10 **Abstract**

11 Tides and internal tides (IT) in the ocean can significantly affect local to regional ocean
12 temperature, including sea surface temperature (SST), via physical processes such as diffusion
13 (vertical mixing) and advection (vertical and horizontal) of water masses. Offshore of the
14 Amazon River, strong ITs have been detected by satellite observations and well modelled;
15 however, their impact on temperature, SST and the identification of the associated processes
16 have not been studied so far. In this work, we use ~~high-resolution (1/36°)~~ numerical simulations
17 with and without the tides from an ocean circulation model (NEMO). This model explicitly
18 resolves the internal tides (IT) and is therefore suitable to assess how they can affect ocean
19 temperature in the studied area. We distinguish the analysis for two contrasted seasons, from
20 April to June (AMJ) and from August to October (ASO), since the seasonal stratification off
21 the Amazon River modulates the IT's response and their influence in temperature.

22 The generation and the propagation of the IT in the model are in good agreement with
23 observations. The SST reproduced by the simulation including tides is in better agreement with
24 satellite SST data compared to the simulation without tides. During ASO season, stronger
25 meso-scale currents, deeper and weaker pycnocline are observed in contrast to the AMJ season.
26 The observed coastal upwelling during ASO season is better reproduced by the model including
27 tides, whereas the no-tide simulation is too warm by +0.3 °C for the SST. ~~In the subsurface~~
28 ~~above the thermocline, the tide simulation is cooler by -1.2 °C, and warmer below the~~
29 ~~thermocline by +1.2 °C compared to the simulation without the tides.~~ The ITs induce vertical
30 mixing on their generation site along the shelf break and on their propagation pathways towards
31 the open ocean. This process mainly explains the cooler temperature at the ocean surface and
32 is combined with vertical and horizontal advection to explain the cooling in the subsurface

"The internal
tide (IT)"

(ITs)"

Abstract
seems long,
careful about
word limits

Confused

induces (you've been writing in the present tense so far)

33 water above the thermocline and a warming in the deeper layers below the thermocline. The
34 surface cooling induced in turn an increase of the net heat flux from the atmosphere to the
35 ocean surface, which could induce significant changes in the local and even for the regional
36 tropical Atlantic atmospheric circulation and precipitation.

37 We therefore demonstrate that IT via vertical mixing and advection along their
38 propagation pathways, and tides over the continental shelf, can play a role on the temperature
39 structure off the Amazon River mouth, particularly in the coastal cooling enhanced by the IT.

40 **Keywords:** internal tides, Amazon continental shelf and slope, temperature, modeling, satellite
41 data, mixing, heat flux.

42 I. Introduction

43 Temperature and its spatial structure play a crucial role in ocean dynamics, including
44 water mass formation (Swift and Aagaard, 1981; Lascaratos 1993; Speer et al. 1995), transport
45 and mixing of other tracers in the ocean and exchanges with other biosphere compartments
46 (Archer et al. 2004, Rosenthal et al. 1997), and most importantly on surface heat exchange at
47 the interface with the atmosphere (Calyson and Bagdanoff, 2013; Mei et al. 2015) and can thus
48 significantly influence the climate (Li et al. 2006; Collins et al. 2010). This oceanic thermal
49 structure can be modified at various spatial and temporal scales by different processes external
50 to the ocean such as incident solar radiation, heat fluxes with the atmosphere, winds,
51 precipitation and freshwater inputs from rivers. Processes internal to the ocean also play a
52 crucial role in this thermal structure, such as mass transport by currents and eddies (e.g.:
53 Aguedjou et al., 2021), mixing by turbulent diffusion (Kunze et al. 2012), tides and internal
54 tidal waves (IT) (Barton et al., 2001; Smith et al., 2016; Salamena et al., 2021). The role of IT
55 on the thermal structure of the ocean is of increasing interest with many studies in recent years,
56 but remains poorly understood in many ocean regions, and especially off the Amazon shelf.

57 In a stratified ocean, the passage of a barotropic tide over a topographic profile with a
58 steep slope (continental slope, seamount, oceanic ridge) generates a disturbance in the flow
59 that gives rise to a so-called baroclinic tide, with the same frequency, but with higher vertical
60 velocities (Zhao et al., 2016). The baroclinic tide, also known as internal tidal waves (IT), thus
61 captures part of the energy of the barotropic tide, propagates it and dissipates it into the global
62 ocean by diapycnal mixing (Zhao et al., 2012), i.e., up to about 1 TW in the deep ocean (Egbert
63 and Ray, 2000; Niwa and Hibiya, 2011) and thus helps to feed the thermohaline circulation
64 (Munk and Wunsch, 1998). These two tidal processes (barotropic tide and IT) thus bring

Diapycnal mixing only a fraction of total dissipation

65 together a set of mechanisms for transferring and redistributing energy from larger to smaller
66 oceanic scales, which can be understood as a tidal energy cascade. The dissipation of IT occurs
67 mainly locally at the generation sites for high-mode IT that are associated with higher vertical
68 shear, while a significant part of the energy dissipates offshore along their propagation path for
69 low-mode IT (Zhao et al., 2016). Results from models in the Indonesian seas (Koch-Larrouy
70 et al., 2007 and Nugroho et al., 2018) and observations in the Celtic Sea (Sharples et al. 2007)
71 and the Yellow Sea (Xu et al., 2020), point out that ITs dissipate most of their energy vertically,
72 where the vertical gradient of stratification is maximal in the water column. IT can also
73 vertically advect water masses during their propagation. They thus induce vertical
74 displacements of the isopycnal levels of several meters to a few tens of meters, observable in
75 the thermocline (Wallace et al., 2008; Xu et al. 2020). Denmann and Garrett (1983) and Bordois
76 et al. (2016) point out that the stratification peak acts as a waveguide for the propagation of ITs

77 The mixing and advection induced by ITs results in a change in temperature structure
78 throughout the water column. In surface waters, Smith et al. (2016) report that ITs can induce
79 surface cooling varying between 1 °C and 5 °C depending on the ocean region. Koch-Larrouy
80 et al. (2007) and Nagai and Hibiya (2015) have shown, for the Indonesian region, that ITs
81 induces a surface cooling of -0.5 °C on average and that this decreases cloud convection in the
82 atmosphere on a local scale, which in turn reduces precipitation by 20% and thus plays an
83 important role on the climate on a regional scale. Furthermore, Jithin and Francis (2020)
84 showed that ITs can also affect the temperature in deep waters (> 1600 m), leading to a warming
85 of the order of 1–2 °C.

86 The barotropic tides dissipate most of their energy in shallow coastal waters by bottom
87 friction when the mean ocean depth becomes less than the amplitude of the tide (Lambeck and
88 Runcorn, 1977; Le Provost and Lyard, 1997), and can thus modify temperature. Furthermore,
89 Gonzalez-Haro et al. (2019) showed that barotropic and baroclinic tidal currents can induce
90 temperature fluctuations by horizontal advection of surface water masses over hundreds of
91 kilometers, and thus contribute to modifying the SST. These two tidal processes (barotropic
92 and baroclinic) can also affect other tracers such as nutrients, chlorophyll and sediments
93 (Heathershaw et al., 1987; da Silva et al., 2002; Sharples et al., 2007; Pomar et al., 2012;
94 Muacho et al., 2014; Tuarena et al., 2016; Barbot et al., 2022).

95 Our study focuses on the oceanic region of northern Brazil off the Amazon River, where
96 ITs have been highlighted in previous studies, but their impact on the thermal structure is not
97 currently known. This region is characterized by a broad, shallow continental shelf at the mouth

High-frequency
↓
Did not read Bordois but my PhD was about this and I think you need to add it.

The connection is unclear. Consider deleting

98 of the Amazon River ended by a steep slope, i.e., a bathymetry variation of 200-2000 m over
99 some tens of kilometers (Fig.1). Along this slope, six sites (A to F) of IT generation have been
100 identified (Fig.1), the most intense of which (A and B) are in the south of the region (Magalhaes
101 et al. 2016, Barbot et al. 2021 and Tchilibou et al. 2022). A strong seasonal coastal current, the
102 Brazilian North Current (NBC), strongly influences the study area and flows along the coast
103 from the southeast to the northwest (Johns et al., 1990).

