineralization vector with a relatively low slope  
 474 indicates that there was a lower dCo source from particulate Co biomass and a rapid turnover of  
 475 recycled dCo back into biomass, suggesting a tight coupling of the dissolved and particulate  
 476 phases.

477

478 **Table 3.** Trace metal :  $dPO_4^{3-}$  stoichiometric regressions for dCo, dZn and dCd in both the surface  
 479 and deep ocean of the Amundsen Sea, Ross Sea and Terra Nova Bay, as shown in Fig. 7. Linear  
 480 regression slopes with  $R^2 < 0.50$  are not shown as the slope values should not be considered  
 481 meaningful stoichiometric values.

482

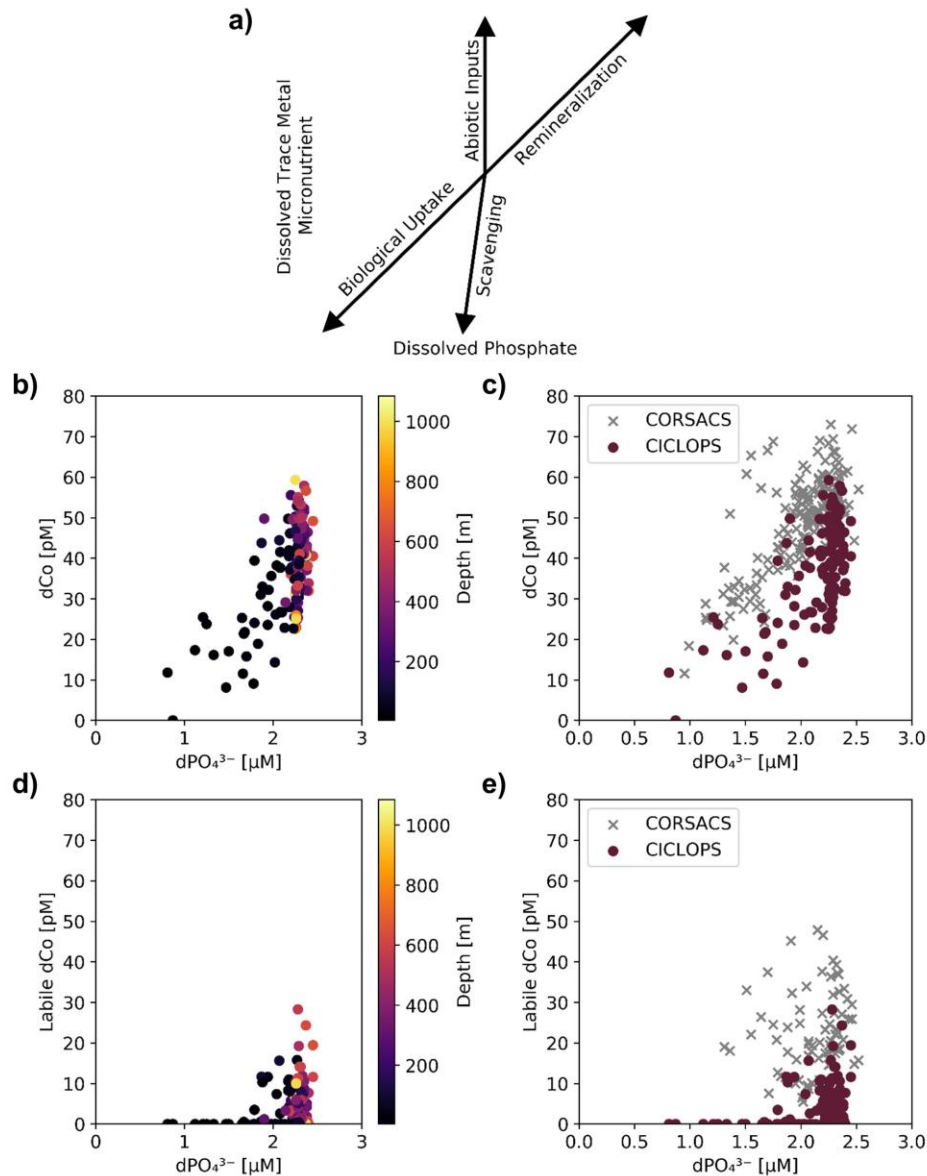

Region	$dCo:dPO_4^{3-}$ [ $\mu mol: mol$ ]				$dZn:dPO_4^{3-}$ [ $mmol: mol$ ]				$dCd:dPO_4^{3-}$ [ $mmol: mol$ ]

483

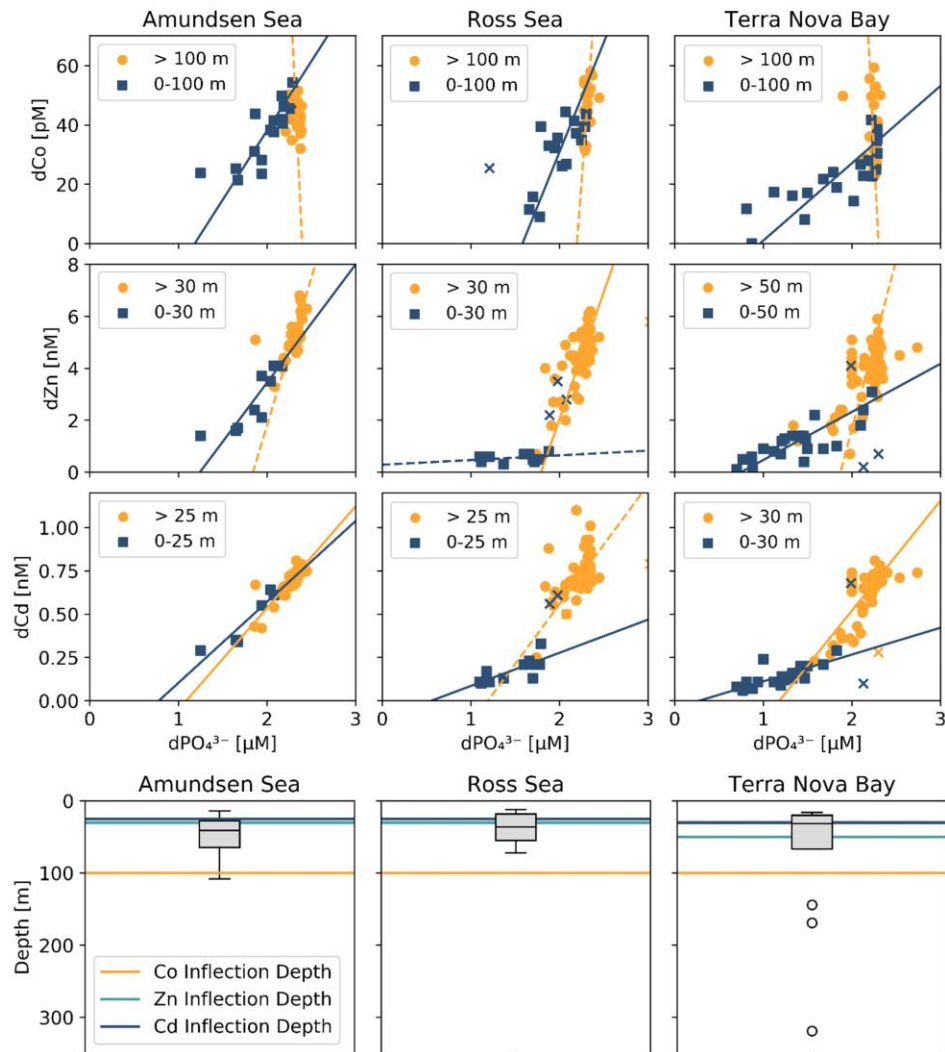

484 Deviations from the linear uptake-remineralization line in the dCo vs.  $dPO_4^{3-}$  relationship  
 485 occur when dCo distributions become decoupled from  $dPO_4^{3-}$  or vice versa, as with Co scavenging  
 486 onto particles and lithogenic dCo sources. In other ocean regions, the dCo vs.  $dPO_4^{3-}$  relationship  
 487 displays a characteristic “curl” towards the high-  $dPO_4^{3-}$ , low-dCo in deeper waters, resulting from  
 488 the net vector sum of both remineralization, which increases both  $dPO_4^{3-}$  and dCo, and scavenging  
 489 to Mn-oxides, which removes dCo in excess of  $dPO_4^{3-}$  from the water column (Noble et al., 2008;  
 490 Hawco et al., 2017; Saito et al., 2017). The dCo vs.  $dPO_4^{3-}$  relationship observed on CICLOPS,  
 491 however, displayed no such scavenging curl, indicating no clear signal of dCo loss due to  
 492 scavenging, at least within timescales relevant to water column mixing. This finding is consistent  
 493 with previous studies of the Ross Sea that have also observed little evidence of dCo loss via  
 494 scavenging in the mesopelagic (Saito et al., 2010; Noble et al., 2013). The lack of a visible  
 495 scavenging signal may be attributable to the deep winter mixed layers of coastal Antarctic seas  
 496 that reach depths of up to 600 m and can extend to the seafloor (Smith and Jones 2015). This deep

497 vertical mixing allows the  $dCo : dPO_4^{3-}$  ratio in the deep ocean to reset on an annual timescale,  
 498 potentially erasing any signals of  $dCo$  scavenging, which would be expected to occur on a  
 499 timescale of decades to centuries (Hawco et al., 2017). Additionally, Oldham et al. (2021)  
 500 concluded that a suppressed  $Co$  scavenging flux might be the result of a unique  $Mn$  cycle in the  
 501 Ross Sea, characterized by low to undetectable concentrations of  $Mn$ -oxide particles, slow rates  
 502 of  $Mn$ -oxide formation, and the stabilization of organic  $dMn$  via  $Mn(III)$  ligands (Oldham et al.,  
 503 2021).

504 **Figure 6.** (a) A vector schematic of the relationship between  $dPO_4^{3-}$  and dissolved trace metals  
 505 like  $dCo$ , and how the various marine processes can affect their distribution and environmental  
 506 stoichiometry. Adapted from Noble et al. (2008). The CICLOPS (b)  $dCo$  vs.  $dPO_4^{3-}$  relationship  
 507 and (d) labile  $dCo$  vs.  $dPO_4^{3-}$  relationship, plotted by depth. Also shown are the CICLOPS (red)  
 508 (c)  $dCo$  vs.  $dPO_4^{3-}$  and (e) labile  $dCo$  vs.  $dPO_4^{3-}$  samples overlaid with CORSACS (gray) samples.

510  
 511 **Figure 7.** (Top 3 rows) Trace metal :  $d\text{PO}_4^{3-}$  relationships from the three CICLOPS regions  
 512 sampled, divided into upper ocean (blue square) and deep ocean (orange circle) bins with a manual  
 513 depth threshold (or inflection point depth) selected to optimize the linear fit of the upper and deep  
 514 ocean trends. Regressions with an  $R^2 \geq 0.50$  are shown as a solid line, and those with an  $R^2 < 0.50$   
 515 are shown as a dotted line. The results of the linear regressions are given in Table 3. Regression  
 516 outliers were selected by hand when including them in the linear regression substantially decreased  
 517 its  $R^2$  value; outliers are marked with an 'x'. (Bottom row) The inflection point depths assigned to  
 518  $d\text{Co}$ ,  $d\text{Zn}$  and  $d\text{Cd}$  relationships are shown compared to a box and whiskers plot of the mixed layer  
 519 depths, with mixed layer depth outliers marked with an 'o'.

#### 520 4.2 Elevated $d\text{Co}$ concentrations within a benthic nepheloid layer

521 The elevated  $d\text{Co}$  signal observed from several depths within 20 m of the seafloor were  
 522 sourced from a benthic nepheloid layer: a near-seafloor region of the water column characterized  
 523 by high particle abundance, turbulence, and isopycnal movement of both dissolved and particulate  
 524 material along the seafloor (Gardner et al., 2018). The Ross Sea has been observed to display  
 525 strong nepheloid layers as cold, dense water flows northward along the Ross Sea shelf until it

