Abstract

The impact of internal and barotropic tides on the vertical and horizontal temperature structure off the Amazon River was investigated during two highly contrasted seasons (AMJ: April-May-June and ASO: August-September-October) over a three-year period from 2013 to 2015. Twin regional simulations, with and without tides, were used to highlight the general effect of tides. The findings reveal that tides have a cooling effect on the ocean from the surface (~ 0.3 °C) to above the thermocline (~ 1.2 °C), while warming it up below the thermocline (~ 1.2 °C). The heat budget analysis indicates that the vertical mixing is the dominant process driving temperature variations within the mixed layer, while it is associated with both horizontal and vertical advection to explain temperature variations below. The increased mixing in the simulations including tides is attributed to breaking of internal tides (IT) on their generation sites over the shelf break and offshore along their propagation pathways. Over the shelf, mixing is driven by the dissipation of the barotropic tides. In addition, the vertical terms of the heat budget equation exhibit wavelength patterns typical of mode-1 IT. The study highlights the key role of tides and particularly how IT-related vertical mixing shapes the ocean temperature off the Amazon. Furthermore, we found that tides impact the interactions between the upper ocean interface and the overlying atmosphere. They contribute significantly to increasing the net heat flux between the atmosphere and the ocean, with a notable seasonal variation from 33.2% in AMJ to 7.4% in ASO seasons. This emphasizes the critical role of tidal dynamics in understanding regional-scale climate.

Keywords: Amazon shelf break, modeling, internal tides, mixing, cooling, heat flux.

36 **I. Introduction**

37 In the ocean, many processes depend on temperature. These processes include water
38 mass formation (Swift and Aagaard, 1981; Lascaratos, 1993; Speer et al., 1995), the transport
39 and mixing of tracers, exchanges with other biosphere compartments (Archer et al., 2004,
40 Rosenthal et al., 1997), and, most importantly, surface heat exchange at the interface with the
41 atmosphere (Clayson and Bogdanoff, 2013; Mei et al., 2015), which significantly influence the
42 climate (Li et al., 2006; Collins et al., 2010). The oceanic thermal structure can be modified at
43 various spatial and temporal scales through external processes such as solar radiation, heat
44 exchanges with the atmosphere, winds, precipitation, and freshwater inputs from rivers, as well
45 as internal processes including mass transport by currents and eddies (e.g., Aguedjou et al.,
46 2021), mixing by turbulent diffusion (Kunze et al., 2012), and the dissipation of internal waves
47 (Barton et al., 2001; Smith et al., 2004; Salamena et al., 2021). Additionally, bottom friction of
48 barotropic tidal currents can lead to intensified mixing, particularly in shallow water conditions
49 over a shelf (see Lambeck and Runcorn, 1977; Le Provost and Lyard, 1997), and significantly
50 modify ocean temperature in surface layers (Li et al., 2020).

51 The barotropic tides, also called external tides, serve as the primary source for
52 generating internal waves. When barotropic tides interact with sharp topography such as ridge,
53 sea mounts, shelf break in a stratified ocean, they generate internal tides (IT) that propagate and
54 dissipate in the ocean interior causing diapycnal mixing (Baines, 1982; Munk and Wunsch,
55 1998; Egbert and Ray, 2000). Several observational and modelling studies have demonstrated
56 that this dissipation occurs at the generation sites, through reflection at the ocean bottom, or
57 near the surface when the energy rays interact with the pycnocline (among others: Laurent and
58 Garrett, 2002; Sharples et al., 2007, 2009; Koch-Larrouy et al., 2015; Nugroho et al., 2018;
59 Whalen et al., 2012). IT also dissipate or lose energy through wave-wave interactions or when
60 they interact with mesoscale or fine-scale structures (Vlasenko and Stashchuk, 2006; Dunphy
61 and Lamb, 2014).

62 The role of IT in shaping the ocean's thermal structure has garnered increasing interest
63 and has been the focus of numerous studies in recent years. In the shallow shelf surface waters
64 of Hawaii, Smith et al. (2016) reported that IT can induce surface cooling ranging from 1–5 °C.
65 Similarly, in the Indonesian region, studies by Koch-Larrouy et al. (2007, 2008), Nagai and
66 Hibiya (2015) and Nugroho et al. (2018) found that IT lead to an average surface cooling of 0.5
67 °C, which subsequently reduces local atmospheric convection and results in a 20% decrease in
68 precipitation. Therefore, IT play a significant role in the regional climate dynamics (Koch-

69 Larrouy et al., 2010; Sprintall et al., 2014, 2019). Furthermore, Jithin and Francis (2020)
70 demonstrated that in the Andaman Sea, IT can influence the temperature of deep waters (> 1600
71 m), resulting in a warming effect of about 1–2 °C. However, the impact of IT on temperature
72 off the Amazon plateau is still not well understood.

73 Our study focuses on the oceanic region of northern Brazil off the Amazon River. This
74 region experiences variations in wind patterns and hence the position of the Intertropical
75 Convergence Zone (ITCZ) throughout the year. These variations directly impact the discharge
76 of the Amazon River, oceanic circulation, eddy kinetic energy (EKE) and stratification (Muller-
77 Karger et al., 1988; Johns et al., 1990; Xie and Carton, 2004). Consequently, two contrasted
78 seasons emerge: April-May-June (AMJ) and August-September-October (ASO). The AMJ (vs.
79 ASO) season features an increasing (vs. decreasing) river discharge, there is a stronger (vs.
80 weaker) and shallower (vs. deeper) pycnocline, while the North Brazilian Current (NBC) and
81 EKE are weaker (vs. stronger) (Aguedjou et al., 2019, Tchilibou et al., 2022). During AMJ
82 season, NBC forms a weak equatorial retroflexion that contributes to the Equatorial Under-
83 Current. In the ASO season, when NBC strengthens, it forms a stronger retroflexion in the
84 northwest, which feeds the North Equatorial Counter Current and transports water masses
85 eastwards into the tropical Atlantic. This intensified retroflexion gives rise to large anticyclonic
86 eddies called NBC Rings, which can exceed 450 km in diameter (Didden and Schott, 1993;
87 Richardson et al., 1994; Garzoli et al., 2003). These eddies play a role in transporting water
88 masses towards the Northern Hemisphere (Bourles et al., 1999; Johns et al., 1998; Schott et al.,
89 2003).

90 In this region, IT are generated at the sharp shelf break, where the depth decreases from
91 200–2000 m over few tens of kilometers (Fig.1). Six main sites (A to F) have been identified,
92 with the most intense sites, A and B, located in the southern part of the region (Fig.1; Magalhaes
93 et al., 2016, Tchilibou et al., 2022). Previous studies have indicated that the propagation of IT
94 in this region is modulated by seasonal variation in currents (Magalhaes et al., 2016; Lentini et
95 al., 2016; Tchilibou et al., 2022). Moreover, changes in stratification throughout different
96 seasons affect the activity of internal tides. In AMJ (vs. ASO) season, there is a stronger (vs.
97 smaller) energy conversion and a stronger (vs. smaller) local dissipation of IT energy (Barbot
98 et al., 2021, Tchilibou et al., 2022). The interaction between the weaker (vs. stronger)
99 background circulation and IT results in fewer (vs. more) incoherent or non-stationary internal
100 tides (Tchilibou et al., 2022).