104 This region shows a seasonal variation in the position of the winds and the Intertropical
105 Convergence Zone (ITCZ) during the year, which directly influences the discharge of the
106 Amazon River, the oceanic circulation (Xie and Carton, 2004), and therefore the stratification.
107 This impacts the activity of internal tidal waves (Barbot et al., 2021). Two seasons can be
108 clearly distinguished by their properties on water masses and currents.

109 The first season runs from March to July, during this time the ITCZ is in its most
110 equatorial position and lies in the heart of our region. The increase in rainfall over the ocean
111 leads to a colder and more homogeneous SST far from the coast. The discharge of the Amazon
112 River into the ocean reaches its peak ($> 3 \times 10^5 \text{ m}^3 \cdot \text{s}^{-1}$) and the surface temperature in the coastal
113 zone, although homogeneous, is warmer than offshore. At the end of this season, driven by the
114 strong river discharge, the Amazon plume along the shelf extends beyond 8°N , and sometimes
115 into the Caribbean region (Müller-Karger et al., 1989; Johns et al., 1998). The stratification is
116 somewhat stronger and more homogeneous horizontally, and the maximum of its vertical
117 gradient (pycnocline) is closer to the surface. This latter point leads to a stronger conversion of
118 energy from barotropic to baroclinic, and a stronger local (first 50 km) dissipation of internal
119 tidal wave energy (Barbot et al., 2021; Tchilibou et al., 2022). NBC and eddy kinetic energy
120 (EKE) are weak in the region (Aguedjou et al., 2019). Close to the equator, the NBC develops
121 a retroflection towards 1°N latitude that feeds the Equatorial Under-Current (EUC) transporting
122 water masses eastwards to the Gulf of Guinea (Didden and Schott, 1993, Dimoune et al., 2022).

123 Contrasting with this first season, due to different oceanic and atmospheric conditions,
124 the second season extends from August to December. During this season, the ITCZ migrates
125 to its northernmost position around 10°N . In response, rainfall in this area decreases and the
126 Amazon River discharge also decreases to its minimum ($\sim 10^5 \text{ m}^3 \cdot \text{s}^{-1}$), the extension of the river
127 plume is therefore reduced to no more than 200–300 km offshore from the mouth of the
128 Amazon between November and December (Johns et al., 1998, Garzoli et al., 2003). During
129 this season, cold water ($< 27.6^\circ\text{C}$) associated with the western extension of the Atlantic cold-
130 water tongue (ACT) enters the region from the south and runs along the edge of the continental

131 shelf to about 3°N (Lentz and Limeburner, 1995; Neto et al., 2014), forming a cold cell often
132 referenced as a seasonal upwelling. The stratification of the study area is strongly modified
133 compared to the previous season. The pycnocline becomes somewhat deeper. The generation
134 of IT on the slope and their local dissipation are weaker compared to the first season (Barbot
135 et al., 2021; Tchilibou et al., 2022). Currents and eddy activity become stronger. The NBC
136 becomes stronger, farther from the coast and deeper, it develops a retroflection (NBCR)
137 between 5°–8° N that feeds the North Equatorial Counter-Current (NECC) transporting the
138 water masses towards the east of the tropical Atlantic. This generates very large anticyclonic
139 eddies (NBC Rings) exceeding 450 km in diameter (Didden and Schott, 1993; Richardson et
140 al., 1994; Garzoli et al., 2004), which in turn transport water masses towards the Northern
141 Hemisphere (Bourlès et al., 1999a; Johns et al., 1998; Schott et al., 2003). In addition, there are
142 more cyclonic/anticyclonic eddies from the Gulf of Guinea during this season. All this
143 contributes to the strengthening of the EKE, which reaches its maximum in this season
144 (Aguedjou et al., 2019). When the baroclinic tidal flow interacts with the general circulation,
145 it is deviated from its trajectory, thus we have a so-called incoherent baroclinic tide (Buijsman
146 et al., 2017). This IT-circulation interaction is thus reinforced during this second season
147 because of the more intensified currents and eddy activity (Tchilibou et al., 2022).

148 On the Brazilian continental shelf, Geyer et al. (1996) suggests the presence of internal
149 tidal waves from current data. Later, Lentini et al. (2016) based on SAR imagery, shows small-
150 wavelength (~ 10 km) internal solitary waves (ISW) packets propagating along and across the
151 continental shelf, and generated by linear non-hydrostatic interactions between the NBC and
152 barotropic tidal currents. Using a model, Molinas et al. (2020) show that baroclinic tidal
153 currents play an important role on sediment transport on this continental shelf. On a global
154 scale, several studies from altimetry observations (Zhao et al., 2012, 2016; Zaron et al., 2017,
155 2019) or models (Munk and Wunsch, 1998; Shriver et al., 2012; Arbic et al., 2012; Niwa and
156 Hibiya, 2011, 2014; Buijsman et al. 2016) have shown intense activity of IT along the steep
157 slope of the continental shelf. At the surface, using SAR imagery, Jackson (2007) and
158 Magalhaes et al. (2016) describe longer wavelength ISW (~ 50–150 km) that propagate
159 offshore from the slope. The latter emphasizes the modulation of their propagation by the
160 seasonal variation of the NECC, and from a model, establishes that these ISW originate from
161 instabilities and energy loss of IT coming from the slope, mainly at sites A and B. Recently, de
162 Macedo et al. (2023) provided a somewhat more comprehensive description of the seasonal
163 characteristics of these ISW, with the predominant origin remaining at sites A and B. Barbot

164 et al. (2021) focused on the influence of stratification on the IT generation on the shelf as well
165 as their propagation offshore. Finally, also in seasonal scale, Tchilibou et al. (2022) looked at
166 the variation of the energy associated with IT from their generation to their dissipation, as well
167 as the interaction of these waves with the general circulation. However, the interactions
168 between IT and tracers such as temperature, salinity or chlorophyll have not received much
169 interest from the scientific community in this region.

170 Hydrodynamic and biogeochemical conditions on the shelf and off the mouth of the
171 Amazon were studied during the AMASSEDS campaigns in the early 1990s (DeMaster and
172 Pope, 1996; Nittouer and DeMaster, 1996) and the various “*Camadas Finas*” campaigns
173 (Araujo et al., 2017, 2021). Furthermore, using data from the two REVIZEE campaigns and
174 TMI-SST satellite data, Neto et al. (2014) studied the seasonal cooling of surface waters, which
175 occurs between the months of July and December. They conclude that the NBC is responsible
176 for the upwelling of cold-water masses ($< 27.5\text{ }^{\circ}\text{C}$) to the more superficial layers. Subsequently,
177 Araujo et al. (2016), using in addition a realistic model, suggest that the tide would have a key
178 role to play in intensifying this cooling. Indeed, through twin simulations with and without tides,
179 they show that with tides there is a $-0.3\text{ }^{\circ}\text{C}$ cooling of the surface temperature. These analyses
180 remain qualitative and do not allow determining what are the processes at work. Knowing that
181 we are in an area with a strong activity of internal tidal waves, the question remains whether
182 and by what processes these IT can structure the temperature both at the surface and inside the
183 water column.

184 In order to answer the above questions, we used a high-resolution model ($1/36^{\circ}$) and a
185 satellite SST product, with the aim of highlighting the impact of IT on the temperature structure
186 and associated processes. These observations, our modeling, as well as the methods used are
187 described in section II. The validation of some barotropic and baroclinic tide’s characteristics
188 as well as SST are present in section III. The impacts of IT on the temperature structure, the
189 influence on heat exchange at the interface between the atmosphere and the ocean, and finally
190 the processes involved, are analyzed in section IV. Summary and discussions of the obtained
191 results are presented in a last section.

192

193 II. Data and Methods

194 II.1. Satellite Data used: TMI SST

195 This dataset derived from Tropical Rainfall Measurement Mission (TRMM), which
196 performs measurements using onboard TRMM Microwave Imager (TMI). The microwaves

cannot determine what are the processes at work. Knowing that we are in an area with a strong activity of internal tidal waves, the question remains whether and by what processes these IT can structure the temperature both at the surface and inside the water column. I will stop making notes of it each time.