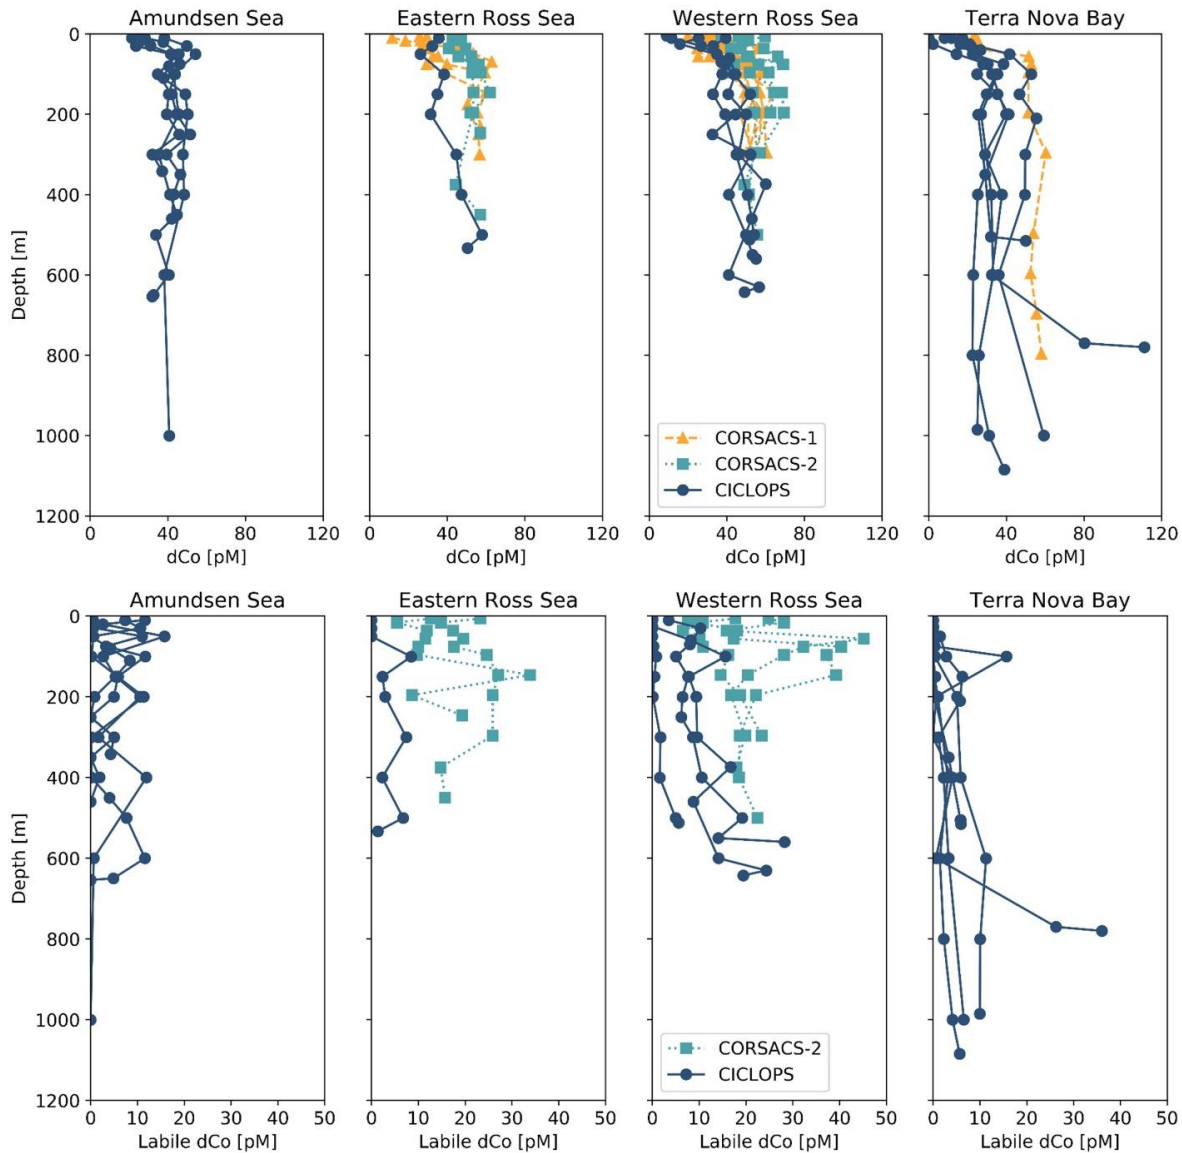

526 reaches the shelf break, carrying suspended sediments with it along the seafloor (Budillon et al.,  
527 2006). Nepheloid layers tend to be enriched in dissolved trace metals like dFe, and can act as a  
528 source of micronutrients if upwelled to the surface ocean (Marsay et al., 2014; Noble et al., 2017).  
529 Elevated dCo concentrations within the Ross Sea nepheloid layer is a novel finding, as previous  
530 expeditions analyzing dCo concentrations in the Ross Sea did not sample as close to the seafloor  
531 as the CICLOPS trace metal rosette was able to (Fitzwater et al., 2000; Saito et al., 2010; Noble et  
532 al., 2013). This finding is evidence of a dCo source to the deep ocean that may be upwelled to  
533 intermediate and upper ocean waters via vertical mixing.

#### 534 4.3 Decreased Ross Sea dCo and labile dCo inventories

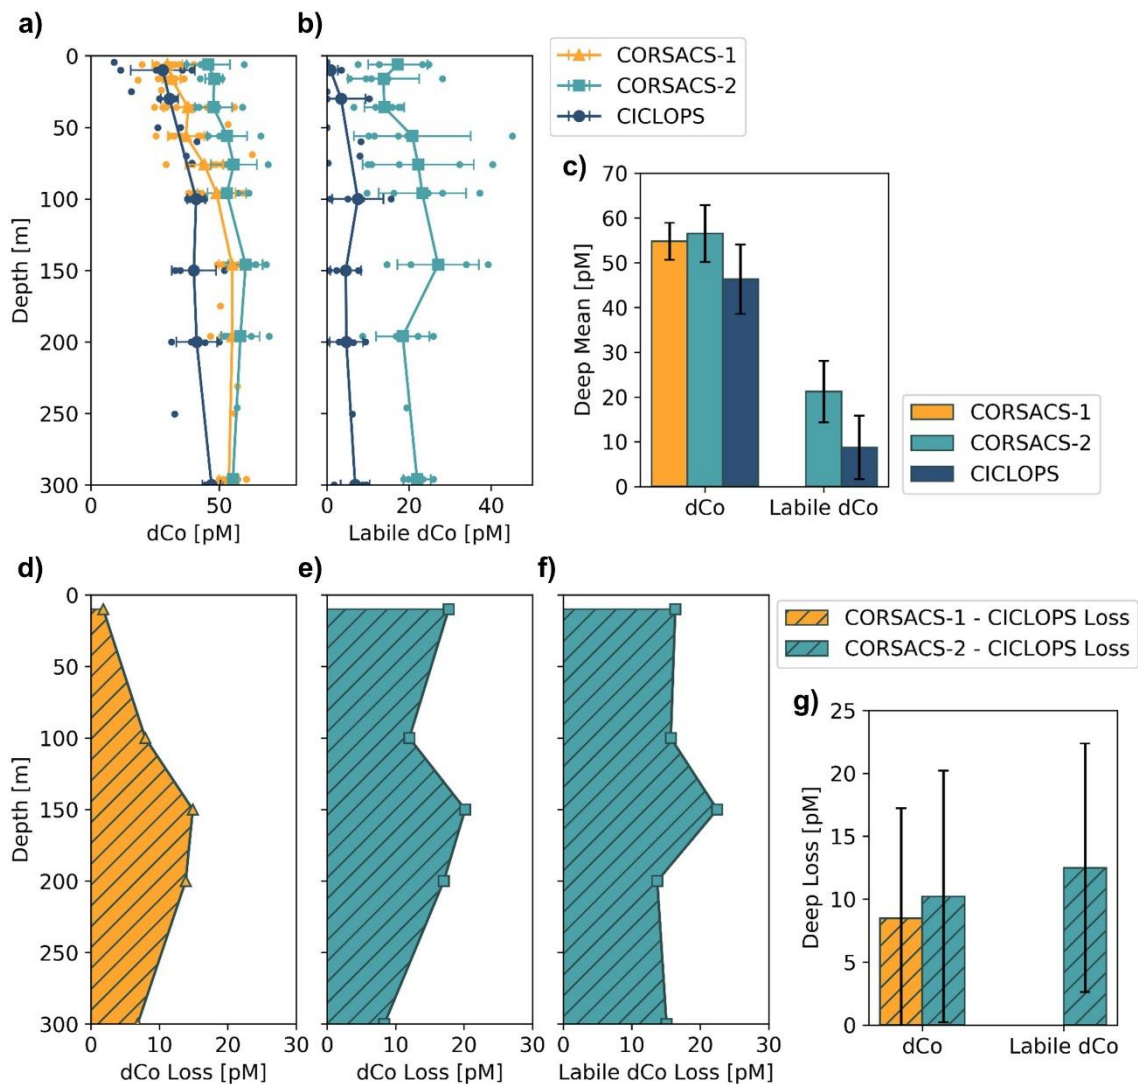

535 The dCo and labile dCo profiles observed along the 2017/2018 CICLOPS expedition  
536 displayed similar vertical structure as those observed along the 2005/2006 CORSACS expeditions;  
537 however, the CICLOPS dCo and labile dCo concentrations were notably lower throughout the  
538 water column compared to the CORSACS datasets (Fig. 8). This trend was particularly clear in  
539 the Ross Sea, where the stations from both expeditions contained the greatest regional overlap  
540 (Fig. A1) and labile dCo distributions from the prior 2006 CORSACS-2 expedition exceeded those  
541 observed on the 2017/2018 CICLOPS expedition (Fig. 9a-c; Table 4). The CORSACS-1 and  
542 CORSACS-2 expeditions displayed average deep ( $\geq 100$  m) dCo concentrations of  $55 \pm 4$  pM and  
543  $56 \pm 6$  pM, respectively, and CORSACS-2 displayed average deep labile dCo concentrations of  
544  $21 \pm 7$  pM; on CICLOPS, in contrast, the Ross Sea displayed average deep dCo and labile dCo  
545 concentrations of  $46 \pm 8$  pM and  $9 \pm 7$  pM, respectively. Note that the CICLOPS expedition mean  
546 deep dCo inventory displayed a higher standard deviation (8 pM) compared to the CORSACS-1  
547 (4 pM) and CORSACS-2 (6 pM) expeditions, indicating a higher variability of deep dCo  
548 concentration within the sites and depths sampled; no difference in standard deviation was  
549 observed within the deep labile dCo inventories of the CICLOPS and CORSACS-2 expeditions  
550 (both 7 pM). Independent t-tests determined that CORSACS-1 and CORSACS-2 deep Ross Sea  
551 dCo values were statistically similar ( $p = 0.27$ ) while deep CICLOPS dCo values were statistically  
552 different from CORSACS-1 and CORSACS-2 deep dCo ( $p < 0.0001$ ; Table 4). This offset  
553 represents a mean dCo inventory loss of 8 – 10 pM dCo in the deep ocean, and approximately all  
554 of the difference can be accounted for by the loss of deep labile dCo (12 pM dCo; Fig. 9d-g), the  
555 more bioavailable form of dCo for biological uptake. Since a plot of temperature vs. salinity shows  
556 largely overlapping hydrography among the three expeditions in the Ross Sea (Fig. A2), the  
557 observed difference in dCo inventories is unlikely to be due to differences in the distributions of  
558 the water masses sampled.

559 In the near-surface (10 m), labile dCo was undetectable at 3 of the 4 stations in the Ross  
560 Sea on CICLOPS, and the near-surface labile : total dCo ratio in the one station where labile dCo  
561 was detectable (station 29; 3.5 pM labile dCo) was only 0.09. In contrast, the 2006 CORSACS-2  
562 expedition reported the presence of labile dCo at five stations with concentrations of  $17 \pm 7$  pM at  
563 6 m depth and  $14 \pm 9$  pM at 16 m depth, with reported labile : total dCo ratios of  $0.37 \pm 0.13$  and  
564  $0.28 \pm 0.17$ , respectively. This trend can be at least partially explained by the seasonality  
565 differences between the spring CORSACS-2 expedition and the summer CICLOPS expedition; as  
566 the phytoplankton bloom progresses in the photic zone of the Ross Sea, labile dCo concentrations  
567 would be drawn down by community uptake and would exhibit lower concentrations later in the  
568 summer season. This seasonal trend was evident in the surface dCo inventory differences between  
569 the summer CORSACS-1 and spring CORSACS-2 expeditions (Fig. 9a,d,e). However, the low,  
570 often undetectable, labile dCo concentrations observed in the surface Ross Sea on the CICLOPS

571 expedition illustrate the intensity of bloom-driven labile dCo depletion in the region, leaving 91–  
 572 100% strong ligand-bound dCo in the surface Ross Sea. These observations are consistent with  
 573 the Co uptake rate measurements, which were found to be higher on CICLOPS (0.84 pM d<sup>-1</sup>, n =  
 574 38) compared to CORSACS-1 and CORSACS-2 (0.67 pM d<sup>-1</sup> and 0.25 pM d<sup>-1</sup>, respectively) (Saito  
 575 et al., 2010; Rao, 2020).

576  
 577 **Figure 8.** Dissolved Co and labile dCo depth profiles from the CORSACS-1 (NBP0601;  
 578 December 27, 2005 – January 23, 2006), CORSACS-2 (NBP0608; November 8, 2006 – December  
 579 3, 2006) and CICLOPS (NBP-1801; December 11, 2017 – March 3, 2018) expeditions in the 4  
 580 regions sampled by the CICLOPS expedition: Terra Nova Bay, the Western Ross Sea, the Eastern  
 581 Ross Sea and the Amundsen Sea. The Eastern and Western Ross Sea stations are defined by being  
 582 either east or west of the 175 °E longitudinal, respectively. The CORSACS expeditions did not  
 583 extend to the Amundsen Sea, and no labile dCo was reported from the CORSACS-1 expedition.  
 584 dCo data from the CORSACS expeditions was reported in Saito et al. (2010) and is accessible at  
 585 <https://www.bco-dmo.org/dataset/3367>.

586  
 587 **Figure 9.** Mean depth profiles of dCo (a) and labile dCo (b) from the Ross Sea from three sampling  
 588 seasons, including the expeditions: CORSACS-1 (Summer 2005/2006), CORSACS-2 (Spring  
 589 2006) and CICLOPS (Summer 2017/2018). Observed profile values are plotted as unconnected  
 590 dots, and the mean profile is plotted for each depth at which at least three samples were analyzed.  
 591 (c) The mean deep ( $\geq 100$  m) dCo and labile dCo concentrations for stations in the Ross Sea on  
 592 each expedition. The mean difference in the dCo (d, e) and labile dCo (f) profiles between the  
 593 CORSACS and CICLOPS expeditions where sample depths were within 5 m of each other. (g)  
 594 The mean deep ( $\geq 100$  m) dCo and labile dCo concentration loss for stations in the Ross Sea. Error  
 595 bars denote one standard deviation from the mean. No labile dCo data is available for the  
 596 CORSACS-1 expedition. Mean values, loss values, and the results of independent t-tests to  
 597 determine the significance of the deep dCo loss are given in Table 4.

