**Abstract.** To fight against the first wave of Coronavirus disease 2019 (COVID-19) in 2020, lockdown measures were implemented in most European countries. These lockdowns had well-documented effects on human mobility. We assessed the impact of the lockdown implementation and relaxation on air pollution by comparing daily particulate matter (PM), nitrogen dioxide (NO<sub>2</sub>), and ozone (O<sub>3</sub>) concentrations, as well as particle number size distributions (PNSD) and particle light absorption coefficients in-situ measurement data with values expected if no COVID-19 epidemic had occurred at 28 sites across Europe for the period 17 February – 31 May 2020. Expected PM, NO<sub>2</sub> and O<sub>3</sub> concentrations were calculated from the 2020 Copernicus Atmospheric Monitoring Service (CAMS) Ensemble forecasts, combined with 2019 CAMS Ensemble forecasts and measurement data. On average, lockdown implementations did not lead to a decrease in PM<sub>2.5</sub> mass concentrations at urban sites, while relaxations resulted in a  $+26 \pm 21\%$  rebound. The impacts of lockdown implementation and relaxation on NO<sub>2</sub> concentrations were more consistent ( $-29 \pm 17\%$ , and  $+31 \pm 30\%$ , respectively). The implementation of the lockdown measures also induced statistically significant increases in O<sub>3</sub> concentrations at half of all sites ( $+13\%$  on average). An enhanced oxidizing capacity of the atmosphere could have boosted the production of secondary aerosol at those places. By comparison with 2017 – 2019 measurement data, a significant change in the relative contributions of wood and fossil fuel burning to the concentration of black carbon during the lockdown was detected at 7 out of 14 sites. The contribution of particles smaller than 70 nm to the total number of particles significantly also changed at most of the urban sites, with a mean decrease of  $-7 \pm 5\%$  coinciding with the lockdown implementation. Our study shows that the response of PM<sub>2.5</sub> and PM<sub>10</sub> mass concentrations to lockdown measures was not systematic at various sites across Europe for multiple reasons, the relationship between road traffic intensity and particulate air pollution being more complex than expected.

## 1 Introduction

The first case of COVID-19 (Coronavirus disease 2019) in Europe was identified in Italy on 21 February 2020, although recent evidence suggests that the virus had already spread across northern Italy by mid-January (Cerqua and Di Stefano, 2022). National authorities took measures to limit the epidemics propagation across Europe and lockdown measures entered into force in various countries from March 2020. These measures led to dramatic decreases in activities such as road traffic (IEA, 2020), and large reductions in air pollutant emissions from these pollution sources were expected. Shortly after the first lockdown measures were implemented, numerous articles unsurprisingly reported about marked improvements in air quality across Europe (see examples in Putaud et al., 2021). These statements were mostly based on simple comparisons between 2020 and previous year data obtained from remote sensing or in-situ observations. Nonetheless, it was quickly shown that the impacts of the lockdown measures on air pollution were quite complex and could not be assessed without implementing sufficiently developed methodologies (Copernicus, 2020; Kroll et al., 2020; Shi et al., 2021; see also quotations in Schiermeier, 2020), including “deweathering” techniques (e.g. Goldberg et al., 2020; Petetin et al., 2020; Venter et al., 2020; Grange et al., 2021; Petit et al., 2021), modelling (Hammer et al., 2021; Yang et al., 2021) or combinations of model and measurement data (Le et al., 2020; Barré et al., 2021; Beloconi et al., 2021; Jiang et al., 2021). The latter were also applied by Putaud et al. (2021) to northern Italy, one of the most polluted areas in Europe, where the first major COVID-19 outbreak occurred in Europe. That work is extended here to about 30 urban and regional background sites across Europe, for which daily in-situ measurement data from February to May 2020 are compared to expected data (as if no COVID-19 epidemics had occurred) across the same period. The objectives of this work were (i) to determine the impact of the lockdown measures on particulate air pollution at urban and regional background sites across Europe, (ii) to discuss our findings after assessing the impact of the lockdown measures on key gaseous pollutants, on the aerosol light absorption spectrum and the shape of particle number size distributions (PNSD), and (iii) to study the relationship between these impacts and changes in human mobility during lockdowns across Europe. The consequences of the lockdown measures could give a hint on the impact of future car exhaust emission reductions on air pollution across Europe.