197 can penetrate clouds and are therefore very important for data acquisition in low latitude
198 regions, cloudy covered during long periods of raining seasons. We use Remote Sensing
199 Systems (RSS) TMI data products v7.1, which is the latest version of TMI SST. It contains a
200 daily mean of SST with a $0.25^\circ \times 0.25^\circ$ grid resolution (~ 25 km). This SST is obtained by inter-
201 calibration of TMI data with other microwave radiometers. The TMI SST fully description and
202 inter-calibration algorithm ~~is~~ ^{are} detailed in Wentz et al. (2015).

203 II.2. Model: *AMAZON36* configuration

204 The numerical model used in this study is the Nucleus for European Modelling of the
205 Ocean (NEMOv4.0.2, Madec et al., 2019). The “*AMAZON36*” model configuration covers the
206 western tropical Atlantic region with a $1/36^\circ$ horizontal grid, from the Amazon River mouth to
207 the open ocean. Several configurations with same grid resolution, but for the former
208 NEMOv3.6 (Madec, 2014), exists for the same region, but either [?] includes Caribbean Sea
209 (Hernandez et al., 2016), or are not far extended to the east even used for tides study (Ruault
210 et al., 2020). The present configuration is wide [?] to capture, on their pathways, all the internal
211 tide ^{radiating} generating from the Brazilian shelf. Hence, the domain lies between 54.7°W – 35.3°W and
212 5.5°S – 10°N (Fig.1). In contrast with former configurations, we do not use multiple nested grids
213 here, but a single grid. The vertical grid comprises 75 vertically fixed z-coordinates levels, finer
214 grid refinement close to the surface with 23 levels in the 100 m, and cell thickness ^{with a} reaching
215 160 m when approaching the bottom. Both horizontal and vertical grid resolutions are therefore
216 ~~acceptable~~ ^{fine enough} to resolve low-mode internal tides and were already used for that purpose (Tchilibou
217 et al., 2022).

218 A third order upstream biased scheme (UP3) with built-in diffusion is used for
219 momentum advection, while tracer advection relies on a 2nd order Flux Corrected Transport
220 (FCT) scheme. A Laplacian isopycnal diffusion with a constant coefficient of $20 \text{ m}^2 \cdot \text{s}^{-1}$ is used
221 for tracers. The temporal integration is achieved thanks to a leapfrog scheme combined with
222 an Asselin filter to damp numerical modes (baroclinic time step is 150 s). The k - ϵ turbulent
223 closure scheme is used for the vertical diffusion coefficients. Bottom friction is quadratic with
224 a bottom drag coefficient of 2.5×10^{-3} , while lateral wall free-slip boundary conditions are
225 assumed. A time splitting technique is used to resolve the free surface, with the barotropic part
226 of the dynamical equations integrated explicitly.

227 We use the General Bathymetric Chart of the Oceans (GEBCO, 2020) interpolated onto
228 the model horizontal grid, with the minimal depth equal to 12.8 m. The ocean model is forced
229 by the ERA-5 atmospheric reanalysis (Hersbach et al., 2020). The river discharges are based

Implemented! ↖

none include?

230 on monthly means from hydrology simulation of ISBA model (Interaction Sol-Biosphère-
 231 Atmosphère, see description in [ISBA - National Centre for Meteorological Research](#)), and are
 232 prescribed as surface mass sources with null salinity, and we use a multiplicative factor of 90%
 233 based on a comparison with the HYBAM interannual timeseries (HYBAM, 2018). The model
 234 is forced at its open boundaries by the fifteen major high-frequency tidal constituents (M2, S2,
 235 N2, K2, 2N2, MU2, NU2, L2, T2, K1, O1, Q1, P1, S1, and M4) and barotropic currents derived
 236 from FES2014 atlas (Lyard et al., 2021). At the open boundaries, we prescribe MERCATOR-
 237 GLORYS12 v1 (Lellouche et al., 2018) for temperature, salinity, sea level, current velocity and
 238 derived baroclinic velocity.

239 The simulation was initialized on the 1st of January 2005, and ran for 10 years until
 240 2015. In this study, we use model outputs from 2013 to 2015. Indeed, the model has reached
 241 an equilibrium in terms of seasonal cycle after 2 years ~~(2005-2006)~~ of run. The same model
 242 configuration without the tides is used to highlight the influence of tides and IT on the
 243 temperature structure. To assess the realism of the model, we perform validation of various
 244 state variables used in this study such as the current's circulation, temperature, salinity,
 245 stratification as well as the barotropic and baroclinic tide properties.

246 II.3. Methods

247 II.3.1. Barotropic/baroclinic tide separation and tide energy budget

248 We follow Kelly et al. (2010) ~~method~~ to separate barotropic and baroclinic tide
 249 constituents: pressure, currents and energy flux. No modal separation is done, then tidal
 250 constituents obtained encompass the energy of all propagation's modes. Note that the
 251 barotropic/baroclinic tide separation is performed directly by the model for better accuracy,
 252 ~~however, by this way~~ even though it has the disadvantage of being very costly in terms of computing time.
 253 We therefore analyze only for one year (2015) the M2 frequency, since M2 is the major tidal
 254 constituent in this region, representing ~ 70% of the tidal energy (Beardsley et al., 1995;
 255 Gabioux et al., 2005 and Tchilibou et al., 2022).

256 The barotropic and baroclinic tide energy budget equations are obtained by ignoring as
 257 ~~the~~ ^a first-order approximation the energy tendency, the nonlinear advection and the forcing
 258 terms (Wang et al., 2016). Then, the remaining equations are reduced to the balance between
 259 the divergence of the energy flux, the dissipation and the energy conversion from barotropic to
 260 baroclinic (Buijsman et al., 2017; Tchilibou et al., 2018, 2020, 2022; Jithin and Francis, 2020
 261 ; Peng et al., 2021) :

$$262 \quad D_{bt} + \nabla_h \cdot F_{bt} + CVR \approx 0 \quad (W \cdot m^{-2}), \quad (1)$$

263
$$D_{bc} + \nabla_h \cdot F_{bc} - CVR \approx 0 \quad (\text{W.m}^{-2}), \quad (2)$$

264 *bt* and *bc* indicate the barotropic and baroclinic terms, *D* is the depth-integrated energy
 265 dissipation, which can be understood as a proxy of the real dissipation since *D* may encompass
 266 the energy loss of other tidal harmonics, non-linear terms and/or numerical dissipation (see
 267 Nugruho et al., 2018), $\nabla_h \cdot F$ represents the divergence of the depth-integrated energy flux,
 268 whilst *CVR* is the depth-integrated barotropic-to-baroclinic energy conversion, i.e. the amount
 269 of incoming barotropic energy which is converted into internal tides energy over the steep
 270 topography, with :

271
$$CVR = \langle \nabla H \cdot U_{bt}^* P_{bc}^* \rangle \quad (\text{W.m}^{-2}), \quad (3)$$

272
$$F_{bt} = \int_H^\eta \langle U_{bt} P_{bt} \rangle dz \quad (\text{W.m}^{-1}), \quad (4)$$

273
$$F_{bc} = \int_H^\eta \langle U_{bc} P_{bc} \rangle dz \quad (\text{W.m}^{-1}), \quad (5)$$

274 where the angle bracket denotes the average over tidal period, ∇H is the slope of the bathymetry,
 275 U_{bt}^* is the barotropic current and P_{bc}^* is the baroclinic pressure perturbation both at the bottom,
 276 *H* is the bottom depth, η the surface elevation, $U(u, v)$ is the horizontal velocity, *P* is the
 277 pressure, then *F* is the energy flux and allows the propagation pathways of the given tide to be
 278 highlighted.