598 Dissolved Co and labile dCo concentrations were also analyzed in the Ross Sea in 2009 by  
 599 sampling the water column below the McMurdo Sound seasonal sea ice in the early spring  
 600 (November 9–23) (Noble et al., 2013). Under the ice, the water column was well-mixed, and the  
 601 dCo and labile dCo profiles showed relative uniformity at all three stations measured (Fig. 2 of

602 Noble et al., 2013). In the deep ocean ( $\geq 100$  m), the mean dCo and labile dCo concentrations were  
 603  $51 \pm 4$  and  $15 \pm 2$  pM, respectively, which is lower than those observed on the 2005/2006  
 604 CORSACS expeditions and higher than those observed on the 2017/2018 CICLOPS expedition  
 605 (Table 4). The mean deep labile dCo concentrations from the McMurdo Sound fieldwork were  
 606 also significantly different from the mean deep labile dCo observed on CICLOPS ( $p = 0.0006$ ),  
 607 displaying an average deep labile dCo difference of 6 pM. This dataset supports the possibility of  
 608 a long-term trend towards a decreasing deep dCo inventory in the Ross Sea, although the more  
 609 coastal location and difference in sea ice cover should be considered when comparing the  
 610 McMurdo Sound dataset to the CORSACS and CICLOPS observations. Notably, the methodology  
 611 and instrumentation used to measure both dCo and labile dCo on both CORSACS expeditions, the  
 612 McMurdo Sound fieldwork and the CICLOPS expedition were functionally identical, with the  
 613 exception of an autosampler (Metrohm 858 Sample Processor) used on the 2017/2018 CICLOPS  
 614 expedition.

615 **Table 4.** The mean dCo and labile dCo observed in the deep ( $\geq 100$  m) Ross Sea, and the average  
 616 deep dCo loss between 3 previous sampling expeditions (CORSACS-1 in summer 2005/2006;  
 617 CORSACS-2 in spring 2006; under-ice sampling in McMurdo Sound in spring 2009) and the  
 618 CICLOPS expedition (2017/2018). Dissolved Co and labile dCo loss values were calculated as the  
 619 difference between mean deep concentrations observed on previous expeditions and those  
 620 observed on the CICLOPS expedition. No labile dCo data (n.d.) is presented from the CORSACS-  
 621 1 expedition. Independent t-tests were performed to determine the significance of difference  
 622 between the deep mean concentrations from previous expeditions compared to the CICLOPS  
 623 expedition; \* indicates a significant difference between CICLOPS and a previous expedition ( $p <$   
 624  $0.005$ ). The mean deep dCo concentrations from the CORSACS expeditions were not significantly  
 625 different from each other ( $p = 0.27$ ).

	dCo <sub>mean</sub> [pM]	n	Labile dCo <sub>mean</sub> [pM]	n	dCo Loss [pM]	<i>p</i> -value	Labile dCo Loss [pM]	<i>p</i> -value
CORSACS-1 <sup>a</sup>	$55 \pm 4$	26	n.d.		$8 \pm 9$	$< 0.0001^*$	--	--
CORSACS-2 <sup>a</sup>	$56 \pm 6$	19	$21 \pm 7$	20	$10 \pm 10$	$< 0.0001^*$	$12 \pm 10$	$< 0.0001^*$
McMurdo Sound <sup>b</sup>	$51 \pm 4$	19	$15 \pm 2$	19	$4 \pm 8$	0.02	$6 \pm 7$	0.0006*
CICLOPS	$46 \pm 8$	32	$9 \pm 7$	32	--	--	--	--

626  
 627 <sup>a</sup> Data originally published in Saito et al. (2010).

628 <sup>b</sup> Data originally published in Noble et al. (2013).

629 The low labile dCo inventory in the Ross Sea was a surprising discovery during CICLOPS  
 630 since relatively high concentrations of labile dCo were previously noted to be a distinctive feature  
 631 of the Ross Sea and Southern Ocean when compared to the tropical and subtropical global oceans  
 632 (Saito et al., 2010). In prior studies in this region, high labile : total dCo ratios were hypothesized  
 633 to be due to the absence of ligand-producing – and vitamin B<sub>12</sub>-producing – marine cyanobacteria  
 634 like *Synechococcus* in the Ross Sea (Caron et al., 2000; DiTullio et al., 2003; Bertrand et al., 2007),  
 635 since *Synechococcus*-dominated communities have been known to produce a substantial amount  
 636 of Co ligands (Saito et al., 2005). However, high Co ligand concentrations and low labile dCo  
 637 concentrations have previously been observed at a more pelagic location in the Southern Ocean

638 near New Zealand, where it was hypothesized that the decay of a eukaryotic phytoplankton bloom  
639 generated higher abundances of Co-binding ligands in the surface ocean (Ellwood et al., 2005).

640 The decrease in the dCo and labile dCo inventories was apparent when the CICLOPS and  
641 CORSACS dCo vs.  $\text{dPO}_4^{3-}$  relationships across all expedition regions were compared (Fig. 6c,e).  
642 Over similar  $\text{dPO}_4^{3-}$  ranges, the CICLOPS dCo concentrations are generally lower than those  
643 observed on CORSACS, and the CICLOPS labile dCo concentrations are considerably lower, with  
644 labile dCo essentially absent from upper ocean samples with a  $\text{dPO}_4^{3-}$  concentration  $< 1.75 \mu\text{M}$ .  
645 Despite the lack of observable scavenging, the CICLOPS dCo vs.  $\text{dPO}_4^{3-}$  relationship appeared to  
646 be noticeably nonlinear throughout the water column ( $R^2 = 0.42$ ), while CORSACS samples  
647 displayed a more linear trend ( $R^2 = 0.57$ ). The CICLOPS dCo vs.  $\text{dPO}_4^{3-}$  relationship creates a  
648 concave, “scooped” shape where dCo was depleted relative to  $\text{dPO}_4^{3-}$ , displaying a lower slope in  
649 the upper ocean than was observed on the CORSACS expeditions (Fig. 6c). This scooped shape  
650 was particularly evident in Terra Nova Bay where the upper ocean dCo :  $\text{dPO}_4^{3-}$  stoichiometric  
651 slope was the lowest ( $26 \pm 4 \mu\text{mol} : \text{mol}$ ;  $R^2 = 0.65$ ). The depletion of dCo relative to  $\text{dPO}_4^{3-}$   
652 observed on CICLOPS appears driven by the shift in Co speciation as a result of near-total uptake  
653 of the upper ocean labile dCo fraction and subsequent dominance of the remaining strong ligand-  
654 bound dCo fraction in the upper ocean. Similar to the deep dCo loss described above, the difference  
655 between the CORSACS and CICLOPS dCo vs.  $\text{dPO}_4^{3-}$  relationship can be accounted for by the  
656 depletion of the labile dCo inventory. In the deep ocean where both dCo and  $\text{dPO}_4^{3-}$  are more  
657 abundant, the large range in dCo concentrations relative to  $\text{dPO}_4^{3-}$  concentrations may be evidence  
658 of deep inputs of dCo and labile dCo from the nepheloid layer, which was more attentively sampled  
659 on CICLOPS than either CORSACS expedition (Sect. 4.1).

#### 660 4.4 Dissolved Co, Zn and Cd stoichiometry

661 Dissolved Zn concentrations observed on CICLOPS were low in the surface ocean,  
662 particularly in Terra Nova Bay, where dZn concentrations in the sub-nanomolar ranges were  
663 observed (average  $\text{dZn} = 0.87 \pm 0.42$  at 10 m depth,  $n = 11$ ). Marine microbes require Zn for a  
664 wide range of metabolic uses; for example, eukaryotic phytoplankton use Zn as a cofactor in  
665 carbonic anhydrase (Roberts et al., 1997; Morel et al., 2020) and bacteria such as  
666 *Pseudoalteromonas* use Zn in a range of proteases (Mazzotta et al., 2021). Prior culture studies  
667 have found that Zn scarcity can lead to co-limitation of both Zn and carbon in several eukaryotic  
668 phytoplankton strains (Morel et al., 1994; Sunda and Huntsman, 2000), and field incubation  
669 experiments have shown evidence for Zn co-limitation with Fe (Jakuba et al., 2012) and silicate  
670 (Chappell et al., 2016) in the Pacific Ocean. During the CICLOPS expedition, an incubation  
671 experiment performed at Station 27 in Terra Nova Bay found compelling evidence for Zn and Fe  
672 co-limitation, which constrained Chl-a production and DIC draw-down by phytoplankton in the  
673 region (Kellogg et al., [Submitted]).

674 Many but not all phytoplankton are able to substitute Co and Cd for Zn as their carbonic  
675 anhydrase metallic cofactor (Lee and Morel, 1995; Sunda and Huntsman, 1995; Lane et al., 2005;  
676 Kellogg et al., 2022), which provides metabolic flexibility and a competitive edge in low-dZn  
677 environments (Kellogg et al., 2020). The Cd-containing carbonic anhydrase CDCA is currently  
678 the only known metabolic use of Cd, and the uptake of dCd and dCo in the photic zone, both metals  
679 which are typically less abundant than dZn in the oceans, often increases under low dZn conditions  
680 (Sunda and Huntsman, 1995, 1996; Jakuba et al., 2008; Kellogg et al., 2020; Morel et al., 2020).  
681 Cations like Zn, Cd and Co that possess similar charge and atomic radii often share the same

682 transporter uptake systems, and the relative availability of different metal cofactors for use in an  
683 organism's metalloproteome is partially determined by the environmental metal concentrations  
684 and the affinity of the metals for ligands associated with a cell's metal transport proteins (Irving  
685 and Williams, 1948; Sunda and Huntsman, 1992, 1995). When dZn concentrations are low, more  
686 Cd and Co are able to bind to the transporter ligands despite the relative stability of their ligand-  
687 bound complexes, which tend to be lower for Co than for Zn. Through this mechanism, dZn  
688 concentrations and cycling can influence the distribution and uptake of Co and Cd, particularly in  
689 low dZn environments like the Ross Sea and Terra Nova Bay.

690 The dZn vs.  $dPO_4^{3-}$  and dCd vs.  $dPO_4^{3-}$  relationships observed in the Amundsen Sea, Ross  
691 Sea and Terra Nova Bay were compared relative to dCo vs.  $dPO_4^{3-}$  (Fig. 7; Table 3). For this  
692 analysis, the depth threshold that separates the upper ocean from the deep ocean was selected  
693 manually in order to optimize the linear fit of the upper and deep ocean trends and to best capture  
694 the depth dependence of the observed trace metal stoichiometries. This depth threshold can best  
695 be conceptualized as an inflection point that represents the largest change in trace metal  
696 concentrations with respect to depth or, in this case,  $dPO_4^{3-}$  concentration. The depth threshold  
697 used for dCo in both the Ross Sea and Terra Nova Bay (100 m) is deeper than those used for dZn  
698 and dCd, (range of 25 – 50 m). Thus, the inflection points of the “scoops” in the trace metal  
699 stoichiometries are driven by the uptake stoichiometry of the region's phytoplankton community  
700 rather than the mixed layer depth of the upper ocean. The shapes observed in the dZn vs.  $dPO_4^{3-}$   
701 and dCd vs.  $dPO_4^{3-}$  relationships were similar to that of dCo vs.  $dPO_4^{3-}$ , exhibiting distinct  
702 differences in slope between surface and deep waters. The stark difference in trace metal  
703 stoichiometry slopes between the upper and deep ocean is likely driven by differences in metal  
704 speciation over depth. In the surface ocean, a shallower trace metal :  $dPO_4^{3-}$  slope suggests a trace  
705 metal fraction that is largely bound to strong organic ligands, with a smaller excess labile fraction.  
706 The more bioavailable labile fraction of metals would have been drawn down by phytoplankton,  
707 whose uptake transport systems preferentially bind to labile metals. At deeper depths, the presence  
708 of labile metals in excess of strong organic ligands results in a higher metal :  $dPO_4^{3-}$  slope.

709 A shallow dCo :  $dPO_4^{3-}$  slope that extends below the photic zone could suggest Co uptake  
710 by heterotrophic bacteria, archaea and possibly sinking phytoplankton below the photic zone.  
711 Heterotrophic prokaryotic uptake of labile Co is largely driven by the bacteria and archaea that  
712 contain a vitamin B<sub>12</sub> synthesis pathway that is absent in all eukaryotes (Warren et al., 2002;  
713 Osman et al., 2021); unlike carbonic anhydrase, the use of Co as a co-factor in the vitamin B<sub>12</sub>  
714 corrin ring structure cannot be substituted for by other divalent cations like Zn and Cd. Many  
715 vitamin B<sub>12</sub>-synthesizing bacteria possess genes for Co(II)-specific transporters in addition to more  
716 general metal ion transporters, and the Co-specific transporters are regulated by cellular  
717 concentrations of vitamin B<sub>12</sub>, illustrating the importance of vitamin B<sub>12</sub> synthesis in driving  
718 bacterial Co uptake (Osman et al., 2021); however, this mechanism has not been observed within  
719 marine bacterial communities. Additionally, vitamin B<sub>12</sub> uptake by both prokaryotes and  
720 eukaryotes has been found to be common in Antarctic coastal communities (Taylor and Sullivan,  
721 2008; Rao, 2020), and likely contributes to the depletion of ligand-bound dCo in both the surface  
722 and mesopelagic ocean.