101 During the ASO season, cold water with temperature below 27.6 °C, associated with
102 the western extension of the Atlantic Cold-water Tongue (ACT), flows into the region from the
103 south and runs along the edge of the continental shelf up to 3°N, forming a cold cell known as
104 seasonal upwelling (Lentz and Limeburner, 1995; Neto and da Silva, 2014). Based on *in situ*
105 observations, the latter suggest that this cooling is backed by the vertical advection triggered by
106 the NBC. Alternatively, Ruault et al. (2020) conducted a modeling study, comparing
107 simulations with and without tides, and demonstrated that the inclusion of tides resulted in a
108 more realistic cooling effect on this upwelling. However, it remains unclear whether the cooling
109 is a result of mixing on the shelf caused by barotropic tides or mixing caused by baroclinic tides
110 at their generation sites and propagation pathways.

111 To answer the previous questions, we use a high-resolution model (1/36°) with and
112 without explicit tidal forcing and a satellite SST product. Our aim is to examine the impact of
113 tides on the temperature structure and quantify the associated processes for the two contrasted
114 seasons (AMJ and ASO) described above. Section II provides a description of the SST product,
115 our model, and the methods used. The validation of tidal characteristics, as well as the
116 temperature is presented in section III. Section IV focuses on the analysis of the impacts of tides
117 on the temperature structure and the associated processes, as well as the influence of tides on
118 heat exchange at the atmosphere-ocean interface. The discussion and summary of the obtained
119 results are presented in sections V and VI, respectively.

120 **II. Data and Methods**

121 **II.1. Satellite Data: TMI SST**

122 This dataset is derived from Tropical Rainfall Measurement Mission (TRMM), which
123 performs measurements using onboard TRMM Microwave Imager (TMI). The microwaves can
124 penetrate clouds and are therefore crucially important for data acquisition in low latitude
125 regions, cloudy covered during long periods of raining seasons. We use TMI data products v7.1,
126 which is the most recent version of TMI SST. It contains a daily mean of SST with a
127 0.25°×0.25° grid resolution (~25 km). This SST is obtained through inter-calibration of TMI
128 data with other microwave radiometers. The TMI SST full description and inter-calibration
129 algorithm are detailed in Wentz (2015).

130 **II.2. The NEMO Model: *AMAZON36* configuration**

131 The numerical model used in this study is the Nucleus for European Modelling of the
132 Ocean (NEMO v4.0.2, Madec et al., 2019). The specific configuration designed for this study

133 is called *AMAZON36* and covers the western tropical Atlantic region from the Amazon River
134 mouth to the open ocean. Other configurations in this region either have a coarse grid ($1/4^\circ$,
135 Hernandez et al., 2016) or, when the grid is fine ($1/36^\circ$), do not extend far enough eastwards
136 and exclude most of the site B (Ruault et al., 2020). The current *AMAZON36* configuration
137 overcomes these limitations. The grid resolution is $1/36^\circ$, and the domain spans between
138 54.7°W – 35.3°W and 5.5°S – 10°N (Fig.1). In this way, we capture the internal tides radiating
139 from all the generating sites on the Brazilian shelf break. The vertical grid consists of 75
140 vertically fixed z-coordinates levels, with a narrower grid refinement near the surface,
141 comprising 23 levels in the first 100 m, whereas cell thickness reaches 160 m near the bottom.
142 The horizontal and vertical resolutions of the grid are therefore fine enough to resolve low-
143 mode IT. This grid resolution has been previously used for similar purpose in this region (e.g.,
144 Tchilibou et al., 2022).

145 A third order upstream biased scheme (UP3) with built-in diffusion is used for
146 momentum advection, while tracer advection relies on a 2nd order Flux Corrected Transport
147 (FCT) scheme (Zalesak, 1979). A Laplacian isopycnal diffusion with a constant coefficient of
148 $20\text{ m}^2.\text{s}^{-1}$ is used for tracers. The temporal integration is achieved thanks to a leapfrog scheme
149 combined with an Asselin filter to damp numerical modes, with a baroclinic time step of 150 s.
150 The k - ε turbulent closure scheme is used for vertical diffusion. Bottom friction is quadratic
151 with a bottom drag coefficient of 2.5×10^{-3} , while lateral wall free-slip boundary conditions are
152 prescribed. A time splitting technique is used to resolve the free surface, with the barotropic
153 part of the dynamical equations integrated explicitly.

154 We use the 2020 release of the General Bathymetric Chart of the Oceans, which has
155 been interpolated onto the model's horizontal grid, with the minimal depth set to 12.8 m. The
156 model is forced at the surface by the ERA-5 atmospheric reanalysis (Hersbach et al., 2020).
157 River runoff are based on monthly means from hydrology simulation of the Interaction Sol-
158 Biosphère-Atmosphère model (ISBA, <https://www.umr-cnrm.fr/spip.php?article146&lang=en>)
159 and are prescribed as surface mass sources with null salinity. We use 90% of ISBA runoff based
160 on a comparison with the HYBAM runoff timeseries (<http://www.ore-hybam.org>). The model
161 is forced at its open boundaries by the fifteen major tidal constituents (M_2 , S_2 , N_2 , K_2 , $2N_2$,
162 MU_2 , NU_2 , L_2 , T_2 , K_1 , O_1 , Q_1 , P_1 , S_1 , and M_4) and barotropic currents, derived from FES2014
163 atlas (Lyard et al., 2021). In addition, we prescribe to the open boundaries the temperature,
164 salinity, sea level, current velocity and derived baroclinic velocity from the recent
165 MERCATOR-GLORYS12 v1 assimilation data (Lellouche et al., 2018).

166 The simulations were initialized on January 1, 2005 and ran for 11 years until December
 167 2015. It was found that the model achieved a seasonal cycle equilibrium after two years.
 168 However, for this study, our focus lies on a three-year period from January 2013 to December
 169 2015. To highlight the influence of tides on the temperature structure, we use a twin model
 170 configuration without tidal forcing.

171 **II.3. Methods**

172 **II.3.1. Tide energy budget**

173 We follow Kelly et al. (2010) to separate barotropic and baroclinic tide constituents.
 174 There is no separation following vertical modes, then we analyze the total energy for all the
 175 resolved propagation modes for a given tidal frequency. Note that the barotropic/baroclinic tide
 176 separation is performed directly by the model for better accuracy. We have only analyzed the
 177 M_2 harmonic which is the major tidal constituent in this region (Prestes et al., 2018; Fassoni-
 178 Andrade et al., 2023), representing $\sim 70\%$ of the tidal energy (Beardsley et al., 1995; Gabioux
 179 et al., 2005).