279 II.3.2. 3-D heat budget equation for temperature

280 The three-dimensional temperature budget was computed online and further analyzed.
 281 It is the balance between the total temperature trend and the sum of the temperature advection,
 282 diffusion and solar radiative and non-solar radiative fluxes (e.g.: Jouanno et al., 2011;
 283 Hernandez et al., 2017):

284
$$\partial_t T = \underbrace{-u\partial_x T - v\partial_y T - w\partial_z T}_{ADV} - \underbrace{\partial_z(Kz\partial_z T)}_{ZDF} + LDF_T + FOR_z + Numdiff \quad (^\circ\text{C.s}^{-1}), \quad (6)$$

285 $\underbrace{-u\partial_x T - v\partial_y T - w\partial_z T}_{ADV}$ where *T* is the model potential temperature, [*u, v, w*] are the ~~space dimensional~~
 286 components, *ADV* is the 3-D temperature advection (left to right: zonal, meridional and vertical
 287 terms), *ZDF* is the vertical diffusion, *LDF_T* is the lateral diffusion, *FOR_z* is the tendency of
 288 temperature due to penetrative solar radiation and has a vertical decaying structure. At the air-
 289 sea interface, the temperature flux is equal to the non-solar heat flux (sum of the latent, sensible
 290 and net infrared fluxes). *FOR_z* can modify temperature in the thin surface layer but will not be

292 shown in the following. *Numdiff* corresponds to ~~the sum of~~ the numerical diffusion for the
293 temperature. In this study, we assume that this last term is of second order and is not highlighted
294 here.

295 **II.3.3. The atmosphere–ocean net heat flux**

296 The atmosphere–ocean net heat flux (Q_t) reflects the balance of incoming and outgoing
297 heat fluxes across the atmosphere–ocean interface (e.g.: Moisan and Niiler, 1998; Jayakrishnan
298 and Babu, 2013), it is defined as follows:

$$299 \quad Q_t = Q_{SW} \pm Q_{LW} \pm Q_{SH} \pm Q_{LH} \quad \cancel{Wm^{-2}}, \quad (7)$$

300 with from left to right: the incident solar radiative flux (Q_{SW}), the net infrared radiative flux
301 (Q_{LW}), the incoming/outgoing sensible heat flux (Q_{SH}) which depends on the temperature
302 difference between the atmosphere and the ocean surface, and the incoming/outgoing latent
303 heat flux (Q_{LH}) which depends on the specific humidity difference between the atmosphere and
304 the ocean surface. All these four components of ~~the~~ Q_t influence the variation of the ocean
305 surface temperature (SST). The last two components (Q_{SH} and Q_{LH}) have in addition a direct
306 dependence relationship with the SST. Since IT can change the SST, we are therefore interested
307 in knowing how it affects the net heat flux at the atmosphere–ocean interface.

308 **III. Model validation**

309 In this subsection we present for the M2 harmonic the barotropic and baroclinic tidal
310 characteristics of the model for the year 2015, and the SST for the whole period from 2013 to
311 2015, and we verify that they agree with the different observations.

312 **III.1. M2 Tides in the model**

313 The barotropic SSH (Fig.2b) of the model is compared with FES2014 (Lyard et al.
314 2021) (Fig.2a), ^{and} there is good agreement in terms of both amplitude and phase. Nevertheless,
315 near the coast, some differences are observed in terms of amplitude. The SSH of the model is
316 lower ($\sim +50$ m) north of the mouth of the Amazon. However, inland and on the southern part
317 of the mouth, the model overestimates the amplitude ($\sim +20$ m and $\sim +40$ m respectively). This
318 is in terms of order of magnitude like the biases in the Ruault et al. (2020) configuration that
319 they compared to the FES2012 product (Carrère et al., 2012) over the same region. Along the
320 steep slope of the bathymetry (see Fig.1), a portion of the incident barotropic tidal energy (black
321 arrows Fig.2c and Fig.2d, for FES2014 and the model, respectively) in the presence of
322 stratification is converted to baroclinic tidal energy. We compared the depth-integrated

Display figures in order of reference.
2a, 2b, ...

323 barotropic-to-baroclinic energy conversion rate (CVR) between the model (Fig.2d) and
324 FES2014 (Fig.2c). The model does reproduce the same conversion patterns of FES2014 but
325 can underestimate the CVR by about 30%. The bathymetry resolution plays a critical role in
326 CVR (Niwa and Hibiya, 2011), ^{meaning that} then the difference in bathymetry resolution between the model
327 (~ 3 km) and FES2014 (~ 1.5 km) could therefore explain ^{the} ~~that~~ difference in CVR.

328 [?] The critical slope for the M2 harmonic on the slope is greater than 1.2 (not shown),
329 consequently, the ~~baroclinic tides~~ (internal tidal waves) thus generated will therefore propagate
330 in the opposite direction to the barotropic tides, i.e., from the slope to the open ocean. The
331 baroclinic tidal flux of the model (black arrows in Fig.2e) highlights the existence of six main
332 sites of IT generation on the continental slope, two of which are more important (A and B), as
333 shown by Maghalaes et al. (2016), Barbot et al. (2021) and Tchilibou et al. (2022). From these
334 two main sites, the flow propagates offshore for nearly 1000 km. On its propagation path, the
335 baroclinic tide ~~signs at the surface in SSH~~. We compared this signature ^{has a SSH signature?} ~~for the~~ model (Fig.2h)
336 with an estimate deduced ~~from the altimeter tracks, produced by Zaron et al. (2019) (Fig.2g).~~
337 The model is in good agreement with the altimetry observations, ^{this is also a model. ≠ methods produce ≠ estimates} with an overestimation of the
338 order of ~ +1.5 cm on the SSH maxima. It is important to note that the baroclinic SSH of ~~the~~ ^{our}
339 model is an average over the year 2015, whilst ~~the observations~~ are an average over about 20
340 years. ~~This longer period may smooth the amplitude of the signal obtained from the altimetry~~
341 ~~observations~~. ^{Except that Zaron's output is less smooth.} Also, the variability contained in the two averages is not the same, and this may
342 explain some differences in the positioning and amplitude of the maxima.

343 Figure 2f shows the full depth-integrated internal tidal energy dissipation for the model.
344 The estimated local dissipation of this energy is defined as follows:

$$345 \quad P = (D_{bc} / CVR) * 100 \quad (8)$$

346 The local dissipation is then integrated at the embankment level in boxes A1, A2 and B
347 (Fig.2f, see coordinates in Table-2 in Tchilibou et al. 2022) and provides information that a
348 significant part of the energy is dissipated locally in the different boxes, i.e., about 30% (not
349 shown). The local dissipation at the generation sites is thus in good agreement with Tchilibou
350 et al. (2022). The remaining energy is exported offshore and dissipates along the propagation
351 path. This dissipation is more extensive offshore along path A, ~ 500 km from the slope, with
352 two patterns spaced approximately 120 km apart corresponding to propagation mode-1, and
353 less extensive offshore along path B, ~ 100-200 km from the slope (Fig.2f).

Why is dissipation in Fig. 2f positive or negative?

354 We have presented here only the dissipation for the M2 harmonic, but in the rest of the
355 paper, we will analyze the temperature fields on a seasonal scale and by this fact, the effect of
356 all the tidal harmonics on the temperature are considered.

357 **III.2. SST Validation**

358 Figure 3 shows the mean SST from TMI SST, tidal simulation and non-tidal simulation
359 over the entire 2013-2015 period. The mean SST of the tidal simulation (Fig.3b) reproduces
360 well spatially the TMI SST observations (Fig.3a) both for cooling on the shelf around 47.5°W
361 and to the southeast between 40°W–35°W and 2°S–2°N, which is almost absent for the non-
362 tidal simulation (Fig.3c). To the northeast, between 50°W–54°W and 3°N–8°N in the Amazon
363 plume, the SST of the non-tidal simulation is in better agreement with the observations, while
364 the SST of the tidal simulation is about ~~1~~ °C cooler than TMI SST. Such a difference is very
365 similar to what is obtained by other models in the same region (Hernandez et al., 2016, 2017;
366 Gévaudan et al., 2022). The seasonal cycle of the SST of the three products for the three years
367 2013-2015 (Fig.3d) is obtained by interpolating the SST of both simulations on the TMI SST
368 grid and averaging in the dashed boxes around the IT generation areas (Fig.3a, b, and c) with
369 the shelf being masked over the 200 m isobath. The tidal and non-tidal simulations of the model
370 reproduce well both the seasonal cycle and the standard deviation of the observations, with a
371 low RMSE of approximately 10^{-2} °C between each simulation and TMI SST (Fig.3d), which
372 indicates the good quality of our model simulations. Nevertheless, over the seasonal cycle, it
373 appears that between January-April and July-December, the tidal simulation is closer to the
374 observations, while the non-tidal simulation seems slightly warmer than the observations; and
375 in May-June, both simulations are colder than TMI SST (Fig.3d).