723 The shallower Zn apparent nutricline could also be explained by the higher stability of Zn  
724 metal-ligand complexes compared to Co complexes within phytoplankton metabolisms, allowing  
725 higher uptake rates of dZn when available (Irving and Williams, 1948; Sunda and Huntsman,  
726 1995). The vertical dimension of trace metal loss captured by a comparison of these apparent

727 nutriclines could be conceptualized as a time-dependent process driven by the phytoplankton  
728 community's preference for each trace metal, with preferred nutrients like Zn exhibiting a  
729 shallower stoichiometric inflection point arising from the rapid depletion of the metal within the  
730 photic zone, and nutrients like dCo, which is often taken up by eukaryotes when dZn is scarce  
731 (Sunda and Huntsman, 1995; Kellogg et al., 2020), exhibiting a deeper stoichiometric inflection  
732 point below the photic zone. This analysis suggests that substitution at the interface of the uptake  
733 mechanism for trace metal transporters at least partially controlled the stoichiometry of Zn/Cd/Co  
734 distributions and uptake in the upper ocean.

#### 735 4.5 Zn/Cd/Co uptake using a shared trace metal membrane transport system

736 This study synthesized dissolved concentration and uptake datasets for Co, Zn and Cd  
737 (Table 5), three trace metal nutrients whose use by phytoplankton is collectively integral to surface  
738 ocean productivity and the biogeochemical cycling of Fe, vitamin B<sub>12</sub> and carbon in the Southern  
739 Ocean. This combined dataset is ideal for interrogating questions of environmental competitive  
740 inhibition of Zn, Cd and Co transport in low-dZn environments. The observation of order of  
741 magnitude trends in trace metal uptake rates over depth profiles ( $\rho\text{Zn} > \rho\text{Cd} > \rho\text{Co}$ ) was novel,  
742 and paralleled the order of magnitude trends of trace metal concentrations in seawater ( $[\text{Zn}] > [\text{Cd}]$   
743  $> [\text{Co}]$ ; Fig 5). This environmental observation reflected the findings of numerous culture  
744 experiments that quantify the uptake of trace metals as a function of the concentration of available  
745 labile metals and the affinity of the metal for a cell transporter's binding ligand (Irving and  
746 Williams, 1948; Sunda and Huntsman, 1992, 1995, 2000; Kellogg et al., 2020).

747 Evidence for elevated Co uptake in the low-dZn environments of the surface ocean were  
748 supported by the trace metal uptake rates. When  $\rho\text{Zn}$  and  $\rho\text{Cd}$  was normalized to  $\rho\text{Co}$  ( $\rho\text{M} : \rho\text{Co}$ ;  
749 Fig. 5), deviations from these order-of-magnitude trends were observed. In particular, at Stations  
750 4 and 11 in the Amundsen Sea and Station 22 in Terra Nova Bay,  $\rho\text{Zn}$  and  $\rho\text{Cd}$  stoichiometry  
751 relative to  $\rho\text{Co}$  tended to decrease towards the surface in the upper 50 m, while the opposite trend  
752 appeared to occur at Station 57 in the late summer. The surface-most trends of stations 20 and 57  
753 were undetermined due to a lack of a 10 m  $\rho\text{Co}$  value. This increasing surface Co uptake  
754 stoichiometry relative to Zn and Cd at Stations 4, 11 and 22 – stations that also displayed  
755 significant phytoplankton blooms – suggests that Co uptake increased in low-Zn environments,  
756 while later in the summer at Station 57,  $\rho\text{Co}$  lessened relative to  $\rho\text{Zn}$ , possibly due to the deepening  
757 of the mixed layer in February, bringing additional dZn to the upper ocean via vertical mixing  
758 (Fig. 4). The increase in the observed  $\rho\text{Co}$  rate was likely due to the upregulation of the shared Zn  
759 and Co uptake transporter system. From laboratory culture experiments aimed at examining the  
760 microbial uptake of Zn and other trace metals, it is apparent that many diatoms and  
761 coccolithophores contain two distinct Zn uptake systems: a low-affinity system that operates at  
762 higher concentrations of dZn and a high-affinity system that functions at lower concentrations of  
763 dZn (Sunda and Huntsman, 1992; John et al., 2007). Both transport mechanisms are relatively  
764 unspecific as to the divalent metals transported into the cell; the low-affinity system is known to  
765 transport Zn, Cd and Mn, while the high-affinity system transports Zn, Cd and Co. (Sunda and  
766 Huntsman, 1995, 1996); thus, Co uptake is often inhibited at high dZn concentrations when the  
767 low-affinity system is active (Sunda and Huntsman, 1995; Sunda 2012). In culture, diatoms have  
768 been observed to switch from the low-affinity to the high-affinity transport system between  $10^{-10.5}$   
769 and  $10^{-9.5}$  M dZn<sup>2+</sup> (Sunda and Huntsman, 1992; John et al., 2007), a relevant range for the lowest  
770 values of total dZn observed in the surface ocean on CICLOPS (dZn minimum =  $1 \times 10^{-10}$  M at

771 Station 46, 10 m depth), and the  $dZn^{2+}$  pool would have been even smaller due to organic  
772 complexation.

773 **Table 5.** Dissolved stoichiometric ratios and uptake stoichiometric ratios of five station profiles  
774 for Co, Cd and Zn. The  $dCo : dCd : dZn : dPO_4^{3-}$  ratio is the dissolved stoichiometry of metals  
775 present in the water column normalized to  $dPO_4^{3-}$ , and the  $\rho Co : \rho Cd : \rho Zn$  ratio is the uptake  
776 stoichiometry of microbial communities normalized to  $\rho Co$ .

777

778

779 \*Denotes depths at which  $\rho Cd$  was under the methodological detection limit.

780 To investigate the influence of transporter competitive inhibition on trace metal uptake via  
781 the high-affinity uptake system, we can estimate the predicted  $\rho Co$ ,  $\rho Cd$  and  $\rho Zn$  values given the  
782 observed trace metal concentrations with an equation adapted from Michaelis-Menten enzyme-  
783 substrate kinetics (Sunda and Huntsman, 1996, 2000):

$$784 \text{ Predicted } \rho M = \frac{V_{max}[M^{2+}]K_M}{[Co^{2+}]K_{Co} + [Cd^{2+}]K_{Cd} + [Zn^{2+}]K_{Zn}}$$

785 where  $M$  is the trace metal (Co, Cd, Zn) whose uptake is being calculated,  $V_{max}$  is the saturation  
786 uptake rate of the transporter system, and  $K_{Co}$ ,  $K_{Cd}$  and  $K_{Zn}$  are steady state affinity constants for

787 the metal-ligand complex associated with the membrane transporter. For this system, we assumed  
 788  $K_{Zn} = K_{Cd} = K_{Co} = 10^{9.6}$ , where  $10^{9.6}$  is the value of  $K_{Zn}$  for the high-affinity uptake system  
 789 determined by Sunda et al. (1992), and that 99% of the dCo, dCd and dZn inventory was bound to  
 790 strong organic ligands, leaving 1% of the total metal concentration labile. Note that the assumption  
 791 that  $K$  and the percent labile multipliers are equal for all metals results in their value being nullified  
 792 by their presence in both the numerator and denominator of the predicted uptake equation, and so  
 793 their assumed values have no numerical impact on the predicted uptake values. It was also assumed  
 794 that  $V_{max}$  values for each trace metal were equal, which is likely a reasonable assumption for metals  
 795 that share an uptake system, although  $V_{max}$  is known to vary with trace metal concentration, a  
 796 function that we have assumed here to be negligible (Sunda and Huntsman, 1985, 1996; Sunda,  
 797 1989).  $V_{max}$  is in units of  $\mu\text{mol} (\text{mol C})^{-1} \text{d}^{-1}$ , and the predicted trace metal uptake rates were  
 798 converted to units of  $\text{M d}^{-1}$  using a C : Chl-a ratio of 130 w/w, derived from the Ross Sea  
 799 phytoplankton community (DiTullio and Smith, 1996).

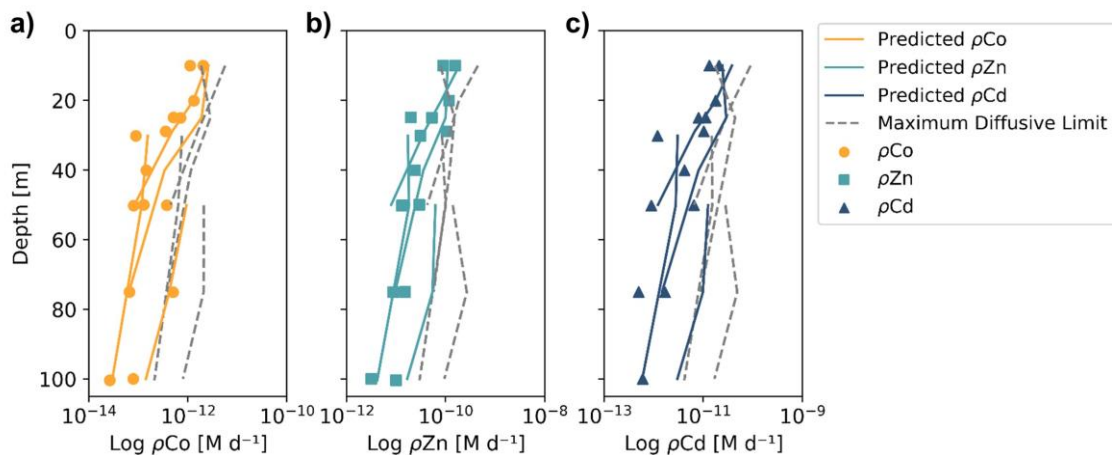

800 When the predicted metal uptake rates were calculated using a  $V_{max}$  value of  $262 \mu\text{mol} (\text{mol}$   
 801  $\text{C})^{-1} \text{d}^{-1}$  from previous Zn culturing experiments (Sunda and Huntsman, 1992), the resulting values  
 802 recreated the trend of the observed trace metal uptake profiles, with higher uptake rates in the  
 803 surface ocean and lower rates below the photic zone, but the predicted values were over an order  
 804 of magnitude greater than the measured uptake rates (Fig. B1). This offset may be due to several  
 805 factors: (1) the assumed C : Chl-a ratio to scale predicted uptake with observed biomass may be  
 806 high, (2) the  $V_{max}$  value calculated from laboratory experiments may be high, or (3) the  
 807 assumptions that the speciation of the dissolved trace metals are 99% strongly-bound at all depths,  
 808 for all metals is incorrect. The final explanation may play a role in the offset between the predicted  
 809 and observed uptake rates, and illustrates the complexities of translating lab-based culture work to  
 810 environmental measurements and in-situ analyses. The  $V_{max}$  value is also relatively unconstrained,  
 811 and it is reasonable to assume it may be lower in the Ross Sea than observed in culture if the  
 812 phytoplankton exhibit suppressed metal quotas to survive in a metal-deplete environment. With  
 813 this in mind, the  $V_{max}$  value was tuned to  $4 \mu\text{mol} (\text{mol C})^{-1} \text{d}^{-1}$  to fit the observed uptake rates,  
 814 which is lower than any Co, Cd or Zn  $V_{max}$  reported in the literature from culture studies (Fig. 10).  
 815 Using the tuned  $V_{max}$  value, the high-affinity uptake system equation properly predicts the order  
 816 of magnitude trends inherent in the observed Co/Cd/Zn uptake rates. This analysis demonstrates  
 817 the measured uptake rates from the Ross Sea were likely driven by the concentration ratios of  
 818 available metals throughout the water column, following a high-affinity transporter model of Co,  
 819 Cd and Zn uptake.

820 The maximum diffusive limit, a calculation of the phytoplankton community's maximum  
 821 diffusion rate for the uptake of trace metal nutrients through their cell membranes, was also  
 822 estimated and compared to the observed and predicted uptake rate profiles. The physical limits of  
 823 uptake via diffusion was determined as a function of the surface area of phytoplankton membranes  
 824 (Sunda and Huntsman, 1992):

$$825 \quad \text{Maximum diffusive limit} = 4\pi rD [M^{2+}]$$

826 where  $r$  is the equivalent spherical radius of a phytoplankton cell, assumed to be  $3 \mu\text{m}$ , a reasonable  
 827 value for diatom species, and  $D$  is a diffusion rate constant of  $2 \times 10^{-6} \text{cm}^2 \text{s}^{-1}$ , calculated for  $\text{Zn}^{2+}$   
 828 at  $20^\circ\text{C}$  (Sunda and Huntsman, 1992). The diffusive limit was converted to units of  $\text{M d}^{-1}$  using a  
 829 C : cell volume ratio of  $12.5 \text{mol C L}^{-1}$ , which is the average of two diatom ratios reported in Sunda  
 830 and Huntsman (1995) ( $11$  and  $14 \text{mol C L}^{-1}$ ), and the same C : Chl-a ratio of 130 w/w used for the  
 831 predicted uptake rate estimate above (DiTullio and Smith, 1996). The resulting diffusive limit

832 profiles are highly dependent on the assumed speciation of each trace metal; when the dCo, dCd  
 833 and dZn inventories were assumed to be 99% bound (Fig. 10), the maximum diffusive limit was  
 834 slightly greater than the predicted and observed uptake rates, but when the inventories were  
 835 assumed to be 100% labile (Fig. B1), the diffusive limit greatly exceeded the uptake rates by  
 836 several orders of magnitude. Since the metal inventories almost certainly vary in their speciation  
 837 of dZn and dCd over depth, as was observed in the dCo inventory, an accurate maximum diffusive  
 838 limit would exist between the two extremes of 0% bound and 99% bound, and might be expected  
 839 to be greater at deeper depths, where a higher fraction of the dissolved metal inventory is labile.  
 840 For additional analysis of the predicted metal uptake ratios and the maximum diffusive limit, see  
 841 Appendix B.