180 The energy budget equations of barotropic and baroclinic tides are obtained assuming
 181 that the energy tendency, the nonlinear advection and the forcing terms are small (Wang et al.,
 182 2016). The remaining equations are reduced to the balance between the energy dissipation, the
 183 divergence of the energy flux, and the energy conversion from barotropic to baroclinic (e.g.,
 184 Buijsman et al., 2017; Tchilibou et al., 2018, 2020; Jithin and Francis, 2020; Peng et al., 2021)
 185 :

$$186 \quad D_{bt} + \nabla_h \cdot F_{bt} + C \approx 0 \quad (1)$$

$$187 \quad D_{bc} + \nabla_h \cdot F_{bc} - C \approx 0 \quad (2)$$

188 bt and bc indicate the barotropic and baroclinic terms, respectively, D is the depth-integrated
 189 energy dissipation, which can be understood as a proxy of the real dissipation since D may
 190 encompass the energy loss of non-linear terms and/or numerical dissipation (see Nugroho et al.,
 191 2018), $\nabla_h \cdot F$ represents the divergence of the depth-integrated energy flux, while C is the
 192 depth-integrated barotropic-to-baroclinic energy conversion, i.e., the amount of incoming
 193 barotropic energy converted into internal tides energy over the steep topography, with:

$$194 \quad C = \langle \nabla H \cdot U_{bt} P_{bc}^* \rangle \quad (3)$$

$$195 \quad F_{bt} = \langle U_{bt} P_{bt} \rangle \quad (4)$$

196
$$F_{bc} = \int_H^\eta \langle U_{bc} P_{bc} \rangle dz \quad (5)$$

197 where the angle bracket $\langle \cdot \rangle$ denotes the average over a tidal period, ∇H is the slope of the
 198 bathymetry, U is the current velocity, P_{bc}^* is the baroclinic pressure perturbation at the bottom,
 199 H is the bottom depth, η the surface elevation, P is the pressure, then F is the energy flux and
 200 indicates the path of tides.

201 II.3.2. 3-D heat budget equation for temperature

202 The three-dimensional temperature budget was computed online and further analyzed.
 203 It is the balance between the total temperature trend and the sum of the temperature advection,
 204 diffusion and solar radiative and non-solar radiative fluxes (e.g., Jouanno et al., 2011;
 205 Hernandez et al., 2017). The three-dimensional heat budget equation for temperature is
 206 expressed as follows:

207
$$\partial_t T = \underbrace{-u\partial_x T - v\partial_y T - w\partial_z T}_{ADV} + LDF - \underbrace{\partial_z(K_z\partial_z T)}_{ZDF} + Forcing + Asselin \quad (6)$$

208 here T is the model potential temperature, (u, v, w) are the velocity components in the (x, y, z)
 209 [respectively eastward, northward and upward] directions, ADV is the 3-D tendency term from
 210 the advection routine of the NEMO code (left to right: zonal, meridional and vertical terms).
 211 Note that in our model, ADV includes some diffusivity of the temperature due to numerical
 212 dissipation of the FCT advection scheme (Zalesak, 1979) in contrast to some non-diffusive
 213 advection scheme like in Leclair and Madec (2009). In previous studies, for lower resolution
 214 ($1/4^\circ$), this mixing has been quantified to be responsible for 30% of the dissipation as part of
 215 the high-frequency effect of the diffusion (Koch-Larrouy et al., 2008). We expect here at $1/36^\circ$
 216 resolution that this effect will be smaller but still non negligible. Note that explicit separation
 217 of this effect is beyond the scope of our study. Furthermore, tides are primarily linear in surface
 218 water, however, non-linear effects intensify due to bottom friction for barotropic tides or as a
 219 result of IT breaking. Consequently, we anticipate a corresponding increase in ADV . ZDF
 220 denotes the vertical diffusion, LDF is the lateral diffusion, $Forcing$ is the sum of tendency of
 221 temperature due to penetrative solar radiation, which includes a vertical decaying structure, and
 222 the non-solar heat flux (sum of the latent, sensible, and net infrared fluxes) at the surface layer,
 223 and $Asselin$ corresponds to the numerical diffusion for the temperature.

224 **III. Model validation**

225 In this section, we assess the quality of our simulations by verifying whether they are in
226 good agreement with the observations and other reference data. Firstly, for the barotropic and
227 baroclinic characteristics of the M_2 tides for the year 2015, and finally for the temperature from
228 2013 to 2015.

229 **III.1. M_2 Tides in the model**

230 We initially examined the barotropic SSH and there is a good agreement in both
231 amplitude and phase between FES2014 and the model, Fig.2a and Fig.2b, respectively.
232 However, near the coast, few differences in amplitude are observed. The model's SSH
233 amplitude is lower (~ 50 cm) north of the mouth of the Amazon, while it overestimates the
234 amplitude by ~ 20 cm and ~ 40 cm, respectively, shoreward and on the southern part of the
235 mouth. These biases are of a similar magnitude as those reported in Ruault et al. (2020). The
236 flux of the barotropic tidal energy flowing inshore is depicted in Fig.2c and Fig.2d for FES2014
237 and the model, respectively. A portion of this energy is converted into baroclinic tidal energy
238 over the steep slope of the bathymetry. We compared the depth-integrated barotropic-to-
239 baroclinic energy conversion rate (\mathcal{C}) between FES2014 and the model, Fig.2c and Fig.2d,
240 respectively. The model successfully reproduces the same conversion patterns of FES2014 over
241 the slope, but less offshore between 42°W – 35°W and 7°N – 10°N . As a result, our model overall
242 underestimates \mathcal{C} by approximately 30%. Niwa and Hibiya (2011) demonstrated that \mathcal{C}
243 increases with higher bathymetry resolution, indicating that there is more conversion with the
244 FES2014 grid (~ 1.5 km) compared to our grid (~ 3 km).

245 Another portion of the barotropic energy is dissipated on the shelf through bottom
246 friction, leading to mixing from the bottom (Beardsley et al., 1995; Gabioux et al., 2005;
247 Bessières, 2007; Fontes et al. 2008). Most of the dissipation of barotropic energy (D_{bt}) occurs
248 in the middle and inner shelf between 3°S – 4°N with a mean value of about 0.25 W.m^{-2} (Fig.2e).
249 The location of this dissipation aligns well with previous studies of Beardsley et al. (1995) and
250 Bessières (2007). The remaining barotropic energy propagates over hundreds of kilometers into
251 the estuarine systems of this region (Kosuth et al., 2009; Fassoni-Andrade et al., 2023).