## 2 Material and methods

This study focuses on the COVID-19 lockdowns that occurred across Europe in spring 2020. For the sake of clarity, the same three periods were considered for all countries: a 3-week-period before lockdowns were implemented (A, “ante”, 17 February – 8 March 2020), a 6-week period for which mobility was minimal across Europe (D, “during”, 23 March – 3 May 2020), and a 3-week-period during which lockdown measures were partially or totally relaxed (P, “post”, 11 – 31 May 2020). Therefore, the 2 week period 9 – 22 March is excluded from the analysis because lockdown measures were unevenly implemented across Europe at this time. Levels of

stringency during periods A, D, and P in the various countries are discussed in Section 3.1 on the basis of mobility data.

Measurements of particulate matter (PM<sub>10</sub> and PM<sub>2.5</sub>), nitrogen dioxide (NO<sub>2</sub>), and ozone (O<sub>3</sub>) surface level concentrations from 16 urban sites and 12 regional background sites located in 13 countries across Europe were examined for the three periods A, D and P. Measurement data from the same periods in 2019, together with model outputs for the same periods in both 2019 and 2020 were used to estimate the pollutant expected concentrations, which would have occurred in 2020 if no lockdown measures were applied. The potential impact of weather conditions on pollutant concentrations was therefore taken into account.

In addition to PM mass concentrations, two other variables characterising particulate air pollution were studied at 13 sites: (i) the Absorption Ångström exponent (AÅE), which describes the wavelength dependence of the particle light absorption coefficient and reflects the relative contributions of fossil fuel burning and wood burning to the atmospheric concentration of black carbon (Helin et al, 2021, and references therein), and (ii) the contribution of “small” particles (N<sub>small</sub>) to the “total” number of particles (N<sub>tot</sub>), as a proxy for primary particle emissions. Indeed, vehicle tail-pipe emissions have been shown to be dominated by particles whose mobility diameters (D<sub>p</sub>) range between 15 and 70 nm (Giechaskiel et al, 2020; Garbariene et al., 2021). Wood combustion particle diameters are highly dependent on the combustion conditions. Particles with D<sub>p</sub><70 nm can also be emitted by wood burners (Hueglin et al., 1997). The growth of new particles produced during nucleation events also leads to particles in this size range. The number of particles in the size range 15 – 70 nm shall therefore be considered as an upper limit for the number of primary particles. Both variables AÅE and N<sub>small</sub>/N<sub>tot</sub> are intensive variables, i.e. they are not directly dependent on pollution dispersion and therefore much less sensitive to weather conditions than pollutant concentrations.

## 2.1 Mobility data

We could not find any statistical data whose time resolution was good enough (i.e. weekly or better) to assess lockdown impacts on human activities in a consistent way across all 13 countries considered in this study. Therefore, we focused on mobility data as proxies for lockdowns’ stringencies. Driving route request data at city and regional scales temporarily made available by Apple® (Figure S1) at [covid19.apple.com/mobility](https://www.apple.com/covid19/mobility) (last accessed 21/03/2022) were used as an indicator of road-traffic intensity for all sites, except those in Cyprus for which such data were not available.

To assess the relationship between Apple® driving route request data and the actual number of vehicle kilometres driven, monthly motor fuel consumption from EUROSTAT ([ec.europa.eu/eurostat](https://ec.europa.eu/eurostat)) and AVENERGY ([www.avenergy.ch](https://www.avenergy.ch)) from January to May 2020 were used. For Cyprus, monthly activity data from the national statistical service CYSTAT ([www.cystat.gov.cy](https://www.cystat.gov.cy)) were used.

## 2.2 Measurement sites

The 28 air pollution measurement sites considered in this study are shown in Figure 1. Details are listed in Table 1 where sites are sorted from North to South. Twenty-four of these sites constitute twin sites – 1 urban site and 1 regional background site in the same area (< 200 km).

## 2.3 Model data

We used CAMS (Copernicus Atmospheric Monitoring Service) Ensemble forecasts for PM<sub>10</sub>, PM<sub>2.5</sub>, NO<sub>2</sub>, and O<sub>3</sub> daily surface level mass concentrations calculated as the median of the concentrations computed independently by nine different regional air quality models (Marecal et al., 2015), namely CHIMERE, DEHM, EMEP, EURAD-IM, GEM-AQ, LOTOS-EUROS, MATCH, MOCAGE, and SILAM. Each model is based on different schemes describing the formation, dispersion and deposition of reactive gases and particles, but uses the same meteorological fields from the ECMWF (European Centre for Medium-Range Weather Forecast) Integrated Forecasting System, and the same pollutant emission data derived from officially reported emissions for previous years, and therefore ignoring any potential lockdown effect (Denier van der Gon et al., 2015; Kuenen et al., 2022). The outputs of the nine individual models are interpolated on a common regular 0.1° x 0.1° latitude x longitude grid (about 10 km x 10 km) on 10 vertical levels from the surface layer (0-40 m) up to about 5 km altitude over Europe (defined as 25°W-45°E, 30°N-72°N). Median values are little sensitive to outliers (Riccio et al, 2007) and model ensembles are expected to yield better estimates than individual models (Galmarini et al., 2018).