842  
 843 **Figure 10.** Observed (markers) and predicted (solid lines) trace metal uptake rate ( $\rho$ ) profiles for  
 844 Co (a) Zn (b) and Cd (c) from Stations 11, 20, 22 and 57. The maximum diffusive limit profiles  
 845 (dashed lines) are shown as an estimate of the physical limits of metal diffusion through uptake  
 846 transporters. The predicted uptake rates were tuned to best fit the observed uptake rate trends by  
 847 using a  $V_{\max}$  value of  $4 \mu\text{mol} (\text{mol C}^{-1}) \text{d}^{-1}$ , and the maximum diffusion limit estimation assumed  
 848 a speciation of 1% labile metals.

#### 849 4.6 Vitamin B<sub>12</sub> and Zn stress, and their implications for increasing biological dCo demand

850 The near-absence of labile dCo and low concentration of ligand-bound dCo in coastal  
 851 Antarctic seas may indicate a larger shift in the region towards vitamin B<sub>12</sub> limitation. Vitamin B<sub>12</sub>  
 852 has been shown to be co-limiting with Fe in the Ross Sea and elsewhere (Sañudo-Wilhelmy et al.,  
 853 2006; Bertrand et al., 2007), and increased vitamin B<sub>12</sub> uptake by both bacterioplankton and  
 854 eukaryotic phytoplankton has been observed in incubation experiments following the alleviation  
 855 of surface ocean Fe limitation (Bertrand et al., 2011). Two primary sources of Fe to the Antarctic  
 856 seas are a flux of lithogenic Fe from melting ice shelves along the continent and sediment  
 857 resuspension along the seafloor, both of which have been observed to be meaningful Fe sources to  
 858 the Amundsen Sea (Planquette et al., 2013; St-Laurent et al., 2017). The source of particulate Fe  
 859 from glacial meltwater to coastal Antarctic seas has been increasing over the past several decades  
 860 and is expected to continue to increase as Antarctic ice shelves and glaciers melt and retreat due  
 861 to global climate change (Monien et al., 2017). The source of particulate Co from glacial meltwater  
 862 would also be expected to increase since Co, like Fe, has been observed to be transported from the  
 863 Antarctic continent via ice melt (Westerlund and Öhman, 1991), and it is unclear what role this

864 presumably increasing source of Co to the surface ocean plays in the reduced inventories of dCo  
865 in the surface ocean.

866 Although it is difficult to definitively conclude that the low dCo inventory observed on  
867 CICLOPS is representative of a decadal trend towards vitamin B<sub>12</sub> limitation and not simply  
868 variation in micronutrient availability and community structure, the inventory and stoichiometric  
869 uptake trends documented in this study are compelling evidence for a changing biogeochemical  
870 Co cycle in the coastal Southern Ocean. Paired with the recent discovery of Zn/Fe co-limitation in  
871 Terra Nova Bay (Kellogg et al., [Submitted]), these results suggest a complex landscape of  
872 micronutrient scarcity and limitation in coastal Antarctic seas where plankton community  
873 structures and Fe additions from melting ice sheets can generate patches of vitamin B<sub>12</sub> and Zn  
874 limitation within a broadly Fe-scarce HNLC region.

875 The bacterial community is essential to the development and alleviation of vitamin B<sub>12</sub>  
876 limitation within a eukaryotic phytoplankton bloom since only prokaryotes possess the metabolic  
877 pathway to synthesize the vitamin (Warren et al., 2002; Croft et al., 2005). In the Southern Ocean,  
878 near-zero counts of photosynthetic bacteria indicate that the heterotrophic bacterial communities  
879 are primarily responsible for vitamin B<sub>12</sub> production in the region (Bertrand et al., 2011). Vitamin  
880 B<sub>12</sub> can become limiting when the bacterial community is low in abundance and/or growth limited  
881 by a different nutrient such as dissolved organic matter (DOM). In the Ross Sea, bacterioplankton  
882 have been found to be growth limited by an inadequate supply of DOM (Church et al., 2000;  
883 Bertrand et al., 2011), and there can be up to a one-month lag between the onset of the spring  
884 phytoplankton bloom and an associated bacterial bloom stimulated by phytoplankton DOM  
885 production (Ducklow et al., 2001). This offset suggests that vitamin B<sub>12</sub> limitation among  
886 eukaryotes is most probable earlier in the season within the spring bloom. Additionally, low  
887 abundances of mesozooplankton and microzooplankton grazing rates in the Ross Sea create  
888 phytoplankton blooms with low grazing pressure (Caron et al., 2000; Ducklow et al., 2001), which  
889 may allow low DOM conditions to persist later into a bloom and exacerbate vitamin B<sub>12</sub> stress  
890 among eukaryotes.

891 A shift towards vitamin B<sub>12</sub> limitation would likely favor phytoplankton with flexible  
892 metabolisms that are able to reduce their demand for Co and vitamin B<sub>12</sub> when necessary.  
893 Organisms that can express the vitamin B<sub>12</sub>-independent *metE* gene may out-compete those  
894 expressing the vitamin B<sub>12</sub>-dependent *metH* gene (Rao et al., [In review]; Rodionov et al., 2003;  
895 Bertrand et al., 2013; Helliwell 2017). *P. antarctica*, for example, may be well suited to periods  
896 of vitamin B<sub>12</sub> limitation due to the symbiotic bacterial microbiomes that form within its colonies  
897 and produce B vitamins that allow the colonies to grow when B vitamins are otherwise unavailable  
898 (Brisbin et al., 2022). *P. antarctica* has also been found to express a novel *metE*-fusion gene when  
899 vitamin B<sub>12</sub> limited and *metH* gene while vitamin-replete, suggesting a highly flexible vitamin B<sub>12</sub>  
900 metabolism (Rao et al., [In review]).

901 There is compelling evidence for high rates of biological Co uptake in the Ross Sea during  
902 the 2017/2018 summer compared to the 2005/2006 summer driven by the uptake of dCo from  
903 vitamin B<sub>12</sub> and Zn scarcity. Together, these two stressors increase the rate of Co uptake as well  
904 as the Co : C stoichiometry of phytoplankton biomass. The stoichiometry of Co uptake has been  
905 observed to be highly plastic in this study and others, responding to the availability of other  
906 micronutrients and the requirements of the microbial community (Sunda and Huntsman, 1995;  
907 Saito et al., 2017). An increase in  $\rho$ Co could then result in a decrease of the Co inventory in coastal  
908 Antarctic seas, following the mechanism detailed below.

909 Biological uptake alone would not permanently remove Co from the water column; uptake  
 910 only shifts Co from the dissolved phase to the particulate phase, where POM remineralization  
 911 restores Co back to the dissolved phase. The net removal pathways of Co include (1) burial as  
 912 POM, (2) particle scavenging and (3) depletion of dCo into Circumpolar Deep Water (CDW) and  
 913 Antarctic Bottom Water (ABW). We have already noted that Co scavenging to Mn-oxides is  
 914 particularly low in the Southern Ocean (Oldham et al., 2021). The advection of dCo into CDW  
 915 may not be at a steady state throughout the year since cycles of ice melt and formation affect the  
 916 mixing of CDW and formation of dense Antarctic Bottom Water (ABW), and so may represent a  
 917 removal pathway for dCo on an annual cycle. However, an increase in the burial flux of Co in  
 918 POM is the most likely pathway for sustained loss of the Co inventory. When the  $\rho\text{Co}$  rate  
 919 increases, the stoichiometry of Co incorporation into biomass relative to P would also increase.  
 920 Over the years, a strengthened demand for Co via vitamin B<sub>12</sub> and Zn stress could result in a steady  
 921 loss of Co if the Co : C and Co : PO<sub>4</sub><sup>3-</sup> stoichiometry of POM increases but the remineralization of  
 922 POM is unchanged, increasing the flux of particulate Co into the deep ocean and sediments. In the  
 923 winter, sea ice covers the Antarctic seas and the water column mixes, a process that would  
 924 propagate the low dCo concentrations from the photic zone into the deep ocean and result in a  
 925 steady loss of the dCo inventory throughout the water column.

926 Additionally, warming surface ocean temperatures likely play a role in phytoplankton  
 927 productivity and nutrient uptake. Increasing both dFe availability and temperature have been  
 928 shown to significantly increase phytoplankton growth and phytoplankton abundance in the Ross  
 929 Sea, and impact community structure (Rose et al., 2009; Spackeen et al., 2018; Zhu et al., 2016).  
 930 From a kinetic perspective, higher surface temperatures would be expected to increase the uptake  
 931 rates of nutrients, including micronutrients like Fe, Co and Zn, by increasing the value of  $K_M$ .  
 932 However, the effects of temperature on productivity and community composition are more  
 933 complex since increasing ocean temperatures would also decrease the solubility of CO<sub>2</sub>, change  
 934 the seasonality of ice cover and thus sunlight availability, and affect water column turnover and  
 935 mixing regimes (Rose et al., 2009). The effects of warming temperatures on the intricate landscape  
 936 of nutrient availability and limitation regimes described here is an open question in this study.

#### 937 4.7 A two-box model that describes a mechanism for deep dCo inventory loss

938 To test the proposed mechanism that higher Co uptake rates and winter mixing can lead to  
 939 a deep inventory loss of ~10 pM Co over 12 years, a time step two-box model of a 1 m<sup>2</sup> water  
 940 column was created in Microsoft Excel to simulate the Ross Sea dCo cycle. A schematic of the  
 941 modeled dCo cycle is presented in Fig. 11, flux equations to describe the biogeochemical cycling  
 942 of Co are presented in Appendix C, and the parameters used to simulate dCo loss over 12 years  
 943 and a hypothetical steady state condition are given in Table 6.

944 The change in dCo concentration over time ( $d[\text{dCo}]/dt$ ) for a surface ocean (0–100 m) and  
 945 deep ocean (100–500 m) was calculated as the sum of the dCo source fluxes minus the sum of the  
 946 sink fluxes:

$$947 \left( \frac{d[\text{dCo}]}{dt} \right)_{\text{Surface}} = \frac{F_{\text{Over}} + F_{\text{Remin}} - F_{\text{Up}}}{V_{\text{Surface}}}$$

$$948 \left( \frac{d[\text{dCo}]}{dt} \right)_{\text{Deep}} = \frac{F_{\text{Remin}} + F_{\text{Neph}} - F_{\text{Up}} - F_{\text{Over}}}{V_{\text{Deep}}}$$

949 where  $F_{Over}$  is the overturning flux between the two boxes,  $F_{Remin}$  is the remineralization flux,  $F_{Up}$   
 950 is the biological uptake flux, and  $F_{Neph}$  is the flux of dCo from the nepheloid layer into the deep  
 951 ocean (Table C1).  $F_{Up}$  was calculated using the measured  $\rho\text{Co}$  uptake rates observed on the  
 952 CORSACS and CICLOPS expeditions, and  $F_{Remin}$  was calculated using an assumed surface and  
 953 deep remineralization factor (RF) of 0.9, indicating that 90% of the POM generated in the surface  
 954 ocean is remineralized back to its inorganic dissolved components. In the Southern Ocean, the  
 955 fluxes of scavenging and aerosol deposition would be relatively negligible, so these fluxes have  
 956 been omitted from the model. The magnitude of  $F_{Neph}$  in the Ross Sea remains unconstrained, and  
 957 in this model, the deep nepheloid dCo source was used as an adjustable parameter to tune the  
 958 magnitude of deep dCo loss to be 10 pM over 12 years, which represents the approximate observed  
 959 differences between the CORSACS and CICLOPS expeditions detailed in Sect. 4.3. A  $F_{Neph}$  was  
 960 calculated to be 3550 pmol dCo  $\text{m}^{-2} \text{d}^{-1}$  to the deep ocean, but this should not be considered a  
 961 meaningful calculation of the observed nepheloid layer flux.

962  
 963 **Figure 11.** A schematic of the dCo cycle (black arrows) and select processes of the particulate Co  
 964 (pCo) cycle (orange arrows) presented as a simplified two-box model. Net fluxes of the dCo cycle  
 965 include sources from aerosol deposition ( $F_{Aero}$ ), bottom sediments and the nepheloid layer ( $F_{Neph}$ ),  
 966 and scavenging to Mn-oxides particles ( $F_{Scav}$ ) which likely represents a minor flux in the coastal  
 967 Antarctic seas. Internal cycling fluxes include horizontal advection ( $F_{Adv}$ ), water column  
 968 overturning or mixing ( $F_{Over}$ ), biological uptake ( $F_{Up}$ ) and remineralization of pCo ( $F_{Remin}$ ). Fluxes  
 969 of pCo shown here include sinking biomass from the surface into the deep ocean ( $F_{Sink}$ ) and pCo  
 970 burial into sediments along the seafloor ( $F_{Bur}$ ). The biological uptake of dCo is influenced by the  
 971 relative stoichiometric uptake of Co, Zn and Cd ( $\rho\text{Co} : \rho\text{Cd} : \rho\text{Zn}$ ) among the microbial  
 972 community. Differential equations that describe and quantify these fluxes are presented in  
 973 Appendix C.

974 In the Ross Sea, the deep winter mixed layer can extend 600 m to the seafloor and turn  
 975 over the whole water column in some locations (Smith and Jones, 2015), mixing the surface and  
 976 deep ocean under the winter sea ice and resulting in near-vertical profiles of dCo in the early spring  
 977 (Noble et al., 2013). Here, the winter mixing process was modeled by combining the surface and  
 978 deep ocean boxes into one homogenized box during the winter season (151 days, ~5 months). The  
 979 dCo concentrations of the winter box were calculated using a volume-weighted average (see  
 980 Appendix C).