252 The energy flux of IT (F_{bc}) indicates that they propagate from the slope towards the
253 open ocean (Fig.2f). F_{bc} indicates the existence of six main sites of IT generation on the slope,
254 with sites A and B being particularly significant in terms of their higher and far extended energy

255 flux, in good agreement with previous studies (Magalhaes et al., 2016; Barbot et al., 2021 and
256 Tchilibou et al., 2022). From these two main sites, IT spread over nearly 1000 km, and dissipate
257 their energy. The model's depth-integrated internal tides energy dissipation (D_{bc}) is at least two
258 times weaker than barotropic energy dissipation, with a mean value of 0.1 W.m^{-2} (Fig.2f).
259 Approximately 30% of IT energy is dissipated locally over generation sites (not shown),
260 consistent with the findings of Tchilibou et al. (2022). The remaining portion is dissipated
261 offshore along the propagation path. This offshore dissipation is more extended along path A,
262 ~300 km from the slope, with two beams spaced by an average distance of 120–150 km
263 corresponding to mode-1 wavelength. On the other hand, there is less offshore dissipation along
264 path B, occurring around 100–200 km from the slope (Fig.2f).

265 Another important characteristic of IT is their SSH imprints along the propagation
266 pathway. The estimate of this signature deduced from the altimeter tracks (Fig.2g) produced by
267 Zaron (2019) is compared with our model (Fig.2h), with the shelf masked over 150 m depth.
268 Our model shows good agreement with this product, albeit with a slight overestimation of about
269 ~1.5 cm on the SSH maxima. It is worth noting that the model's baroclinic SSH is an average
270 over the year 2015, while the satellite estimate is an average over a longer period of about 20
271 years. The longer period of the satellite estimate may introduce greater variability in the
272 altimeter tracks, potentially reducing the amplitude of the estimates and explaining the slight
273 differences with the model in the positioning and amplitude of the maxima.

274 **III.2. Temperature validation**

275 Figure 3 shows the mean SST over the entire 2013–2015 period for TMI (Fig.3a), the
276 tidal simulations (Fig.3b) and the non-tidal simulations (Fig.3c). We obtain the bias between
277 TMI SST and the two simulations by linear interpolation of the simulations data on the
278 observation grid. The simulations with tides accurately reproduce the spatial distribution of the
279 observations, as indicated by the weak bias ($< \pm 0.1^\circ\text{C}$) with TMI SST. This is particularly
280 evident for the cooling on the shelf around 47.5°W and to the southeast between 40°W – 35°W
281 and 2°S – 2°N (Fig.3d). In contrast, the non-tidal simulations exhibit a warm bias of about 0.3°C
282 in this cooling region (Fig.3e). To the northeast, between 50°W – 54°W and 3°N – 8°N in the
283 Amazon plume, the SST of the non-tidal simulations is in better agreement with the
284 observations, while the SST of the tidal simulations is about 0.6°C cooler than TMI SST
285 (Fig.3d). This bias is consistent with other models that include tides in this northern zone (e.g.,
286 Hernandez et al., 2016, 2017; Gévaudan et al. (2022). Far offshore, between 50°W – 40°W and

287 6°N–10°N, both simulations exhibit a negative bias of about 0.2–0.3 °C (Fig.3d–e). We
288 averaged the observations and interpolated simulation data within the dashed box (Fig.3a–c),
289 with a depth of less than 200 m masked. This location of the boxes comprises IT generation
290 sites and part of their pathways. We then computed the seasonal cycle of the three products
291 (Fig.3f). The tidal and non-tidal simulations accurately reproduce both the seasonal cycle and
292 the standard deviation of the observations, with low root mean square errors of approximately
293 $2 \times 10^{-2} \text{°C}$ and $4 \times 10^{-2} \text{°C}$, respectively, when compared to the TMI SST. This indicates the
294 robustness of the model's simulations. Over the seasonal cycle, the tidal simulations are closer
295 to the observations from January to March, July to September, and November to December.
296 During the rest of the year, either both simulations are equally close to the observations, or the
297 non-tidal simulations are closer.

298 To gain insight into our model performance along the depth, we used the mean
299 WOA2018 climatology (2005–2017) and simulation data (salinity and temperature) for the
300 three years 2013–2015, averaged in the same region as in Fig.3f. Figure 3g shows the
301 Temperature-Salinity (T-S) diagram for WOA2018 and the two simulations. The data are
302 averaged in the box as before, and we use $\sigma_{\theta} [\rho-1000]$ to represent the density contours, with
303 ρ the water density. Both simulations exhibit similar patterns as WOA2018 for deeper waters,
304 i.e., $T < 17 \text{°C}$ and $\sigma_{\theta} > 25.6 \text{ kg.m}^{-3}$. However, there exist minor discrepancies for the surface
305 layer waters, i.e., $T > 17 \text{°C}$ and $22.4 > \sigma_{\theta} < 25.6 \text{ kg.m}^{-3}$. At that level, the tidal simulations
306 better reproduce the T-S profile of the observations. These slight differences between
307 WOA2018 observations and the two simulations, especially with the tidal simulations, further
308 demonstrate the ability of our model to reproduce the observed water mass properties.

309 **IV. Results**

310 In this section, we present the influence of tides on temperature, the associated
311 processes, and the impact on the atmosphere-ocean net heat exchange. The analyses were
312 performed on a seasonal scale between April-May-June (AMJ) and August-September-October
313 (ASO) for the three years 2013–2015.

314 **IV.1. Tide-enhanced surface cooling**

315 During the first season, warm waters, which are defined as $> 27.6 \text{°C}$, dominate near the
316 coast, especially in the middle shelf and in the south-east, and cold waters are present offshore
317 north of 6°N (Fig.4a–c). Off the mouth of the Amazon River, water colder than 28.2 °C spreads
318 between 43°W–51°W for TMI SST (Fig.4a) and tidal simulations (Fig.4b), while warmer

319 waters are present in the same area for the simulations without tides (Fig.4c). Figures 4d–f show
320 the SST, averaged over the ASO season. TMI SST (Fig.4d) shows an upwelling cell represented
321 by the extension of the 27.2 °C isotherm (white dashed contour) along the slope to about 49°W–
322 3°N towards the north-east of the region, which forms the extension of the ACT. This extension
323 also exists in the tidal simulations (Fig.4e), whereas ≤ 27.2 °C waters are not crossing 45.5°W
324 and remain in the southern hemisphere in the simulations without tides (Fig.4f). This means
325 that waters colder than 27.2°C can only extend further into the northeast because of tides. In
326 addition, we can note that the mean SST shows a very contrasting distribution between the two
327 seasons. There are warm waters along the shelf and cold waters offshore during the AMJ season
328 (Fig.4a-c). This is followed by warming along the Amazon plume and offshore, and an
329 upwelling cell in the south-east (Fig.4d-f).

330 The general impact of the tides, illustrated by the SST anomaly between the tidal and
331 the non-tidal simulations, is a cooling over a large part of the study area with maxima up to 0.3
332 °C (Fig. 5a–b). For ASO, tides induce a warming (> 0.3 °C) on the shelf at the mouth of the
333 Amazon River (Fig.5b), while for AMJ it is a cooling of the same intensity (Fig.5a). That
334 difference will be further discussed. Out of the shelf, the structure of temperature anomaly
335 varies depending on the season, probably because of seasonal mesoscale variability.