376 **IV. Results**

377 In this section, we will present the influence of IT on the SST, the associated processes,
378 and the impact on the net atmosphere-ocean heat flux from the model's tidal and non-tidal
379 simulations. The analyses were performed on a seasonal scale between April-May-June (AMJ)
380 and August-September-October (ASO) for the three years 2013-2015.

381 **IV.1. Tide-enhanced surface cooling**

382 Beginning in July, a tongue of cold water (< 27 °C) begins to form to the southeast and
383 enters the central part of the plateau in August and remains there until October. Figure 3e-g
384 show the SST, averaged over the ASO season. The tidal simulation (Fig.3f) shows that the
385 upwelling cell, represented by the extension of the 27.2 °C isotherm along the slope to about

Should
this be
its own
figure?

386 49°W–3°N, extends further north than in the non-tidal simulation (Fig.3g, 45°W–0°N) which
 387 is in better agreement with the TMI SST observations over the same period (Fig.3e).

4a first

388 The general impact of the tide, illustrated by showing the difference in SST between
 389 the tidal and the non-tidal simulations in both seasons (Fig.4c-d, respectively for AMJ and
 390 ASO), is a cooling over a large part of the study area with maxima (up to -0.3 °C): in the
 391 Amazon plume downstream of the river mouth (northeast beyond 3°N), and on the path of
 392 propagation of IT for both seasons. For ASO, tides induce a warming (> +0.3 °C) on the shelf
 393 at the mouth of the Amazon River, while for AMJ it is a cooling (-0.3 °C). East of 45°W, the
 394 tide-induced cooling for each of the two seasons has different spatial structures, but this is
 395 probably due to different mesoscale variability between the two seasons.

redundant

396 **IV.2. Impact in the Atmosphere–Ocean Net heat flux (Q_T)**

Q_T or Q_t ?

397 Associated with the cooling of the SST, the tide induces Q_t anomalies whose spatial
 398 structure is very similar to the SST. Indeed, the difference in Q_t is essentially positive over the
 399 whole domain during the AMJ season (Fig.4a) with average maximum values around 25 W.m⁻²
 400 in the plume and the Amazon retroflection to the northeast and along A and B. During the ASO
 401 season, there is as for the temperature at the mouth of the Amazon an inverse anomaly of ~~1~~-25
 402 W.m⁻² (Fig.4b). In each season, the spatial structure of the Q_t difference almost perfectly
 403 matches that of the SST difference. Knowing that the atmosphere and the underlying ocean are
 404 in a certain equilibrium, the cooling of the SST by the water masses arriving at the surface will
 405 disturb this balance. In response, a consequent variation of the net heat flux from the
 406 atmosphere to the ocean, will try to restore the balance. As shown by the very strong and
 407 significant negative correlation between the difference in Q_t and the difference in SST. For the
 408 AMJ season, we have a negative correlation of -0.97 with a significance of $R^2 = 0.95$, and about
 409 the same as for the ASO season with -0.98 and 0.96 respectively for negative correlation and
 410 its significance (Fig.9f). You don't have a Fig. 9f.

verb missing

411 The integral over the entire domain of the net heat flux for each season and for each
 412 simulation (Fig.4e) shows that during the AMJ season, the Q_t increases from 23.85 TW for the
 413 non-tidal simulation to 35.7 TW for the tidal simulation, an increase of +33.2 %, two times
 414 greater than that found (15 %) by Tchilibou et al. (2020) in Solomon Sea. Thus, the tide and IT
 415 are responsible for a third of the variation in net atmosphere-ocean heat flux during this season.
 416 While during the second ASO season, there is a smaller increase in Q_t of +7.4%, i.e., a variation
 417 from 73.03 TW to 78.83 TW between the non-tidal and tidal simulations.

418 We also note the considerable difference in integrated Q_t between seasons. We start
419 from values below 36 TW in the AMJ season to values above 73 TW in the ASO season, i.e.,
420 a multiplication by a factor of at least order 2. These larger values could probably be related
421 with the appearance of the upwelling cell described above, knowing that cooler SSTs induce
422 stronger Q_t .

423 IV.3. Vertical structure of the Temperature along A

424 To further analyze the temperature changes between both simulations, we made vertical
425 sections following the path of IT emanating from sites A and B (blue and red line in Figure 2e
426 respectively). We will show only the results following path A, but the results are similar for
427 path B.

428 Figure 5 shows vertical sections of temperature for the two seasons following A. For
429 the AMJ season, over the slope and near the coast, cold water ($< 27.6^\circ\text{C}$) remains below the
430 surface at ~ 20 m for the tidal simulation (Fig.5a) and deeper at ~ 60 m for the non-tidal
431 simulation (not shown), it then rises to the surface more than 400 km offshore for both
432 simulations. Although at the surface the difference in SST between the two simulations (tide -
433 no-tide) is relatively small ($\sim -0.3^\circ\text{C}$, Fig.4c), because the SST is damped by the heat fluxes,
434 further down the water column, this difference becomes much larger ($> \pm 1.2^\circ\text{C}$, Fig.5c).

435 Above the thermocline (< 120 m, cyan and yellow lines in Fig.5c), the simulation with the tides
436 is colder by $+1.2^\circ\text{C}$ from the slope where the IT are generated to the open ocean following their
437 propagation path. Conversely, below the thermocline, the tidal simulation is warmer by $+1.2$
438 $^\circ\text{C}$ up to ~ 300 m along the same propagation path. During this AMJ season, the thermocline
439 (~ 100 m ± 15 m, thick dashed black line, Fig.5a) and the mixing layer (~ 40 m ± 20 m, thick
440 dashed white line, Fig.5a) have a very weak slope between the coast and the open ocean.

441 Furthermore, the difference in isodensity depths between the two simulations is small (not
442 shown), as are the depths of the thermocline (~ 10 m, Fig.5c) and the mixing layer (not shown),
443 although these different depths are closer to the surface for the tidal simulation (not shown).

444 Over the whole domain (not shown), the thermocline is deeper by 15 m on average in the non-
445 tidal simulation, following the propagation paths of the IT energy flow, on the Amazon shelf
446 and plume. While the mixing layer in the non-tidal simulation is deeper by an average of 13 m
447 over the shelf, 4 m on average along the IT propagation paths and close to zero in the Amazon
448 plume.

449 During the ASO season, cold waters ($< 27.6^\circ\text{C}$) previously confined below the surface
450 during the previous season (AMJ) then rise to the surface. These cold waters extend over the

Your definition of cold water keeps changing between 27° and 27.6°

"colder by -1.2° "
=
"warmer by $+1.2^\circ$ "

Did you ever define what it was?

Is the deepening only along the paths?

451 slope and up to about 150 km offshore in the non-tidal simulation (not shown) and up to 250
452 km offshore in the tidal simulation (Fig.5b). The isotherm 27.2 °C reaches the surface above
453 the slope in the tidal simulation but remains below the surface (~ 30 m) in the non-tidal
454 simulation (not shown). At the surface and in the surface layers, the temperature in the presence
455 of the tide and IT is therefore cooler. The temperature difference between the two simulations
456 in the ASO season (Fig.5d) is smaller (< 0.4 °C) in the surface layers (< 40 m) near the coast
457 compared to the AMJ season (Fig.5c). In contrast, during the ASO season, this cooling reaches
458 the surface and results in a colder SST (-0.3 °C) (Fig.4d) along A. The strongest cooling (~ -
459 1.2 °C) is deeper between 60 and 140 m depth. Below the thermocline, warming (+1.2 °C) is
460 also present, but extends slightly less (~ 650 km) offshore (Fig.5d) compared to the AMJ season
461 (~ 1000 km, Fig.5c). During this ASO season, the coastward slope of the thermocline and
462 mixing layer becomes somewhat steeper compared to the other season. In both simulations,
463 there is a dip of ~ 80 m (~60 m offshore and ~140 m inshore) and ~40 m (~30 m offshore and
464 ~70 m inshore), respectively for the thermocline (thick dashed black line, Fig.5b) and the
465 mixing layer (thick dashed white line, Fig.5b). Over the entire domain (not shown) between
466 the two simulations (tide - no-tide), the tide deepens the thermocline depth by +6 m on the shelf
467 and +12 m at the plume and along the propagation path of A. As for the mixing layer, which is
468 deeper in the tidal run by 12 m along the shelf and along the propagation path of A.