981 **Table 6.** Parameters of the Co cycle two-box model, run as both a steady state model with lower  
 982 Co uptake rates ( $\rho\text{Co}$ ) and as a mechanism for deep dCo inventory loss driven by higher  $\rho\text{Co}$   
 983 values. The calculated burial flux of particulate Co within each model variation is also given, but  
 984 note that the burial flux values should be interpreted as a comparison of the Co sink via the  
 985 biological pump when  $\rho\text{Co}$  is varied, and not as observed or meaningful Co flux magnitudes.

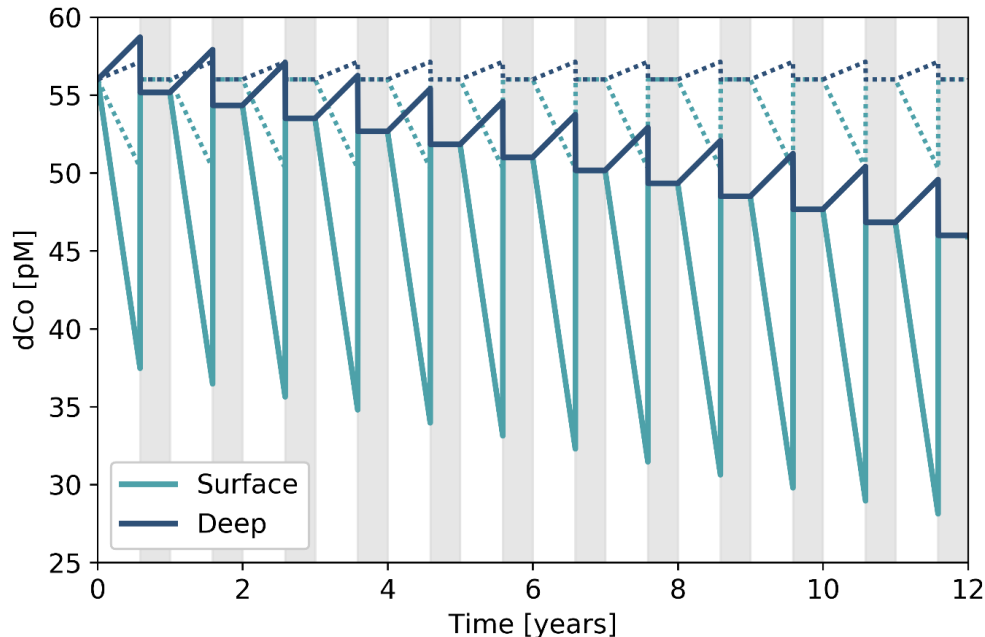

<b>Model Parameters</b>	<b>Value</b>	<b>Units</b>
Bloom season length	214	days
Surface box height	100	m
Deep box height	500	m
Remineralization Factor (RF)	0.9	
Deep Nephloid Flux	3550	pmol Co m <sup>-2</sup> d <sup>-1</sup>
Overturning Water Flux	0	m <sup>3</sup> d <sup>-1</sup>
<b>Steady State Parameters</b>		
Surface $\rho\text{Co}$	0.27	pmol Co L <sup>-1</sup> d <sup>-1</sup>
Deep $\rho\text{Co}$	0.66	pmol Co L <sup>-1</sup> d <sup>-1</sup>
Burial Flux	3550	pmol Co d <sup>-1</sup>
<b>Co Loss Parameters</b>		
Surface $\rho\text{Co}$	0.87	pmol Co L <sup>-1</sup> d <sup>-1</sup>
Deep $\rho\text{Co}$	0.1	pmol Co L <sup>-1</sup> d <sup>-1</sup>
Burial Flux	5870	pmol Co d <sup>-1</sup>

986

987 This model provides a plausible mechanism by which increases in  $\rho\text{Co}$  such as those  
 988 observed along the CICLEPS expedition might increase the burial flux of particulate Co, resulting  
 989 in a net loss to the deep dCo inventory. The uptake rate of Co both within and below the photic  
 990 zone, as well as the fraction of POM that is remineralized, dictated the flux of particulate Co into  
 991 the sediments via burial. The initial dCo concentration was set at 56 pM, which approximates the  
 992 mean deep dCo concentrations observed on both CORSACS-1 and CORSACS-2. When the model  
 993 was run for 12 years, the time period between the first CORSACS expedition and the CICLEPS  
 994 expedition, it generated a sawtooth pattern; the surface and deep boxes diverged over the course  
 995 of the summer bloom season as biological uptake removed dCo from the surface box and  
 996 remineralization replenished dCo in the deep box (Fig. 12). Winter mixing then unified and reset  
 997 the water column, replenishing the surface dCo inventory. The model was run at a steady state  
 998 using the average surface  $\rho\text{Co}$  rate observed on CORSACS-1 (0.27 pmol L<sup>-1</sup> d<sup>-1</sup>; Table 6) (Saito  
 999 et al., 2010) and deep  $\rho\text{Co}$  values that were tuned to allow no change in the deep dCo inventory  
 1000 every winter. When the model was run using representative surface and deep  $\rho\text{Co}$  values observed  
 1001 on the CICLEPS expedition (0.87 and 0.1 pmol Co L<sup>-1</sup> d<sup>-1</sup>, respectively), the surface depletion of

1002 dCo was more pronounced by the end of the bloom season compared to the steady state model,  
 1003 and winter mixing resulted in a steady annual decrease of the deep dCo inventory. The mechanism  
 1004 of dCo loss was driven by increasing  $\rho\text{Co}$ , particularly in the surface ocean, and the propagation  
 1005 of dCo loss into the deep ocean via vertical mixing. The resulting burial flux when the model  
 1006 exhibited a deep dCo loss mechanism was higher than when the model was run at a steady state  
 1007 (Table 6), demonstrating how higher Co uptake rates among plankton paired with a deep winter  
 1008 mixed layer can result in a diminishing dCo inventory on a decadal timescale.

1009 **Figure 12.** Results of the two-box model illustrating a potential mechanism for the loss of the dCo  
 1010 inventory over time. Gray boxes represent the winter season when the surface and deep boxes mix.  
 1011 The dotted lines represent a system at a steady state, where the dCo inventory stays consistent  
 1012 annually. The solid lines represent a system exhibiting dCo loss, where increased Co uptake rates  
 1013 in both the surface and deep ocean result in an annually decreasing dCo inventory. The initial deep  
 1014 dCo concentration was 56 pM, which approximates the mean deep dCo concentrations observed  
 1015 on CORSACS-1 and CORSACS-2. Over 12 years, the dCo loss model depicts the loss of 0.83 pM  
 1016 year<sup>-1</sup> to end at a deep dCo inventory of 46 pM, the mean deep dCo concentration observed on  
 1017 CICLOPS.  
 1018

1019 The purpose of this model was to illustrate a possible mechanism for a dCo inventory loss  
 1020 over the 12-year period between the CORSACS and CICLOPS expeditions using reasonable  
 1021 estimates of Co uptake and other Co cycle fluxes to achieve the observed 10 pM deep inventory  
 1022 loss. This box model successfully shows the directionality of the changes to the deep ocean dCo  
 1023 inventory and deep burial flux when the  $\rho\text{Co}$  values increase, but the magnitude of the estimated  
 1024 Co burial or the nepheloid Co source should not be considered meaningful flux values. The model  
 1025 represented a greatly simplified version of the carbon pump in the Southern Ocean, and it is likely  
 1026 that at least some of the unquantified Co cycle fluxes were not negligible, including horizontal  
 1027 advection, overturning water during the summer season, Co scavenging, and a surface aerosol  
 1028 source. Additionally, it is a simplifying assumption that  $\rho\text{Co}$  values would be consistent throughout  
 1029 a surface or deep depth region, as well as consistent over an entire summer season. Despite its

1030 simplicity, the box model presented a concise and reasonable mechanism for this study's  
1031 observation of a shrinking dCo inventory in the Ross Sea.

## 1032 **5 Conclusion**

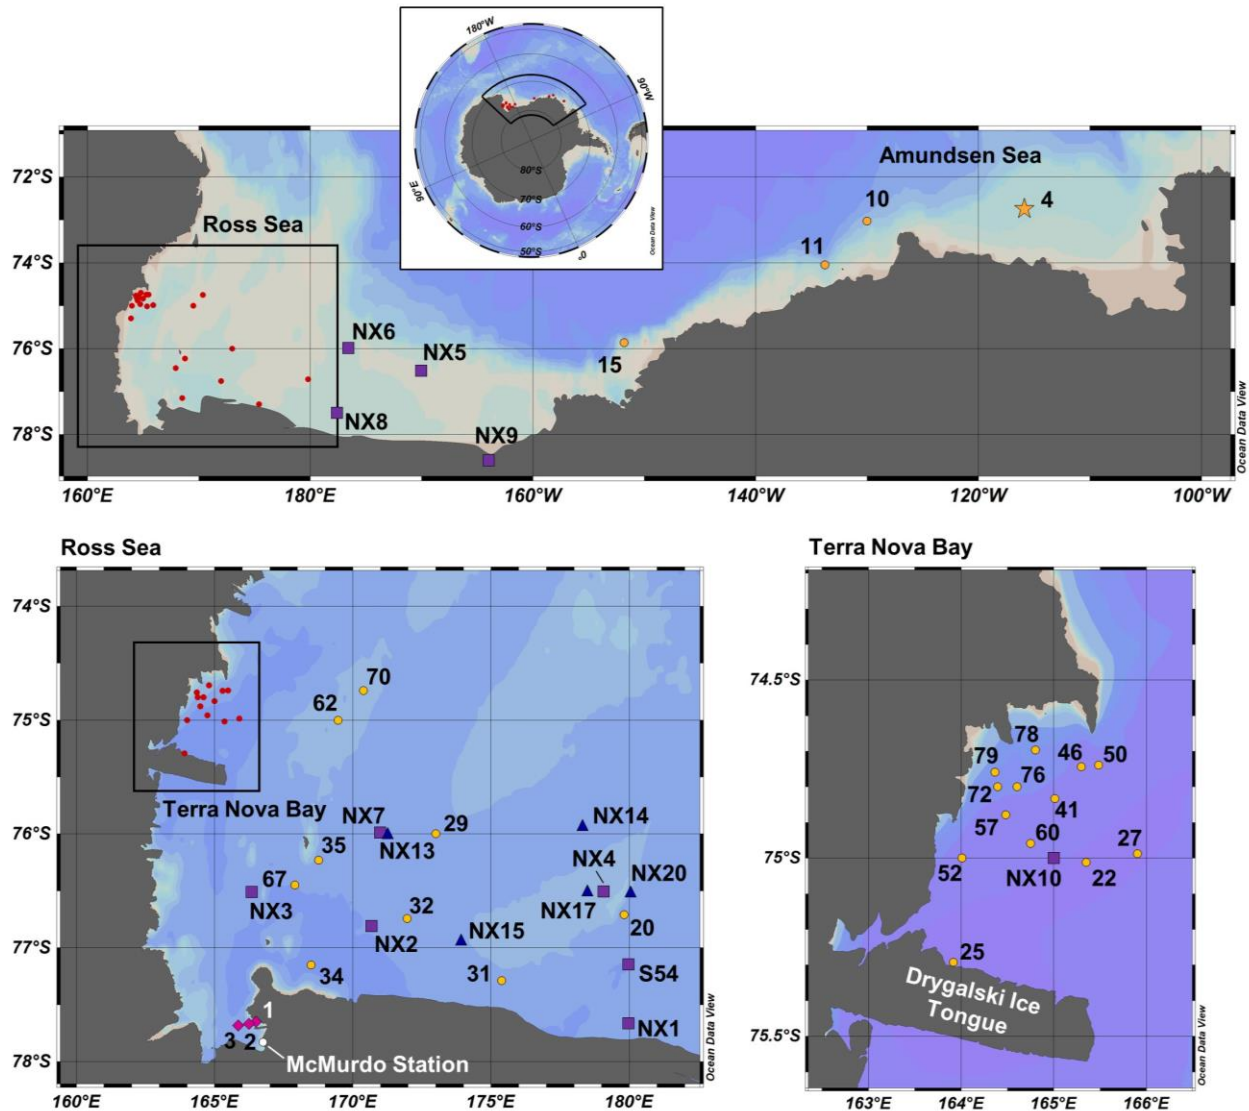

1033 The Ross Sea, Amundsen Sea and Terra Nova Bay displayed lower dCo and labile dCo  
1034 inventories during the 2017/2018 austral summer relative to prior observations in the region, which  
1035 is consistent with observations of higher rates of Co use and uptake by phytoplankton and  
1036 heterotrophic bacteria. The near-100% complexation of the dCo inventory reveals that the dCo  
1037 loss is primarily due to the uptake of labile dCo, the most bioavailable form of dCo to marine  
1038 microbes. The decrease in dCo throughout the water column compared to prior observations is  
1039 indicative of a multi-year mechanism, whereby the removal of dCo from the surface mixed layer  
1040 via uptake over the summer has been propagated into the deep ocean via winter mixing, resulting  
1041 in a decrease in dCo concentration throughout the water column. This mechanism is reliant upon  
1042 increased dCo uptake into organic matter and an increase in the burial rate of Co as organic matter.  
1043 The observed biogeochemical differences may be due to the alleviation of Fe limitation through  
1044 inputs from increased glacial melting and subsequent development of intermittent vitamin B<sub>12</sub>  
1045 and/or Zn limitation, both of which would be expected to increase the demand for Co among  
1046 plankton communities.