336 **IV.2. Impact of the tides on the atmosphere-ocean net heat flux**

337 The atmosphere-ocean net heat flux (Q_t) reflects the balance of incoming and outgoing
338 heat fluxes across the atmosphere-ocean interface (see details on Moisan and Niiler, 1998;
339 Jayakrishnan and Babu, 2013). During AMJ, tides mainly induce positive Q_t anomalies over
340 the whole domain. The average values are around 25 $W.m^{-2}$ in the plume and the Amazon
341 retroflection to the northeast and along A and B (Fig.5c). Negative SST anomalies ($\sim 0.3^\circ C$)
342 occur throughout the domain in the same location. During the ASO season, at the mouth of the
343 Amazon, there are negative Q_t anomalies but of the same magnitude as during the previous
344 season (Fig.5d). At this location, positive temperature anomalies ($\sim 0.3^\circ C$) are observed
345 (Fig.5b). Elsewhere, there are positive Q_t anomalies and negative SST anomalies. It therefore
346 appears that negative SST anomalies induce positive Q_t anomalies and vice versa. Hence, the
347 spatial structures of Q_t anomalies and SST anomalies fit together for the two seasons. There is
348 a strong negative correlation of 0.97 with a significance of $R^2 = 0.95$ for the AMJ season, and
349 almost the same in ASO season with 0.98 and 0.96, respectively for the correlation and its
350 significance (Fig.5e). This is consistent with the fact that the atmosphere and the underlying
351 ocean are balanced. Then, the SST cooling induced by upwelled cold water will try upset this

352 balance. As a result of this, an equivalent variation in the net heat flux from the atmosphere to
353 the ocean will attempt to restore it.

354 Figure 5f the integral over the entire domain of the net heat flux for each season and for
355 each simulation. During the AMJ season, Q_t increases from 23.85 TW (1 TW = 10^{12} W) for the
356 non-tidal simulations to 35.7 TW for the tidal simulations, i.e., an increase of 33.2 %. That is,
357 the tides are responsible for a third of Q_t variation. This is very large compared to what is
358 observed elsewhere in other IT hotspots (e.g., 15% in Solomon Sea, Tchilibou et al., 2020).
359 During the second season, there is a smaller increase in Q_t of about 7.4% between the two
360 simulations, i.e., from 73.03 TW to 78.83 TW for the non-tidal and tidal simulations
361 respectively (Fig.5f).

362 It is also worth noting the significant difference in integrated Q_t between the two
363 seasons. The values are less than 36 TW during the AMJ season, whereas they are around twice
364 as high, > 73 TW, during the ASO season. Given that colder SST induce a stronger Q_t , these
365 higher values are likely related to the arrival of cold waters from ACT, which forms upwelling
366 cells (Fig.4d–f) with a secondary tidal effect.

367 **IV.3. Vertical structure of Temperature along internal tides pathway**

368 To further analyze the temperature changes between the two simulations, we made
369 vertical sections following the path of IT radiating from sites A and B (respectively black and
370 red line in Fig.2f). Hereunder, only the transects following the pathway A are presented, since
371 the vertical structure is similar following pathway B especially for AMJ season and because
372 some processes tend to be null along pathway B during the ASO season. The mixed layer refers
373 to a quasi-homogenous surface layer of temperature-dependent density that interacts with the
374 atmosphere (Kara et al., 2003). Its maximum depth, also known as mixed-layer depth (MLD),
375 is defined as the depth where the density increases from the surface value, due to temperature
376 change of $|\Delta T| = 0.2$ °C with constant salinity (e.g., Dong et al., 2008; Varona et al., 2019).

377 Figure 6 shows the vertical sections of temperature for the two seasons following A. In
378 AMJ season, over the slope and near the coast, cold waters (< 27.6 °C) remain below the surface
379 at ~ 20 m for the tidal simulations (Fig.6a) and deeper at ~ 60 m for the non-tidal simulations
380 (not shown). The cold waters rise to the surface more than 400 km offshore for both simulations.
381 In surface layers (< 40 m), the temperature anomaly is more than -0.8 °C at the shelf beak and
382 less than -0.2 °C elsewhere (Fig.6b). Further down (< 60 m) the water column, this anomaly
383 becomes much larger along the transect. Above that thermocline (< 120 m), the simulations
384 with tides are colder by 1.2 °C from the slope, where IT are generated and following their

385 propagation pathway. Conversely, below the thermocline, the tidal simulations are warmer by
386 the same intensity along the propagation path and down to ~ 300 m depth (Fig.6b). In AMJ
387 season, the thermocline depth is about 100 ± 15 m and MLD is about 40 ± 20 m (Fig.6a). They
388 both have a very weak slope between the coast and the open ocean. Over the whole domain, the
389 thermocline is deeper by about 15 m on average in the non-tidal simulations, following the
390 propagation paths of internal tides, on the Amazon shelf and plume (Fig.6c). Similarly, the
391 MLD in the non-tidal simulations is deeper by approximately 10 m over the shelf, ~ 4 m along
392 IT propagation paths and close to zero in the Amazon plume (Fig.6d).

393 In ASO season, cold waters previously confined below the surface during the previous
394 season (AMJ) rise to the surface. These cold waters extend over the slope and up to about 150
395 km offshore in the non-tidal simulations (not shown) and up to 250 km offshore in the tidal
396 simulations (Fig.7a). The 27.2 °C isotherm only reaches the surface above the slope in the tidal
397 simulations and remains below the surface (~ 30 m) in the non-tidal simulations (not shown).
398 This aligns with the absence of that isotherm at this location in the corresponding SST map
399 (Fig.4f). For the tidal simulations, the temperature anomaly in the ASO season is smaller (\sim
400 0.4 °C, Fig.7b) in the surface layers (< 40 m) near the coast compared to the AMJ season
401 (Fig.6b). In contrast, during the ASO season, this cooling can drive more SST anomalies along
402 A (-0.3 °C, Fig.5b). A stronger cooling of about 1.2 °C occurs deeper between 60 and 140 m
403 depth, and a warming of about 1.2 °C below, which extends less offshore than during AMJ
404 season, 650 km vs. ~ 1000 km. In ASO season, the coastward slope of the thermocline and MLD
405 becomes steeper compared to AMJ season. In both simulations, there is a dip of ~ 80 m, i.e.,
406 ~ 60 m offshore and ~ 140 m inshore, for the thermocline (Fig.7a), and a dip of ~ 40 m, i.e., ~ 30
407 m offshore and ~ 70 m inshore, for MLD (Fig.7a). Over the entire domain, tides reduce the
408 thermocline depth by ~ 6 m on the shelf and ~ 12 m at the plume and far offshore along the
409 propagation path of A (Fig.7c), and they MLD by about 10 m along the shelf and ~ 4 m along
410 the propagation path of A (Fig.7d).