469 Between the two seasons, there is also a change in the vertical density gradient between
470 the coast and the open sea. In the simulation with tide (Fig.5a) and without tide (not shown),
471 during the AMJ season, a strong vertical density gradient is present near the coast and decreases
472 towards the open sea. In contrast, during the second ASO season, the vertical density gradient
473 is weaker inshore than offshore. This clearly highlights a seasonality in the vertical density
474 gradient profile in agreement with Tchilibou et al. (2022). The transect of the temperature
475 differences between the two simulations (Fig.5c-d) show that IT (and probably the tide) can
476 influence the temperature in the ocean from the surface to the bottom, with a greater effect on
477 the first 300 meters. One question we address in this paper is to better understand what
478 processes are at work that explain these temperature changes.

479 IV.4. Processes involved modifying the temperature

480 To explain the observed surface and water column temperature changes, we calculated
481 the trend terms of the temperature evolution equation (see Section II.3.2, Equation 6) for both
482 seasons (AMJ and ASO) also averaged over the three years from 2013 to 2015.

483 IV.4.1. Vertical diffusion of Temperature

484 Figure 6 shows the vertical temperature diffusion term (ZDF) for both seasons AMJ
485 (left panel) and ASO (right panel). The ZDF is averaged between 2–20 m, i.e., within the
486 mixing layer depth range. For the AMJ season, the ZDF of the tidal simulation (Fig.6a) shows
487 a negative trend (cooling) in the whole domain, which is maximum on the continental slope
488 where the IT are generated and on their propagation path ($< -0.4 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$), with larger
489 horizontal extent along A (~700 km from the coasts) compared to B (~300 km from the coasts).
490 Over the rest of the domain, it remains very low ($> -0.1 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$). For the non-tidal simulation
491 (Fig.6c), the ZDF is very weak ($> -0.1 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$) over the entire domain, demonstrating that
492 internal tidal waves would be the main driver of the vertical temperature diffusion in this region
493 during this season. For the second ASO season, the tidal simulation (Fig.6b) shows a decrease
494 of the ZDF along the coast and a strengthening offshore following A, but with the same cooling
495 trend ($< -0.4 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$). While along B, it becomes almost closed to zero, both at the coast and
496 offshore (Fig.6b). In addition, the mesoscale circulation intensifies during this season.
497 Therefore, to the northeast, approximately between 4°N – 8°N , and 47°W – 53°W , there is a
498 cooling on the shelf ($\sim +0.3 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$) with NBCR-like patterns, both in the tidal simulation
499 (Fig.6b) and in the non-tidal simulation (Fig.6d).

500 On the vertical following A, we notice an inter-thermocline vertical profile for the
501 simulation with tide in the two seasons AMJ and ASO (respectively Fig.6e and 6f), with a
502 cooling tendency ($< -0.4 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$) above the thermocline and a warming ($> +0.4 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$)
503 below the thermocline, with an average vertical extension of ~ 350 m depth for the maximum
504 values, but which exceeds 500 m depth for the low values ($< +0.1 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$). Over the slope,
505 we see, as for the horizontal averages, this weakening of the ZDF between the AMJ (Fig.6e)
506 and ASO (Fig.6f) seasons and the strengthening offshore. On the other hand, on the vertical,
507 we observe towards the open sea ($> 200 \text{ km}$) that the ZDF maxima seem to be discontinuous
508 and spaced of about 120–150 km during the AMJ season (Fig.6e), while we have a more
509 continuous diffusion for the ASO season (Fig.6f). This is consistent with the ZDF vertical
510 averages (Fig.6a-b). For the non-tidal simulation, the vertical temperature diffusion tends
511 towards $0 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$ within the water column but remains quite large ($> -0.2 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$) in the
512 thin surface layer (Fig.6g-h).

513 During the AMJ season, the ITCZ is close to the equator and thus the trade Winds have
514 their maximum intensity in the heart of the domain, while they migrate northward for the ASO
515 season. As a result, more wind-generated diapycnal mixing is expected in the domain during

going in which direction?

Not how you use "while"

Doesn't quite work in the sentence

516 the AMJ season compared to the ASO season. But the average value of the ZDF (~ -0.2
517 $^{\circ}\text{C}\cdot\text{day}^{-1}$) is the same between the two seasons and for both simulations (not shown) over most
518 of the domain (except for the areas of the NBC backscatter for both simulations, on IT's
519 generation sites and on their propagation path for the tidal simulation). This implies that the
520 ability of the wind to generate diapycnal mixing in the underlying ocean surface layer could be
521 limited by various oceanic processes in this region or is not well considered in the model.

522 Furthermore, it is important to note that along the IT propagation's pathway, the
523 maximum of the ZDF follows the maxima of the baroclinic tidal energy dissipation (Fig.2f).
524 Thus, the dissipation of IT generated on the continental slope generates vertical mixing that
525 enhances the cooling observed at the surface along the coast. In addition, this temperature
526 diffusion contributes to greater subsurface cooling, and warming in the deeper layers beneath
527 the thermocline.

528 In section IV.3 the seasonality of the vertical gradient of stratification was highlighted,
529 which is stronger at the coast relative to the open ocean during the AMJ season, and reverses
530 during the ASO season to become stronger offshore relative to the coast. This could explain
531 why the ZDF is stronger along the slope and along the near-coastal pathway B during the AMJ
532 season (Fig.6a), while it is weaker along the slope and closed to zero following B during the
533 ASO season (Fig.6b). The vertical gradient of density (and thus stratification) over the slope
534 influences the generation of IT, by controlling the propagation mode of the IT that are generated
535 (e.g.: Tchilibou et al., 2020 and Barbot et al., 2021). We show here that this vertical gradient
536 also plays on the fate of these IT, in this case on their dissipation. The vertical gradient of the
537 stratification thus determines where the internal tidal waves dissipate their energy in the water
538 column.

539 **IV.4.2. Vertical advection of Temperature**

540 The vertical temperature advection (z -ADV) averaged between 2–20 m is almost zero
541 in these surface layers throughout the region (Fig.7a, b, c, and d). For both seasons, some weak
542 extreme values are in the northwest on the plateau between 54°W – 50°W and 3°N – 3°N) and
543 are of the same intensity between the two simulations. With a slight intensification when
544 moving to the ASO season (~ -0.3 $^{\circ}\text{C}\cdot\text{day}^{-1}$). The z -ADV is zero at the IT generation sites and
545 along their propagation pathways, so the almost zero difference between the two simulations
546 for each season shows that the IT and barotropic tide do not generate vertical temperature
547 advection within these ocean surface layers. The z -ADV does not contribute to the temperature
548 change in the surface layers of the ocean, and therefore does not influence the cooling observed

549 from the surface on the SST. On the other hand, deeper, under the mixed layer and close to the
550 thermocline, the z -ADV structure is more marked.

551 Vertical sections following A (Fig.7e, f, g and h) show an intensification of z -ADV
552 below the mixing layer and near the thermocline between 80 and 200 m ($\sim \pm 0.8$ °C.day⁻¹).
553 During the AMJ season, over the vertical, the z -ADV appears to be rather dominated by a
554 cooling trend. The tidal simulation (Fig.7e) shows a cooling trend (~ -0.8 °C.day⁻¹), on the
555 slope where the IT are generated, with an average vertical extension from ~ 20 to 200 m depth.
556 Then offshore, two cooling hotspots (~ -0.8 °C.day⁻¹) followed by a weaker one (~ -0.3
557 °C.day⁻¹) spaced about 120–150 km apart, ^{separated} interspersed by two warming zones, respectively \sim
558 $+0.6$ °C.day⁻¹ and $\sim +0.3$ °C.day⁻¹ from the coast. For the non-tidal simulation (Fig.7g), the z -
559 ADV is much less intense with lower values ($< \pm 0.3$ °C.day⁻¹) near the coast until ~ 300 km
560 offshore, followed by a cooling hotspot (~ -0.8 °C.day⁻¹) between 300 km and 500 km. For
561 both simulations, the extreme values appear to be centered around the mean depth of the
562 thermocline (thick black outline) and do not cross the mixing layer depth (thick magenta
563 outline). They are on average located between 40 m and 200 m depth and follow the position
564 of the maximum vertical density gradient between isodensity anomalies 23.8–26.3 kg.m⁻³.