1047 In coastal Antarctica and other regions impacted by global climate change, Co is a  
1048 noteworthy trace metal nutrient to investigate because its small inventory and flexible  
1049 phytoplankton stoichiometry make its biogeochemical cycle particularly vulnerable to  
1050 perturbation. In the Arctic Ocean, for example, the dCo and labile dCo inventories have increased  
1051 as melting ice and permafrost have increased the flux of Co-enriched riverine waters and sediments  
1052 to the upper ocean (Bundy et al., 2020). Like many other trace nutrients, the Co cycle is integrally  
1053 connected to that of other elements like Zn, Cd, Fe and carbon, and observations of perturbed Co  
1054 inventories and changing nutrient limitation regimes would affect their biogeochemical cycles as  
1055 well. In highly productive coastal Antarctic seas, shifts in micronutrient inventories and growth  
1056 limitation could have implications for the composition of regional phytoplankton blooms and the  
1057 magnitude of the Southern Ocean carbon sink.

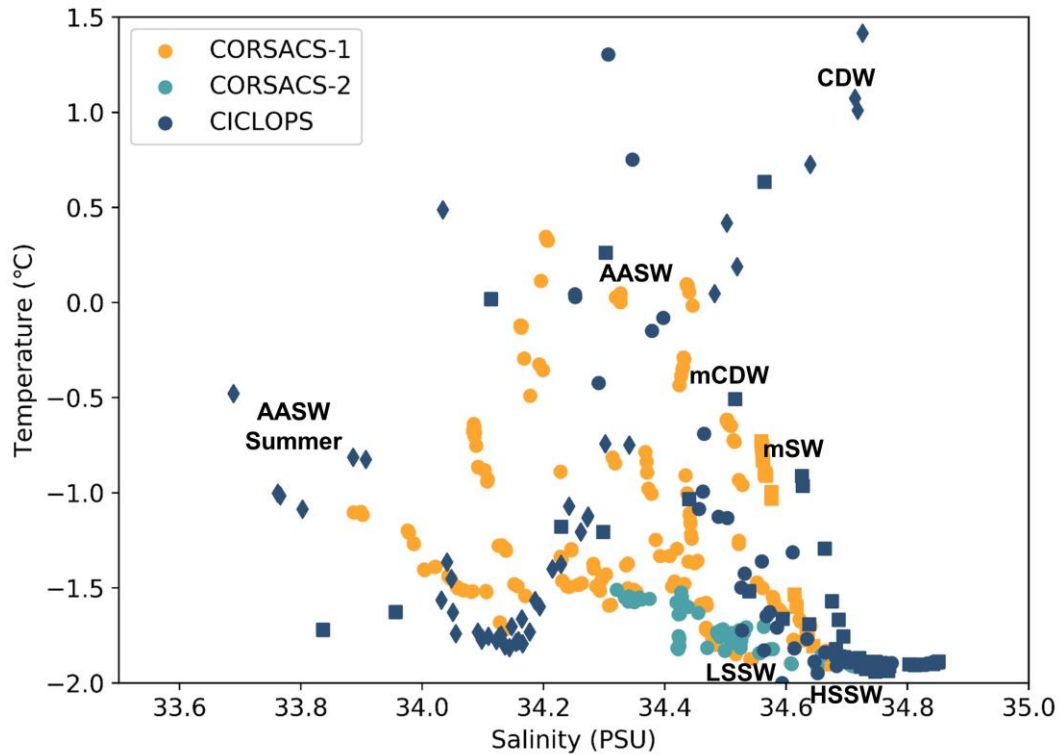

1058 Since the late 1980s, it has been hypothesized that the primary productivity and net carbon  
1059 sequestration flux of the Southern Ocean is controlled by the supply of Fe to surface waters (Martin  
1060 1990; Martin et al., 1990). This theory, called the “iron hypothesis”, posits that the addition of  
1061 bioavailable Fe to an Fe-limited surface ocean stimulates productivity and, in turn, increases the  
1062 regional and possibly global carbon sequestration flux from the atmosphere into deep ocean  
1063 sediments. When applied to potential carbon dioxide removal (CDR) geoengineering projects, the  
1064 iron hypothesis provides a theoretical framework for ocean iron fertilization (OIF), where  
1065 significant quantities of Fe are introduced to the surface Southern Ocean to enhance the net  
1066 sequestration of CO<sub>2</sub> and reduce global atmospheric CO<sub>2</sub> concentrations (Emerson, 2019). Over  
1067 the past three decades, several mesoscale Fe fertilization experiments have shown that large  
1068 phytoplankton blooms can be stimulated by the addition of Fe to the surface Southern Ocean, and  
1069 that the impact on the CO<sub>2</sub> sink is variable, modest and often difficult to assess (Coale et al., 1996;  
1070 Boyd et al., 2000; de Baar et al., 2005; Smetacek et al., 2012). This study provides additional  
1071 insights into the potential of OIF, suggesting that the alleviation of Fe limitation might shift the  
1072 region towards the limitation of another trace nutrient such as vitamin B<sub>12</sub>, Zn, and potentially Co.  
1073 The nutrient limitation regimes of the Southern Ocean are complex, heterogeneous and possibly

1074 shifting on decadal timescales, and these intricacies must be examined when considering future  
 1075 OIF projects.

1076 **Appendix A. Locations and hydrography of historical Ross Sea and Terra Nova Bay stations**

1077  
 1078 **Figure A1.** Map of CICLOPS (yellow circles), CORSACS-1 (purple squares), CORSACS-2 (blue  
 1079 triangles) and McMurdo Sounds fieldwork (magenta diamonds) stations in coastal Antarctic  
 1080 waters, including insets of stations within the Ross Sea and Terra Nova Bay. Only stations from  
 1081 the CORSACS-1 and CORSACS-2 expeditions whose data is used in this study are shown.  
 1082 Stations marked in red are CICLOPS stations shown in more detail in an inset. Note that the grey  
 1083 coastline marks both terrestrial coastline and areas of consistent ice, including ice shelves and  
 1084 glaciers; this includes the Drygalski Ice Tongue, a glacier to the south of Terra Nova Bay.

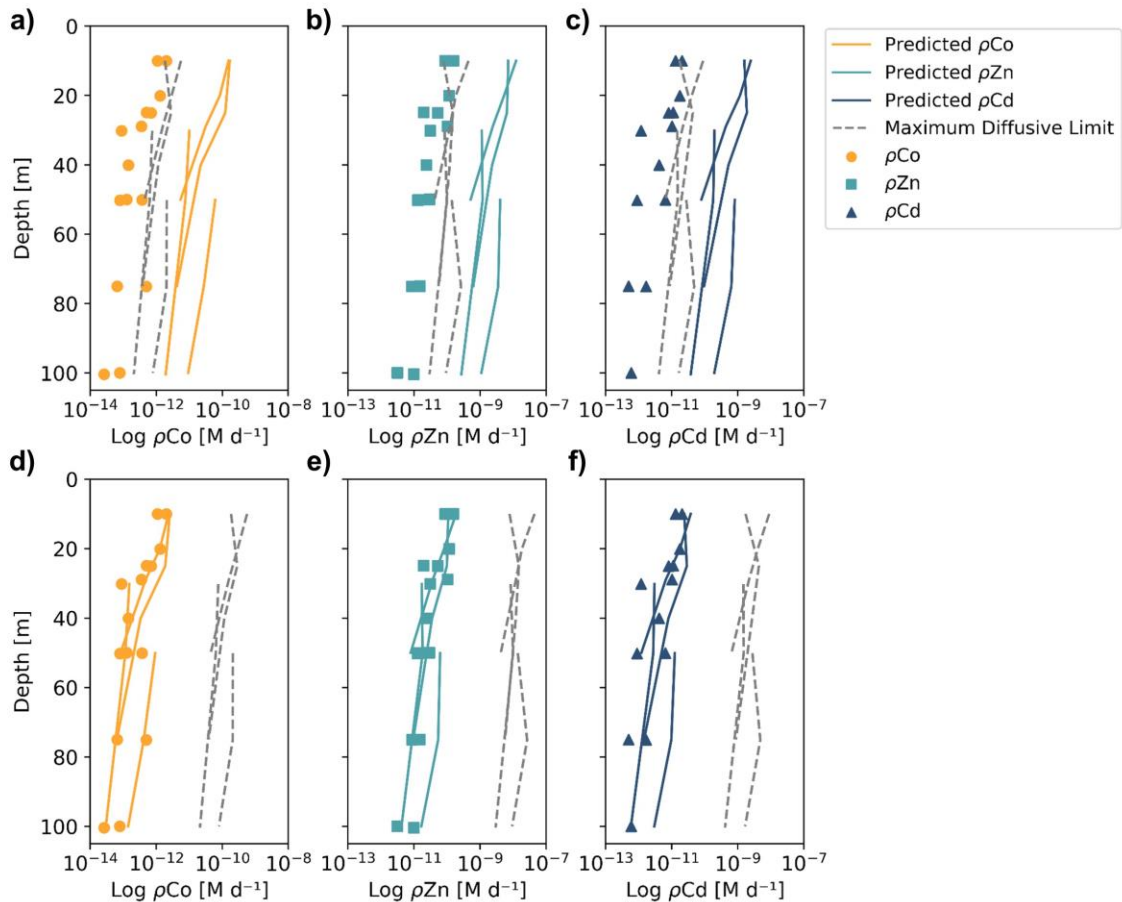

1085

1086 **Figure A2.** The Temperature-Salinity relationship and water mass classification of samples from  
 1087 the Amundsen Sea (diamonds), Ross Sea (circles) and Terra Nova Bay (squares). Sample data is  
 1088 shown only from samples used to compare dCo data from the CORSACS-1, CORSACS-2 and  
 1089 CICLOPS expeditions in Sect. 4.3. Labeled water masses include Circumpolar Deep Water  
 1090 (CDW), modified Circumpolar Deep Water (mCDW), modified Shelf Water (mSW), Low  
 1091 Salinity Shelf Water (LSSW), High Salinity Shelf Water (HSSW), Antarctic Surface Water  
 1092 (AASW), and the fresher summertime AASW (AASW Summer). Classification of water mass  
 1093 samples from the CICLOPS expedition are taken from Rao (2020), Figure 3-25 and references  
 1094 therein. Note that the CORSACS-1, CORSACS-2 and CICLOPS expeditions largely overlapped  
 1095 in their water mass distribution in the Ross Sea and Terra Nova Bay.

1096 **Appendix B. Estimating trace metal uptake and maximum rate of dissolution profiles from**  
 1097 **classic competitive inhibition equations.**

1098

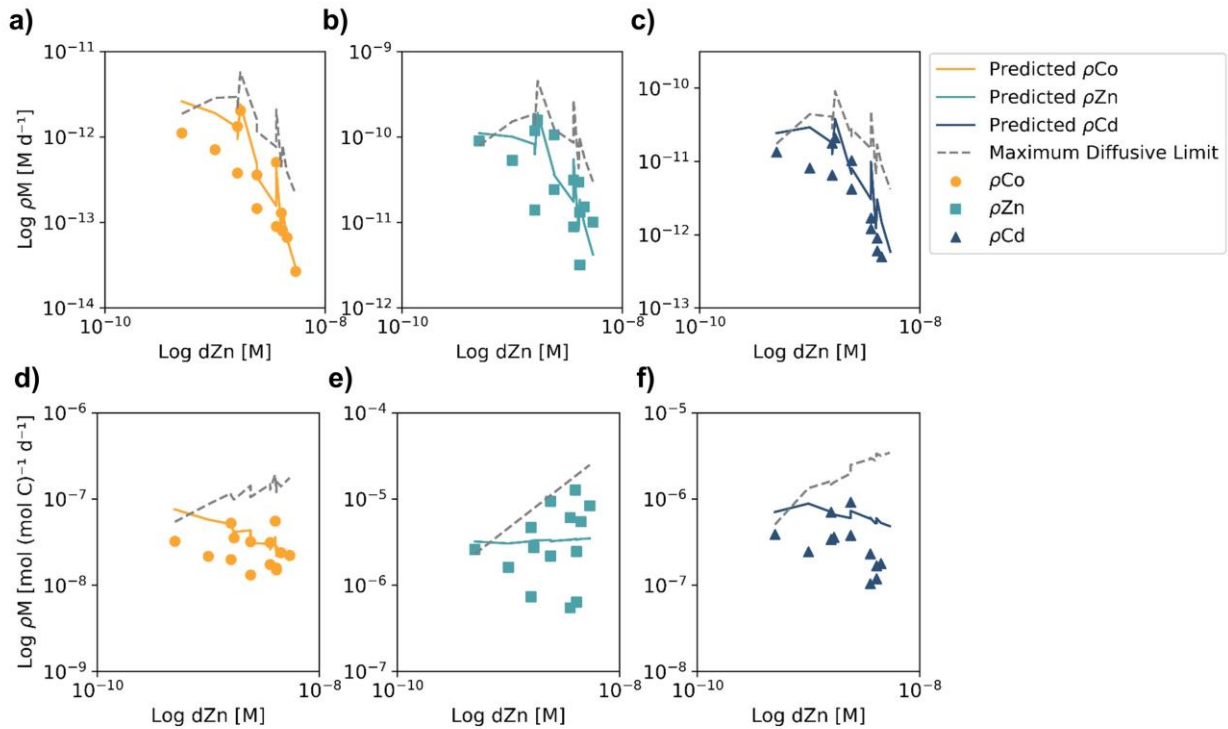

1099

1100 **Figure B1.** Observed (markers) and predicted (solid lines) trace metal uptake rate ( $\rho M$ ) profiles  
 1101 and the estimated maximum diffusive limit profiles (dashed line) for Co (**a,d**) Zn (**b,e**) and Cd (**c,f**)  
 1102 from Stations 11, 20, 22 and 57, using different equation parameters than those used in Fig. 10. In  
 1103 panels a-c, the predicted uptake rates used a literature  $V_{\max}$  value of  $262 \mu\text{mol} (\text{mol C}^{-1}) \text{d}^{-1}$   
 1104 determined from  $\text{Zn}^{2+}$  uptake experiments in *Emiliania huxleyi* cultures (Sunda and Huntsman,  
 1105 1992), resulting in predicted uptake rates that were orders of magnitude greater than the observed  
 1106 values. In panels d-f, the estimated maximum diffusive limit profiles assumed that 100% of the  
 1107  $d\text{Co}$ ,  $d\text{Zn}$  and  $d\text{Cd}$  inventories were labile and 0% were bound to strong organic ligands, resulting  
 1108 in diffusive limits that were also orders of magnitude greater than the observed values. This  
 1109 analysis helps to show how parameter assumptions can greatly influence the predicted uptake rates  
 1110 and illustrates the difficulty of assigning kinetic parameters to environmental analyses.