411 Between the two seasons, there is also a change in the vertical density gradient between
412 the coast and the open sea. In tidal simulations, during AMJ season, the isopycnals layers are
413 thin near the coast and thicken towards the open sea (Fig.6a). This means that a strong
414 stratification is present near the coast and decreases towards the open sea. In contrast, during
415 ASO season, the isopycnals layers are thicker near the coast and tight offshore (Fig.7a). As the
416 result of this, the stratification is weaker inshore than offshore. This clearly highlights a
417 seasonality in the vertical density gradient profile in agreement with Tchilibou et al. (2022).

418 Note that this behavior also appears in the simulations without tides (not shown). The transects
419 of the temperature anomaly show that tides influence the temperature in the ocean from the
420 surface to the deep layers, with a greater effect on the first three hundred meters. One question
421 we address in this paper is to better understand what processes are at work that explain these
422 temperature changes.

423 **IV.4. What are the processes involved?**

424 To explain the observed surface and water column temperature changes, we computed
425 and analyzed the terms of the heat balance equation (see Section II.3.2, Equation 6) for both
426 seasons (AMJ and ASO).

427 **IV.4.1. Vertical diffusion of Temperature**

428 Figure 8 shows the vertical temperature diffusion tendency (ZDF). ZDF is averaged
429 between 2–20 m, i.e., within the mixed layer. For the AMJ season, ZDF in the tidal simulations
430 (Fig.8a) shows a negative trend (i.e., cooling) in the whole domain. The maximum values ($>$
431 $|0.4|^\circ\text{C}\cdot\text{day}^{-1}$) are located along the slope where IT are generated and on their propagation
432 path. There is a larger horizontal extent along A of ~ 700 km from the coasts compared to B,
433 where it is ~ 300 km from the coasts. Elsewhere, ZDF is weak ($> -0.1^\circ\text{C}\cdot\text{day}^{-1}$). For the non-
434 tidal simulations (Fig.8b), ZDF is weak over the entire domain ($> -0.1^\circ\text{C}\cdot\text{day}^{-1}$). In ASO
435 season, the tidal simulations (Fig.8c) show a decrease of the ZDF near the coast (< 100 km) and
436 a strengthening offshore along A compared to the previous season, but with the same cooling
437 trend ($< -0.4^\circ\text{C}\cdot\text{day}^{-1}$). Along B, it tends to be null, both at the coast and offshore (Fig.8c). In
438 addition, the mesoscale circulation and eddy activity intensify during this season. To the
439 northeast, between 4°N – 8°N , and 47°W – 53°W , there is a cooling on the shelf of $\sim 0.3^\circ\text{C}\cdot\text{day}^{-1}$
440 with eddy-like patterns in the tidal simulations (Fig.8c). The processes by which these features
441 might arise are discussed in more details in Section V. Unsurprisingly, ZDF is weak everywhere
442 for the non-tidal simulations (Fig.8d). IT are the dominant driver of vertical diffusion of
443 temperature along the shelf break and offshore, while the mixing induced by barotropic tides
444 prevail on the shelf.

445 On the vertical following A, there are opposite sign ZDF values, with mean magnitude
446 of $\sim |0.4|^\circ\text{C}\cdot\text{day}^{-1}$. These values are centered around the thermocline for the simulations with
447 tides in the two seasons AMJ and ASO (respectively Fig.8e and 8f). There is a cooling trend
448 above the thermocline and a warming trend below. The average vertical extent is up to ~ 350 m
449 depth for the maximum values but exceeds 500 m depth for the low values ($< 0.1^\circ\text{C}\cdot\text{day}^{-1}$).

450 As for the horizontal averages (Fig.8a and 8c), from one season to another there is a weakening
451 of ZDF above the slope and a strengthening offshore, Fig.8e and 8f, for AMJ and ASO,
452 respectively. Furthermore, offshore ZDF maxima are discontinuous and spaced of about 140–
453 160 km during the AMJ season (Fig.8e) but are more continuous for the ASO season (Fig.8f).
454 For the non-tidal simulations, the mean ZDF tends to be null in the ocean interior but remains
455 quite large ($> -0.2 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$) in the thin surface layer during the two seasons (Fig.8g–h).

456 Furthermore, it is worth to noting that along IT propagation's pathway, the maximum
457 of the ZDF follows the maxima of the baroclinic tidal energy dissipation (Fig.2f). This proves
458 that the dissipation of IT causes vertical mixing that enhances SST cooling. In addition, this
459 temperature diffusion contributes to greater subsurface cooling within the mixed layer and
460 warming in the deeper layers beneath the thermocline.

461 The seasonality of the stratification, highlighted above, could explain why the ZDF is
462 stronger along the slope and the near-coastal pathway B during the AMJ season (Fig.8a and
463 8e), and why in ASO season ZDF is weaker along the slope, close to zero following B, and
464 reinforce offshore of A (Fig.8c and 8f). Previous studies have shown that stratification
465 influences the generation of internal tides and controls their modal distribution. Here we show
466 that stratification also plays a role on the fate of these internal tides, in this case on their
467 dissipation. The stratification could determine where IT dissipate their energy in the water
468 column, as mentioned by de Lavergne et al. (2020).

469 **IV.4.2. Advection of temperature**

470 The vertical (z -ADV) and the horizontal (h -ADV) terms of the temperature advection
471 tendency are averaged in the same depth-range as above for the two seasons.

472 **IV.4.2.a Vertical advection of Temperature**

473 Tides fail to generate vertical temperature advection within surface layers. As expected,
474 z -ADV is almost null throughout the region in that depth-range (Fig.9a–d). Nevertheless, for
475 both seasons, there are extreme values located in the northwest on the plateau between 54°W –
476 50°W and 3°N – 6°N with the same intensity in the two simulations ($< 0.3 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$). But deeper,
477 vertical sections (Fig.9a–h) show an intensification of z -ADV of about $\pm 0.8 \text{ }^\circ\text{C}\cdot\text{day}^{-1}$ located
478 below the MLD and seems to be centered around the thermocline, with a vertical extension
479 from 20–200 m depth. z -ADV is stronger in tidal simulations during both seasons (Fig.9e–f)
480 and presents sparse extrema offshore ($> 300 \text{ km}$) for the non-tidal simulations (Fig.9g–h). For
481 the simulations with tides, z -ADV appears to be dominated by a cooling trend, with a marked

482 hotspot on the slope followed by other hotspots offshore. These extreme values are spaced about
483 120–150 km apart, i.e., a mode-1 wavelength as for the baroclinic tidal energy dissipation
484 (Fig.2f). Note that for both simulations (Fig.9e–h), the extreme values are located within the
485 narrow density (σ_θ) contours [23.8–26.2 kg.m⁻³], i.e., within the pycnocline. The location of
486 the extreme values of z -ADV at the shelf break and along IT propagation pathways and its
487 negative sign suggest that the diffusive part of the advection scheme may account significantly
488 in z -ADV.