565 For the ASO season, the simulation with tide (Fig.7f) still shows the same cooling
566 intensity on the slope, although deeper (~ 60 m and 250 m), as well as offshore with this time
567 the third cooling hotspot more intense (~ -0.8 °C.day⁻¹) than during the AMJ season (Fig.7e).
568 The non-tidal simulation (Fig.7h) shows a less intense z -ADV ($< \pm 0.1$ °C.day⁻¹) near the slope,
569 and a little stronger offshore ($\sim \pm 0.3$ °C.day⁻¹) between 300 and 600 km from the slope,
570 although less intense than the previous season.

571 As in the AMJ season, the extreme values of z -ADV follow the vertical density gradient
572 in both simulations. During the ASO season, the maximum of the vertical density gradient is
573 between 23.8 and 26.2 kg.m⁻³ and is deeper at the coast and is closer to the surface offshore.
574 Thus, the extreme values of z -ADV are located a little deeper, between 80 and 300 m.
575 Furthermore, for the non-tidal simulation and during both seasons, the position relative to the
576 coast of the extreme values are shifted regarding those ones of the same polarity in the
577 corresponding tidal simulation, which means that the presence of the IT and the tides could
578 modify the intensity and patterns of the z -ADV produced by the other oceanic processes.

579 In addition, we averaged the z -ADV between deeper depths above the thermocline
580 depth (20–70 m) and below the thermocline (148–250 m) depth for all simulations and both
581 seasons (not shown). This allows to highlight the NBC's pathway through the extreme values

582 of the z -ADV close to the coast and its retroreflection offshore to the northeast for both
583 simulations, but also the propagation of the IT from the coast to the open sea from the two main
584 sites A and B for the simulation with tide. Thus, we see that the IT and the general circulation
585 are the main drivers of the vertical temperature advection in the subsurface and deeper layers
586 in this region.

587 **IV.4.3. Horizontal advection of temperature**

588 Horizontal advection of temperature (h -ADV) is defined as the sum of the zonal (x -
589 ADV) and meridional (y -ADV) terms of temperature advection. The h -ADV is also averaged
590 between 2–70 m for each simulation during both seasons (Fig.8a, b, c and d). As obtained with
591 z -ADV, horizontal advection of temperature tends to zero over the entire domain in the surface
592 layers for both seasons in both simulations, with some weak extreme values located in the
593 northwest on the plateau between 54°W – 50°W and 3°N – 3°N that intensify during the ASO
594 season ($\sim \pm 0.2^{\circ}\text{C}\cdot\text{day}^{-1}$) (Fig.8b and d). Along the slope between sites A and B during the AMJ
595 season, the h -ADV generates a small warming ($\sim +1^{\circ}\text{C}\cdot\text{day}^{-1}$) that is more pronounced in the
596 tidal simulation (Fig.8a) than in the non-tidal simulation (Fig.8c), and thus appears to be related
597 to the IT generated along the slope. On the other hand, the small difference between the two
598 simulations in the surface layers shows that the tidal processes (IT and barotropic tide) hardly
599 generate horizontal temperature advection. The low values observed here clearly show that the
600 h -ADV could not influence the cold-water tongue observed over the surface SST (Fig.3e-g)
601 during the ASO season.

602 Along the vertical following A, the h -ADV maxima remain essentially confined below
603 the mixing layer, with much more intense values in the tidal simulation compared to the non-
604 tidal simulation. The h -ADV contributes to both warming and cooling of the temperature (\sim
605 $\pm 0.4^{\circ}\text{C}\cdot\text{day}^{-1}$) from the slope to more than 500 km offshore, with an average vertical extension
606 between the surface and 400 m depth for the tidal simulation (Fig.8e and f) and a little less
607 extended between 20–300 m depth for the non-tidal simulation (Fig.8g and h) during both
608 seasons. The h -ADV ~~which~~ is low in the surface layers (2–20 m) but maximum in the
609 subsurface where the stratification is stronger. We also see for the tidal simulation in both
610 seasons a warming above the slope that reaches the surface with an intensity of about $+0.4$
611 $^{\circ}\text{C}\cdot\text{day}^{-1}$ (Fig.8e and f) but remains below the surface (~ 20 m) in the non-tidal simulation
612 (Fig.8g and h). This vertical excursion that is observed elsewhere for ZDF and z -ADV is a
613 marker of local dissipation of IT at their generation site on the slope, which clearly affects both
614 vertical diffusion and advection of the temperature. But we have almost null values along the

615 slope when averaging h -ADV or z -ADV between 2-20 m and much more strong values for
616 the ZDF (Fig.6a, b, c and d). This means that the IT's energy loss is mostly transferred to the
617 turbulent scale (mixing). Furthermore, unlike the ZDF (Fig.6e) and z -ADV (Fig.7e and f), on
618 the vertical it is difficult to identify a wave structure characteristic of IT propagation in the h -
619 ADV.

620 **V. Summary and Discussions**

621 In this paper, the impact of internal tidal waves (IT) on temperature, off the Amazon,
622 especially on the surface and on net heat fluxes is explored through outputs of two twin oceanic
623 simulations (with and without tides) from a realistic model. The AMAZON36 configuration,
624 based on the $1/36^\circ$ resolution NEMO model, can reproduce the generation of internal tides (IT),
625 i.e., the conversion of energy from barotropic to baroclinic tides, from two most energetic sites
626 A and B, in good agreement previous studies (Magalhaes et al., 2016 and Tchilibou et al.,
627 2022). As for dissipation, the model reproduces 30% local dissipation, the rest propagating
628 offshore from the different generation sites, the two main ones being A and B (Fig.2e). During
629 their propagation, the IT dissipate most of their energy after two beams of mode-1 reflection
630 (120–150 km), that is less than 300 km from the slope.

631 The analyses are based on data from three years (2013 to 2015), averaged over two
632 seasons, AMJ (April-May-June) and ASO (August-September-October) which are highly
633 contrasted in terms of stratification, circulation and EKE. During ASO, the cold waters (< 27.5
634 $^\circ\text{C}$) of the Atlantic Cold Tongue (ACT) enter our domain along the coast, and are affected by
635 IT and tides, which leads to a cooler seasonal upwelling.

636 The impact of the tides on temperature was assessed by comparing our twin simulations
637 with and without tides for each season. For ASO and AMJ, the tides create a cooling of SST of
638 the order of ~ -0.3 $^\circ\text{C}$ in the plume of the Amazon offshore and along the paths of propagation
639 A and B of the internal tide. Concerning the Amazon shelf, the tides induce a warming ($\sim +0.3$
640 $^\circ\text{C}$) in ASO and a cooling (of ~ -0.3 $^\circ\text{C}$) in AMJ. These cooler/warmer waters are responsible
641 in the same location for an increase/decrease in the net heat flux from the atmosphere to the
642 ocean, leading to an increase (Q_t) of +33.2% in AMJ and of +7.4% in ASO between runs with
643 and without tides. In the subsurface, above the thermocline (< 120 m), the IT and tides induce
644 a stronger cooling than on the surface of about ~ -1.2 $^\circ\text{C}$ and an associated warming of about
645 $\sim +1.2$ $^\circ\text{C}$ under the thermocline (> 120 m to 300 m).

646 By increasing the atmosphere to ocean net heat flux (Q_t), the IT and tides might reduce
647 the cloud convection in the atmosphere, as we are in an intertropical convergence zone (ITCZ).

648 Impact on overall atmospheric circulation and precipitation is expected to be significant, as
649 previously shown in other regions such as Indonesia (Tidal induced cooling of $-0.3\text{ }^{\circ}\text{C}$ can
650 reduce precipitation by -20% , see Koch-Larrouy et al., 2010).