## 2.4 Measurement data

145 2019 and 2020 PM<sub>10</sub>, PM<sub>2.5</sub>, NO<sub>2</sub>, and O<sub>3</sub> measurement data from urban sites were collected from the local air  
quality monitoring networks, except for Athens, for which PM and NO<sub>2</sub> data originated from the ACTRIS  
(Aerosol, Clouds and Trace gases Research Infrastructure) Observatory operated by the National Centre for  
Scientific Research “Demokritos”. Measurement data from regional background sites were also all produced by  
ACTRIS Observatories operated by research performing organisations or EMEP (co-operative programme for  
150 monitoring and evaluation of the long range transmission of air pollutants in Europe) monitoring sites, and  
provided by the ACTRIS Data Centre. Pollutant concentrations were measured from 3 to 9 m above the ground  
with methods listed in Tables S1 and S2 (Supplement).

PNSD and particle light absorption data from 2017 to 2020 originated from the authors’ organisations. Data from  
ACTRIS sites were provided by the ACTRIS Data Centre, and data from other sites were specifically made  
available for this work. PNSD and particle light absorption coefficients were determined using instruments listed  
155 in Table S3.

## 2.5 Data analysis

Data were analysed as in Putaud et al., 2021. Briefly, 2020 expected daily concentrations ( $Exp_{2020}$ ) were estimated  
from 2020 CAMS-Ensemble daily forecasts ( $CAMS_{2020}$ ) and the ratio between 2019 daily observations ( $Obs_{2019}$ )  
and 2019 CAMS-Ensemble daily forecasts ( $CAMS_{2019}$ ) according to Eq. 1:

$$160 \quad Exp_{2020} = \frac{Obs_{2019}}{CAMS_{2019}} CAMS_{2020} \quad (1)$$

2020 CAMS–Ensemble forecasts account for actual meteorological conditions and seasonal changes in emission  
source strengths, ignoring lockdown measures. The ratio  $Obs_{2019}/CAMS_{2019}$  represents the time dependent  
normalisation of CAMS forecasts to the observations performed at each measurement site, as estimated from 2019  
data. Applying this normalisation factor to CAMS 2020 forecasts aims at correcting for the bias between CAMS  
165 forecasts and observation data, which can vary across the year. It should be noted that only sites for which forecasts  
and observations reasonably agreed ( $R^2 \geq 0.5$ ) across February – May 2019 were considered in this study (see Table  
S4). Obviously, expected concentrations ( $Exp_{2020}$ ) cannot be compared to observations ( $Obs_{2020}$ ) on a daily basis,  
since  $Exp_{2020}$  values are affected by random variations in the daily  $Obs_{2019}/CAMS_{2019}$  ratio. Instead, mean  
 $Obs_{2020}/Exp_{2020}$  ratios were compared for the 3 periods A (before lockdowns), D (during lockdowns), and P  
170 (after lockdowns), as defined in Section 2. The statistical significance of the difference in  $Obs_{2020}/Exp_{2020}$  ratios  
between the 3 time periods A, D, and P was assessed by applying a 2-sided  $t$  test to the averages  $\bar{A}$ ,  $\bar{D}$ , and  $\bar{P}$ ,  
defined as:

$$\bar{A} = \text{mean} \left( \log \frac{Obs_{2020}}{Exp_{2020}} \right)_A, \bar{D} = \text{mean} \left( \log \frac{Obs_{2020}}{Exp_{2020}} \right)_D, \bar{P} = \text{mean} \left( \log \frac{Obs_{2020}}{Exp_{2020}} \right)_P \quad (2)$$

The null hypotheses ( $\bar{D} = \bar{A}$  and  $\bar{D} = \bar{P}$ ) were tested at the 95% confidence assuming unequal variances.