489 **IV.4.2.b Horizontal advection of temperature**

490 Horizontal advection of temperature (h -ADV) is defined as the sum of the zonal (x -
491 ADV) and meridional (y -ADV) terms of temperature advection tendency. As for z -ADV, the
492 mean of h -ADV tends to be null over the entire domain in the surface layers for both seasons
493 in both simulations (Fig.10a–d). Nevertheless, weak extremums exist in the northwest of the
494 plateau between 54°W–50°W and 3°N–7°N. These intensify during the ASO season in both
495 simulations, $\sim \pm 0.2$ °C.day⁻¹, Figure 10c and 10d for the tidal and non-tidal simulations,
496 respectively. In AMJ season, h -ADV is slightly stronger, ~ 0.1 °C.day⁻¹, around sites A and B
497 in the tidal simulations (Fig.10a), which appears to be related to IT generated along the slope.
498 However, there is a slight distinction between the two simulations in the surface layers,
499 suggesting that tides have a minimal effect on h -ADV, as expected. Consequently, h -ADV has
500 a negligible influence on the cold-water tongue observed in the surface SST during the ASO
501 season (Fig.4d–f).

502 Along the vertical following A, h -ADV maxima are confined below the mixed-layer
503 depth. The tidal simulations (Fig.10e–f) exhibit significantly more intense values compared to
504 the non-tidal simulations (Fig.10g–h). h -ADV contributes to both warming and cooling of the
505 temperature, with a magnitude of about ± 0.4 °C.day⁻¹, extending from the slope to over 500
506 km offshore. In both seasons, the average vertical extension lies between the surface and 400
507 m depth for the tidal simulations, and between 20–300 m depth for the non-tidal simulations.
508 Similarly to z -ADV, h -ADV is stronger within the pycnocline. In the tidal simulations, a
509 warming effect is observed above the slope (0.4 °C.day⁻¹), reaching the surface in both seasons.
510 This vertical excursion is also observed for ZDF and z -ADV, and it is a marker of local
511 dissipation of IT at their generation sites. It is noteworthy that the location of h -ADV maxima
512 does not coincide with the dissipation hotspots of IT, in contrast of ZDF and z -ADV.

513 **IV.4.3. Heat budget balance**

514 From the sections above, it is evident that IT-induced mixing within the mixed layer
515 emerges as the primary driver among the ocean's internal processes in explaining changes in
516 SST. However, below MLD, advective processes play a more significant role in structuring
517 temperature. Figure 10 presents the average of the terms of the Equation 6 below MLD within
518 the depth range of 60–400 m. The analysis focuses on a specific region with latitude and
519 longitude ranging between 0°N–6°N and 40°W–48°W, respectively. This region includes the
520 two main IT paths, as well as a portion of the along-coast upwelling region. During the AMJ
521 season, ADV is the dominant process over diffusion terms in both tidal (Fig.11a) and non-tidal
522 (Fig.11b) simulations. However, in the ASO season, ADV only dominate in tidal simulations
523 (Fig.11c), while ZDF dominates in non-tidal simulations (Fig.11d).

524 It therefore appears that ADV only have a considerable influence on temperature below
525 MLD, contrasting with the study of Neto and da Silva (2014), which identify ADV as the
526 primary driver causing along-coast SST cooling. However, we can assume that advection and
527 mixing are interconnected. In other words, the water masses that are advected below MLD may
528 undergo mixing within the surface layers due to the overall mixing occurring throughout the
529 water column. Additionally, it is worth mentioning that in our simulations, *Asselin* has a
530 negligible impact on temperature. Conversely, *Forcing* term does impact the temperature
531 within the surface layers. However, we have not discussed this aspect in our analysis as our
532 primary focus was on understanding the internal processes of the ocean.

533 **V. Discussion**

534 **V.1. The mode-1 wavelength in the vertical terms of the heat budget equation**

535 Along the vertical and towards the open ocean, both ZDF and z-ADV exhibit a wave-like
536 structure, with patches that are spaced apart by about 120–160 km typical of mode-1
537 wavelength. However, during the ASO season, this pattern is not observed for ZDF. Instead,
538 ZDF values appear more continuous along the transect, likely due to additional mixing caused
539 by the breaking of incoherent IT that intensify during that season. Furthermore, de Macedo et
540 al. (2023) recently provided a detailed description of internal solitary waves (ISW) in the same
541 region based on remote sensing data. These ISWs originate from instabilities and energy loss
542 or dissipation of IT radiating from the slope, primarily along pathways A and B (Magalhaes et
543 al., 2016). The first study demonstrated that the inter-packet distance of ISWs corresponds to
544 the mode-1 wavelength. Interestingly, the positions of IT dissipation hotspots, as well as z–

545 ADV patches in both seasons and ZDF patches, especially during the AMJ season, in our model
546 align with the observed occurrences of ISWs (refer to Figure 2 in their study). This provides
547 evidence that our model accurately reproduces the location of IT dissipation.

548 **V.2. Temperature changes over the shelf: two main competitive processes**

549 In the simulation without tides, there is a strong along-coast current exiting northwesterly
550 the mouth of the Amazon River (e.g., Ruault et al., 2020) with an average intensity lower
551 than $0.5 \text{ m}\cdot\text{s}^{-1}$ in the first 50 meters for both seasons (Fig.12a–b). When including tides in the
552 model, the latter study showed that there is an increase in the vertical mixing in the water
553 column due to stratified-shear flow instability, which weakens and deflects the along-coast
554 current north-eastwards at the mouth of the Amazon River (Fig.12c–d) and favors cross-shore
555 export of water. We can therefore establish that there are at least two processes at work: (i)
556 vertical mixing and (ii) horizontal transport, backed respectively by ZDF and h–ADV. We then
557 looked at the latter two processes along the vertical following the cross-shore transect (C–S)
558 defined in Figure 10c. Hereinafter, “inner mouth” refers to the part of the transect within 200
559 km from the shore, whereas “outer shelf” refers to the part beyond.

560 During the AMJ season, in the inner mouth of the region, the flow of the river becomes
561 dominant. The tide-induced vertical mixing in the narrow water column results in the warming
562 and deepening of the thermocline (Fig.13a–b). Conversely, on the outer shelf, this mixing
563 occurs in a thicker water column, leading to cooling above the thermocline and warming below
564 (Fig.13a). This pattern extends across the shelf and along the pathways of internal tides, as
565 shown in Section IV.4.1 (refer to Fig.8a and 8e). In this season, the weaker circulation may
566 result in low values of h–ADV (Fig.13b). Therefore, during the first season, the dominant
567 process that explains the average negative SST anomaly over the shelf appears to be vertical
568 mixing.