1111

1112

1113

1114

**Figure B2.** Observed (markers) and predicted (solid lines) trace metal uptake rates ( $\rho M$ ) and the

estimated maximum diffusive limit profiles (dashed line) plotted against total dZn concentrations,

assuming a  $V_{\max}$  of  $4 \mu\text{mol (mol C}^{-1}\text{) d}^{-1}$  and that 99% of the trace metal inventory was bound to

strong organic ligands. Panels **a-c** show  $\rho M$  in units of  $\text{M d}^{-1}$ , which tended to decrease at high

dZn concentrations. This is attributable to higher dZn concentrations below the photic zone, where

much lower rates of micronutrient uptake occur. Panels **d-f** show  $\rho M$  when normalized to biomass

using Chl-a concentrations and a C : chl-a ratio of 130 w/w (DiTullio and Smith, 1996). The

normalized predicted  $\rho Z\text{n}$  values are relatively stable over the observed range of dZn

concentrations, while the predicted  $\rho\text{Co}$  and  $\rho\text{Cd}$  values decrease slightly as dZn increases,

suggesting that competitive inhibition of  $\rho\text{Co}$  and  $\rho\text{Cd}$  may have occurred at higher dZn

concentrations due to the smaller inventories of dCo and dCd compared to dZn.

1125

1126 **Appendix C. Description of a two-box model of the dCo cycle in coastal Antarctic seas, and**  
 1127 **a potential mechanism for deep dCo loss with changing microbial uptake stoichiometry.**

1128 The two-box model described below was used to conceptualize the biogeochemical cycling  
 1129 of dCo in the surface and deep ocean. The model describes a 1 m<sup>2</sup> column of water with a total  
 1130 depth of 600 m and a depth threshold between the surface and deep box of 100 m. Within each  
 1131 box, the net change of dCo over time is equivalent to the sum of the source fluxes minus the sum  
 1132 of the sink fluxes:

$$1133 \left( \frac{d[dCo]}{dt} \right)_{Surface} = \frac{\sum(F_i)_{Sources} - \sum(F_i)_{Sinks}}{V_{Surface}}$$

$$1134 \left( \frac{d[dCo]}{dt} \right)_{Deep} = \frac{\sum(F_i)_{Sources} - \sum(F_i)_{Sinks}}{V_{Deep}}$$

1135 where fluxes ( $F_i$ ) are in units of mols dCo d<sup>-1</sup>. A summary of the sources and sinks relevant to  
 1136 dCo in coastal Antarctic seas is shown below in Table C1. In the Southern Ocean, we would  
 1137 expect the fluxes of scavenging ( $F_{Scav}$ ) and aerosol deposition ( $F_{Aero}$ ) would be relatively  
 1138 negligible, and so these fluxes have been omitted from the model. Additionally, we can assume  
 1139 that horizontal advection is at a steady state, and thus the net advection flux is  $\approx 0$  mols dCo d<sup>-1</sup>.  
 1140 This gives us the net equations for both boxes:

$$1141 \left( \frac{d[dCo]}{dt} \right)_{Surface} = \frac{F_{Over} + F_{Remin} - F_{Up}}{V_{Surface}}$$

$$1142 \left( \frac{d[dCo]}{dt} \right)_{Deep} = \frac{F_{Remin} + F_{Neph} - F_{Up} - F_{Over}}{V_{Deep}}$$

1143 **Table C1:** The source and sink fluxes of dCo in the surface and deep ocean boxes. Fluxes are  
 1144 theoretically in units of mols dCo d<sup>-1</sup>.

Surface Sources		Surface Sinks		Deep Sources		Deep Sinks	
Remineralization	$F_{Remin}$	Microbial Uptake	$F_{Up}$	Remineralization	$F_{Remin}$	Microbial Uptake	$F_{Up}$
Overturning	$F_{Over}$	Advection	$F_{Adv}$	Nepheloid Layer	$F_{Neph}$	Overturning	$F_{Over}$
Aerosols	$F_{Aero}$			Advection	$F_{Adv}$	Scavenging	$F_{Scav}$
Advection	$F_{Adv}$					Advection	$F_{Adv}$

1146 Uptake fluxes

1147 The flux of dCo incorporation into microbial biomass via uptake by protein transporters  
 1148 can be described using the uptake rates ( $\rho Co$ ) measured by <sup>57</sup>Co incubation experiments, where  
 1149 units of  $\rho Co$  are in mols dCo L<sup>-1</sup> d<sup>-1</sup>:

$$1150 F_{Up, Surface} = (\rho Co_{Surface} * V_{Surface})$$

$$1151 F_{Up, Deep} = (\rho Co_{Deep} * V_{Deep})$$

1152

1153

1154

## 1155 Remineralization fluxes

1156 In this model, the remineralization flux of particulate Co in organic matter to dCo is  
 1157 quantified by a Remineralization Factor (RF), which can be applied to the amount of particulate  
 1158 matter present in each box. Typical RF values tend to be between 0.90 and 0.99 (Glover et al.,  
 1159 2011), meaning that between 90% and 99% of all microbial biomass produced tends to be  
 1160 remineralized before sinking out of its respective box. It is not clear that the RFs for the surface  
 1161 and deep box should be represented by the same value, and so we have defined both surface  
 1162 ( $RF_{Surface}$ ) and deep ( $RF_{Deep}$ ) variables here. In the surface ocean, excess Co in un-remineralized  
 1163 biomass will sink into the deep box ( $F_{Sink}$ ), where it is further able to be remineralized in the deep  
 1164 ocean. In the deep ocean, excess Co in un-remineralized biomass is assumed to flux into the  
 1165 sediments via burial ( $F_{Bur}$ ), representing a key sink of dCo biomass out of the two-box system. The  
 1166 surface box remineralization flux is represented with a relatively simple equation:

$$1167 \quad F_{Remin, Surface} = RF_{Surface} * F_{Up, Surface}$$

$$1168 \quad F_{Remin, Surface} = RF_{Surface}(\rho Co_{Surface} * V_{Surface})$$

1169 The deep ocean remineralization flux can then be calculated as the sum of the  
 1170 remineralization flux from excess biomass that sinks as particulate Co and biomass generated in  
 1171 the deep ocean:

$$1172 \quad F_{Remin, Deep} = RF_{Deep}(F_{Up, Surface} - F_{Remin, Surface}) + RF_{Deep}(F_{Up, Deep})$$

$$1173 \quad F_{Remin, Deep} = RF_{Deep}(\rho Co_{Surface} * V_{Surface} - RF_{Surface}(\rho Co_{Surface} * V_{Surface}))$$

$$1174 \quad + RF_{Deep}(\rho Co_{Deep} * V_{Deep})$$

## 1175 Overturning fluxes

1176 An overturning dCo flux represents the flux of a volume of water from the deep ocean box  
 1177 into the shallow ocean box, and a corresponding flux of the same volume from the shallow ocean  
 1178 box into the deep ocean box for mass conservation. In a dynamic coastal upwelling system like  
 1179 the Ross and Amundsen Seas, the reality of this overturning flux is almost certainly much more  
 1180 complicated, as coastal upwelling processes overlap with meltwater processes and deep water mass  
 1181 formation processes. For the purposes of this two-box model, the flux of dCo via overturning can  
 1182 be estimated as a function of the overturning water flux ( $F_{Water}$ ) and the dCo concentrations of each  
 1183 box:

$$1184 \quad F_{Over, Surface} = (F_{Water}[dCo]_{Deep} - F_{Water}[dCo]_{Surface})$$

$$1185 \quad F_{Over, Deep} = (F_{Water}[dCo]_{Surface} - F_{Water}[dCo]_{Deep})$$

1186 In the model presented in Sect. 4.7, the  $F_{Water}$  and both  $F_{Over}$  fluxes are assumed to be  
 1187 negligible for the sake of modeling simplicity, but the introduction of a nonzero overturning flux  
 1188 would help to make the seasonal change in the dCo inventory in both the surface and deep oceans  
 1189 nonlinear, as it is currently the only flux in this model that is calculated using the time step's dCo  
 1190 concentrations.

## 1191 Flux from the nepheloid layer

1192 At several CICLOPS stations, a distinct nepheloid layer was detected as dCo concentration  
 1193 increased sharply at depths immediately above (~10 m) the ocean floor. The nepheloid layer tends

1194 to contain high levels of particles moving horizontally along the seafloor, and is likely a significant  
 1195 source of dCo to the surrounding water column. The source of dCo from the nepheloid layer is  
 1196 somewhat unclear; it could be via dissolution of particles suspended within the nepheloid layer or  
 1197 from a porewater flux of dCo out of the sediments. In this model, the flux of deep dCo inputs into  
 1198 the deep ocean, assumed to be from the nepheloid layer, was derived using the Microsoft Excel  
 1199 solver tool, given the parameter that 10 pM of deep dCo was lost over 12 years. The deep source  
 1200 of dCo was calculated to be 3550 pmol dCo m<sup>-2</sup> d<sup>-1</sup>. This value should be considered an adjustable  
 1201 parameter used to tune the model to our conceptual understanding of dCo inventory loss, and not  
 1202 a meaningful calculation of observed Co flux from the deep nepheloid layer, which has yet to be  
 1203 constrained.

#### 1204 The cobalt burial sink

1205 The loss of cobalt from the deep ocean box into the sediments via burial can be quantified  
 1206 with the equation:

$$1207 \quad \left(\frac{d[Co]}{dt}\right)_{Bur} = F_{Sink} + F_{Up,Deep} - F_{Remin,Deep}$$

1208 where  $F_{Sink}$  is described by:

$$1209 \quad F_{Sink} = (\rho Co_{Surface} * V_{Surface}) - RF_{Surface}(\rho Co_{Surface} * V_{Surface})$$

1210 This estimate of the loss of dCo due to burial assumes that all biogenic particulate Co that is not  
 1211 remineralized in the surface ocean sinks into the deep ocean, and all biogenic particulate Co that  
 1212 is not remineralized in the deep ocean is sequestered in sediments and “lost” to the model.

#### 1213 Modeling seasonality: the winter mixed layer

1214 In the Ross and Amundsen Seas, sea ice covers the surface ocean for a larger portion of the  
 1215 year (~ 5 months). During this time, the water column mixes – a process that was modeled by  
 1216 combining the two-box model into one homogenized box after the 7-month bloom season to  
 1217 simulate the winter season. This process can be modeled by a volume-weighted average with the  
 1218 volume of each box.

$$1219 \quad [dCo]_{Winter} = \frac{(V_{Surface} * [dCo]_{Surface}) + (V_{Deep} * [dCo]_{Deep})}{(V_{Surface} + V_{Deep})}$$

#### 1220 Data availability

1221 The CICLOPS dCo dataset has been submitted to the Biological and Chemical Oceanography Data  
 1222 Management Office (BCO-DMO) website (<https://www.bco-dmo.org/project/774945>) and is  
 1223 pending approval for publication. The dissolved metals (dZn, dCd) dataset ([https://www.bco-](https://www.bco-dmo.org/dataset/877466)  
 1224 [dmo.org/dataset/877466](https://www.bco-dmo.org/dataset/877466)), Zn and Cd uptake rate dataset ([https://www.bco-](https://www.bco-dmo.org/dataset/877681)  
 1225 [dmo.org/dataset/877681](https://www.bco-dmo.org/dataset/877681)), and macronutrient dataset (<https://www.bco-dmo.org/dataset/874841>)  
 1226 are publicly available on the BCO-DMO website.

#### 1227 Author contribution

1228 RC collected and analyzed dCo samples and wrote the manuscript. RK collected and analyzed  
 1229 dZn and dCd samples and measured Zn and Cd uptake rates. DR measured Co uptake rates. GD

1230 collected and analyzed phytoplankton pigment samples. All authors assisted in the collection and  
 1231 processing of dissolved seawater samples and incubation experiment samples, and all authors  
 1232 helped write the manuscript.

### 1233 **Competing interests**

1234 The authors declare that they have no conflict of interest.

### 1235 **Acknowledgments**

1236 The authors thank the captain, crew and science party of the RVIB *Nathaniel B. Palmer* for their  
 1237 support during the CICLOPS expedition. We also thank Joe Jennings (OSU) for dissolved  
 1238 macronutrient analysis, Véronique Oldham for sampling assistance, and Matthew Charette,  
 1239 Stephanie Dutkiewicz, and Alessandro Tagliabue for writing insights. This work was funded by  
 1240 grants from the National Science Foundation's Office of Polar Programs (OPP-1643684, OPP-  
 1241 1644073 and OPP-1643845).