651 Therefore, it becomes important to note that the interannual or even climatic scale
652 evolution of internal tidal waves activity must be considered to better understand the future
653 evolution of the global climate. Especially since thanks to the CanESM5 global climate model,
654 Yadidya and Rao (2022) have just shown that in the Andaman Sea and Bay of Bengal, towards
655 the end of this century, for both optimistic and pessimistic SSP scenarios, the increase in depth-
656 averaged stratification will result in an increase in IT activity in these two regions. Knowing
657 that the continental slope of northern Brazil is a place of high generation of IT, which therefore
658 depends on stratification, it is hereby critical to understand how IT activity will evolve in the
659 coming decades in order to better anticipate the climate, and thus better adapt public policies
660 at national and international levels to the global context of climate change.

661 Another objective of our study was to understand the processes responsible for these
662 temperature changes. For this, we analyzed the trend terms of the temperature evolution
663 equation. Where IT dissipate their energy, there is an intense vertical mixing that generates
664 vertical diffusion of temperature (ZDF) ($-0.4\text{ }^{\circ}\text{C}\cdot\text{day}^{-1}$) according to pathway A and to a lesser
665 extent according to pathway B, stronger at shore than offshore during AMJ and inverse during
666 ASO. The ZDF is the only process that reaches the surface layer, and then appears in first
667 approximation to be the main process contributing to the surface cooling observed on SST. The
668 atmospheric heat flux terms (FOR_z) could also modify this SST but was not highlighted in this
669 study. The mixing takes place up to about 800 km off the slope following A, and 300 km
670 following B. It is also responsible on a seasonal scale, but also daily for a negative average
671 variation (cooling) of temperature of about $-0.4\text{ }^{\circ}\text{C}\cdot\text{day}^{-1}$ above the thermocline, and a warming
672 of $+0.4\text{ }^{\circ}\text{C}\cdot\text{day}^{-1}$ below 350 m and decreasing to $+0.1\text{ }^{\circ}\text{C}\cdot\text{day}^{-1}$ around 500 m depth.

673 IT propagation induce vertical advection of water masses around the thermocline level,
674 which has the effect of producing a subsurface mean temperature cooling ($\sim -0.8\text{ }^{\circ}\text{C}\cdot\text{day}^{-1}$) at
675 a depth varying between 20–200 m AMJ and 60–250 m in ASO, with three extreme values off
676 the coast spaced approximately 120–150 km along of the pathway A, which seem to follow the
677 dissipation patterns, and thus correspond to the horizontal scale of the mode-1 propagation of
678 IT. Other processes such as zonal and meridional advection of temperature also induce
679 temperature change in subsurface and deeper layers. Finally, the horizontal (zonal and

680 meridional) advection of temperature in this region is more related to the general circulation
681 (NBC, mesoscale) but is increased by tides and IT.

682 Thus, it is the combination of these different processes that explains the temperature
683 change in the water column in this region. Furthermore, in order to explain the cooling of the
684 SST at the surface, Neto et al. (2014) indicated that the northward transport of water masses by
685 the constant circulation of the NBC was compensated by a vertical advection of colder water
686 masses towards the surface. We now know that this vertical advection process fails to modify

and ?

687 the SST but is rather limited below the mixing layer. The same is true for zonal and meridional
688 advection of temperature (which form horizontal advection). It should be remembered that
689 vertical diffusion extends from the surface, through the mixing layer, into the deep layers. It is
690 therefore possible that water masses cooled by both vertical and horizontal advection below
691 the mixing layer can be recovered and transported vertically to the surface by the effect of
692 vertical mixing. The change in SST and temperature above the mixing layer then comes from
693 (i) vertical diffusion of temperature and (ii) a combination of this vertical diffusion and the
694 advection (vertical and horizontal) of temperature that takes place below the mixing layer.

695 This study focuses on temperature, but other analyses we have done on salinity show
696 that IT also affects the haline structure of the ocean in this region. A future work would be to
697 look at the impact on salinity, which is also a key parameter in the functioning of the ocean as
698 in exchanges with the atmosphere, and thus can play a role on the climate. In addition, internal
699 waves can also influence the biogeochemical cycles of elements and the entire marine
700 ecosystem, since they can induce nutrient uptake and thus participate in structuring the spatial
701 distribution of phytoplankton and zooplankton, and in consequence of the rest of the food chain
702 that depends on them.

703 It would also be important to compare the results of our model with fields observations.
704 Two high frequency PIRATA anchorages have been installed offshore at the extremity of our
705 region between 35°W–38°W and 0°N–5°N (see Bourlès et al. 2019) and could be used for this
706 purpose. In addition, recently, the “AMAZOMIX” campaign entirely dedicated to IT (27 August
707 and 8 October 2021) will provide a better understanding of the impact of IT on the marine
708 environment in this region. In the meantime, a coupled physical/biogeochemistry simulation
709 (NEMO/PISCES), currently under analysis, will begin to answer these crucial questions of the
710 impact of internal waves on biogeochemistry.

711 Finally, in this first part, we have focused on describing the effects of internal tidal
712 waves on temperature variation on a seasonal scale, while the remainder of this work will
713 address temperature changes on finer time scales, notably on the tidal scale.

714

715

716 **Data availability**

717 The TMI SST v7.1 data are publicly available online from the REMSS platform:
718 <https://www.remss.com/missions/tmi/>, was accessed on 27 June 2022. The model simulations
719 are available upon request by contacting corresponding authors.

720 **Authors contributions**

721 Funding acquisition, AKL; Conceptualization and methodology, FA, AKL and ID.
722 Numerical simulations, GM and FA. Formal analysis, FA; FA prepared the paper with
723 contribution from all co-authors.

724 **Competing interests**

725 The authors declare that they have no conflict of interest.

726

727 **Acknowledgments**

728 This work is part of the Fernand Assene PhD thesis, cofounded by Institut de Recherche
729 pour le Développement (IRD) and Mercator Ocean International (MOI). The numerical
730 simulation was founded by CNRS/CNES/IRD via the projects A0080111357 and
731 A0130111357 and were performed tank to the IDRIS platform calculator (Jean-Zay).

Figure 1: The horizontal gradient (∇H) of the model's bathymetry with different internal tide generation sites (A^* , B^* , C^* , D^* , E^* and F^*) along the high slope (blue) of the shelf break, with the main sites (in red) being A^* and B^* , as mentioned in Magalhaes et al. (2016) and Tchilibou et al. (2022). Solid lines represent the circulation χ as described by Didden and Schott, 1993; Richardson et al., 1994; Bourlès et al., 1999a; Johns et al., 1998; Schott et al., 2003; Garzoli et al., 2004 with NBC, NBCR and NECC pathways in black, and the EUC pathway in brown red. Tin black contours are 200 m, 2000 m, 3000 m and 4000 m isobaths.

1114 *Figure 2: M2 tides (coherent) characteristics. Barotropic sea surface height for FES2014 (a)*
1115 *and model (b), depth-integrated energy conversion rate (CVR) (color shading) for FES2014*
1116 *(c) and model (d) with barotropic energy flux black arrows, model depth-integrated baroclinic*
1117 *energy flux black (e) arrows with transect lines along A (blue) and B (red) IT's pathways,*
1118 *model depth-integrated baroclinic energy dissipation (f), and baroclinic sea surface height*
1119 *from observation (Zaron, 2019) (g) and model (h).*

1178

1179

What's this???

Authors state earlier that paths A and B are similar, but they look very different here, especially in panel (b).

1180

1181 *Figure 6: The vertical diffusion of temperature (ZDF) for both seasons, respectively AMJ (left*

1182 *panel) and ASO (right panel). Vertical mean between 2–20 m for AMJ season in tidal (a) and*
1183 *non-tidal (c) simulation; then for ASO season in tidal (b) and non-tidal (d) simulations. Black*
1184 *thin contours are, from the coast to open ocean, 200 m and 2000 m isobaths. Vertical section*
1185 *following A for AMJ season in tidal (e) and non-tidal (g) simulations; then for ASO season in*
1186 *tidal (f) and no-tidal (h) simulation. The black and magenta ticker dot-dashed lines are*
1187 *respectively thermocline depth and mixed layer depth. Thin black contours are for density*
1188 *anomaly.*