569 During the second season, there is a significant increase in solar radiation on the shelf, with
570 an average value of $60 \text{ W}\cdot\text{m}^{-2}$, compared to the previous season (Fig.13c). Additionally, the
571 average depth of the thermocline deepened further offshore (Fig.13d and 13e). In this season,
572 mixing processes lead to warming in the thin surface layer, specifically in depths less than 2m
573 (Fig.13d). NBC is stronger, resulting in an increase of the transport over the shelf (Prestes et
574 al., 2018). It is also important to consider the small mean tidal residual transport (Bessières et
575 al., 2008), which reinforces the stronger current transport. These factors contribute to a more
576 dynamic region and an increase in h–ADV (Fig.13e). Consequently, h–ADV plays a significant

577 role in determining SST on the shelf. For this season, the combination of these two processes
578 explains the observed positive SST anomaly.

579 Additionally, from the AMJ to ASO seasons, there is a notable deepening of the thermocline
580 depth on the outer shelf. This observation has previously been highlighted by Silva et al. (2005)
581 from REVIZEE (Recursos Vivos da Zona Econômica Exclusiva) campaign data, further
582 validating of our simulations.

583 **V.3. Mixing in the NBC retroflection area**

584 To the north-west of the domain [3°N – 9°N and 53°W – 45°W], in the surface layers (2–
585 20m), eddy-like or circular patterns exist in ZDF during the ASO season for the simulation
586 including tides (Fig.8c). NBC intensifies and retroflects, and strong eddy activity takes place
587 there during ASO. We can assume that this intense mesoscale activity influences the mixing
588 and subsequent temperature diffusion. However, it is not yet clear how these mesoscale features
589 produce mixing. Fronts exist in such region and are associated with high horizontal temperature
590 gradient (∇T) and significant vertical mixing (see Chapman et al., 2020). We therefore
591 examined the mean ∇T in the same depth range as ZDF (2–20 m). During the AMJ season, ∇T
592 is on average equal to $4 \times 10^{-2} \text{ }^{\circ}\text{C}/10 \text{ km}$. As expected, it does not reveal any circular fronts for
593 the two simulations since mesoscale activity is low (Fig.14a–b). ∇T increases in ASO season
594 [$> 5 \times 10^{-2} \text{ }^{\circ}\text{C}/10 \text{ km}$] in the north-west and exhibits circular and filamentary fronts in both
595 simulations (Fig.14c–d). Therefore, one would expect to see the same circular patterns in ZDF
596 for both simulations, this is not actually the case (see Fig.8c–d). Another hypothesis is that these
597 circular patterns could be originated from the interaction between IT and near-inertial
598 oscillations, which can enhance mixing and vertical transport processes in the ocean. But
599 quantifying this interaction requires further analysis and is beyond the scope of this study.

600 **VI. Summary**

601 This paper investigates the influence of internal tidal (IT) on temperature and associated
602 processes through twin simulations including or excluding tidal forcing, using the NEMO
603 model configuration called AMAZON36. Our tidal simulations accurately reproduce the
604 generation and dissipation of IT. When comparing the simulations including tides to
605 observations, there is a better agreement in sea surface temperature (SST) and water mass
606 properties along the vertical. We then focus our analysis on a three-year period (2013–2015)
607 and two seasons, AMJ and ASO, which have contrasting stratification, circulation and IT
608 activity.

609 Results demonstrate that tides cause a cooling effect in SST of 0.3°C in the Amazon
610 offshore plume and along the paths of IT in both seasons. In the ASO season particularly, tides
611 enhance seasonal upwelling, leading to cooler SST. Over the Amazon shelf, tides induce
612 cooling in AMJ and warming in ASO. These cooling/warming patterns over the region affect
613 the net heat flux between the atmosphere and the ocean (Q_t). As the result, there is an overall
614 increase of Q_t from 33.2% in AMJ to 7.4% in ASO. Changes in Q_t in such large atmospheric
615 convection regions can reduce cloud convection into the atmosphere (Koch-Larrouy et al.,
616 2010). Therefore, understanding changes in tidal activity become crucial to better assess climate
617 change (Yadidya and Rao, 2022).

618 In the subsurface in both seasons, the findings reveal that tides induce stronger cooling
619 above the thermocline (<120m) and warming below (> 120–300m), with a mean magnitude of
620 about 1.2°C.

621 The analysis of the heat budget equation reveals that within the mixed layer, the
622 temperature changes are primarily influenced by the vertical diffusion of temperature (ZDF).
623 This diffusion is driven by diapycnal mixing, which results from barotropic tide bottom friction
624 over the shallow shelf and the breaking of IT at their generation sites and along their
625 propagation pathways. It is noteworthy that the ZDF values are highest in these latter two areas.
626 In deeper layers below the mixed layer, ZDF combines with vertical and horizontal advection
627 terms (z -ADV and h -ADV) to explain temperature changes. Notably, ZDF and z -ADV patches
628 coincide with dissipation hotspots of IT energy.

629 This study highlights the importance of the intensified mixing of IT for temperature
630 structure. We focused hereabove on describing the impacts of tides in temperature on a seasonal
631 scale. However, a companion paper will then analyze the variability of temperature at tidal and
632 subtidal scales using our simulations and remote sensing data.

633 Furthermore, other analysis from our simulations revealed a significant impact on
634 salinity. In addition, IT was reported to be a source of nutrient uptake and impact the spatial
635 distribution of phytoplankton and zooplankton, and therefore on the entire food chain (Sharples
636 et al., 2007, 2009; Xu et al., 2020). Ongoing investigations is conducted to assess the impacts
637 of tides on marine ecosystems using a combined approach including:

- 638 1- the new designed coupled physical/biogeochemistry simulations from NEMO/PISCES
639 called *AMAZON36-BIO* and;
- 640 2- *in situ* data, consisting of long-term PIRATA mooring data (Bourles et al., 2019) and
641 the recent Amazon mixing campaign (AMAZOMIX, Bertrand et al., 2021).

642
643 *Data availability statements.* The 2020 release of GEBCO bathymetry is publicly available
644 online through:
645 https://www.gebco.net/data_and_products/gridded_bathymetry_data/gebco_2020/. The TMI
646 SST v7.1 data are publicly available online from the REMSS platform:
647 <https://www.remss.com/missions/tmi/>, last access: 27 June 2022. WOA2018 climatology is
648 publicly available online at: <https://www.ncei.noaa.gov/access/world-ocean-atlas-2018/>, last
649 access: 27 June 2022. The model simulations are available upon request by contacting the
650 corresponding author.

651 *Authors contributions.* AKL: Funding acquisition; FA, AKL, and ID: Conceptualization and
652 methodology; GM and FA, with assistance from JC and AKL: Numerical simulations; Formal
653 analysis: FA with interactions from all co-authors; Preparation of the manuscript; FA with
654 contributions from all co-authors.

655 *Competing interests.* The authors declare that they have no conflict of interest.