175 The mean  $Obs_{2020}/Exp_{2020}$  ratios plotted and discussed below were calculated as:

$$\langle A \rangle = 10^{\bar{A}}, \langle D \rangle = 10^{\bar{D}}, \text{ and } \langle P \rangle = 10^{\bar{P}} \quad (3)$$

Particle light absorption Ångström exponent (ÅÅE) values were calculated as the slope of the linear regression  
between the logarithm of the particle light absorption coefficients and the logarithm of the wavelengths (WL) of  
the light sources used in the multi-wavelength absorption photometers across the whole WL range available below  
180 900 nm. WL ranges were different across the various sites (Table S3) but constant at each site. ÅÅE values were  
calculated across the ultraviolet – near infrared range (370 – 880 nm) for the urban sites in Lille (FR), Bern (CH),  
Athens (GR), Nicosia (CY) and the regional background sites SIR (FR), PAY (CH), IPR (IT) and MSY (ES). At  
Brussels (BE), measurements were available at 370 and 660 nm, and at ARN (ES), HYY (FI) and KOS (CZ), in  
the visible range (470 – 660 nm) only.

185 The ratio between the number of small particles ( $N_{\text{small}}$ ) and the “total” number of particles ( $N_{\text{tot}}$ ) was calculated  
from PNSD measurements.  $N_{\text{small}}$  was calculated by integrating PNSD from 15 to 70 nm at all sites, except  
Copenhagen and RIS (DK), for which PNSD lower bound was 41 nm.  $N_{\text{tot}}$  was calculated by integrating PNSDs  
from 15 nm to the upper bound of the distribution at all but both sites in Denmark (41 nm). The upper bound was  
800 nm at most but not all sites (Table S3), and was constant at each site across the time period 2017 -2020.

190 Particle light absorption coefficients and PNSDs are not computed by the CAMS model. Therefore, 2017 – 2019  
 measurement data were used to calculate the expected values of the Absorption Ångström exponent ( $A_{\text{ÅE}}$ ) and  
 the contribution of small particles to the total particle number concentration ( $N_{\text{small}} / N_{\text{tot}}$ ) for sites at which  
 measurements were available for at least 2 years between 2017 and 2019 across the studied period (17 February  
 195 – 31 May). Both being intensive variables (i.e. intrinsic aerosol properties), these variables are much less sensitive  
 to weather conditions than e.g. atmospheric concentrations. Daily values expected for 2020 ( $Exp_{2020}$ ) were  
 calculated as the average of 2017 – 2019 data, and lockdowns' impacts were assessed comparing the arithmetic  
 means of  $Obs_{2020}/Exp_{2020}$  ( $\bar{A}$ ,  $\bar{P}$ , and  $\bar{D}$ ) for the 3 time periods A, D, and P, as described above.

The mean impact of the lockdown implementation and relaxation discussed below and listed in Table 2 were  
 calculated for each variable as:

$$200 \quad \text{lockdown implementation mean impact} = \frac{1}{n} \sum_{i=1}^n (\langle A_i \rangle / \langle D_i \rangle - 1) \quad (4a)$$

$$\text{and lockdown relaxation mean impact} = \frac{1}{n} \sum_{i=1}^n (\langle D_i \rangle / \langle P_i \rangle - 1) \quad (4b)$$

where indices (1, ..., n) represent the sites considered for each variable. Mean impacts were expressed as  
 percentages (%).

### 3 Results and discussion

#### 205 3.1 Impact of lockdown measures on road traffic intensity

Biases in traffic intensity estimates derived from mobility data have been reported in business as usual conditions  
 (Meppelink et al., 2020). However, data relative to the lockdown period in the USA have highlighted a clear  
 covariation between Apple® mobility data and gasoline demand (Ou et al., 2020), which is in turn a robust  
 indicator for the cumulative distance covered by cars. We compared monthly mean motor fuel consumptions and  
 210 Apple® driving direction requests for the 12 countries of this study for which data were available. Table S5 shows  
 that gasoline national consumptions are generally well correlated with country mean driving direction requests  
 across January – May 2020, while diesel consumptions are anti-correlated or not-significantly correlated with  
 driving direction requests in all countries but 3 (FR, IT, ES). This suggests that Apple® driving direction requests  
 are good qualitative proxies for personal car traffic but not for commercial (diesel powered) vehicular traffic. This  
 215 is confirmed by data from Athens, for which a reduction between A and D of up to 70% and 40% in Light Duty  
 Vehicle and Heavy Duty Vehicle traffic, respectively, was reported (Eleftheriadis et al., 2021), to be compared  
 with a -73% decrease in driving route requests. However, changes in gasoline consumption are everywhere less  
 than the variations in Apple® driving route requests (range 38% –88%, average 59%) as shown in Table S5.

For the set of cities where urban measurement sites were located, the Apple® mobility data show that driving  
 220 route requests dropped by -31 % (Helsinki) to -90 % (Seville) between periods A and D, and increased again by  
 +40 % (Helsinki) to +270 % (Paris) between periods D and P (Figure 2). The data recorded in the areas  
 surrounding the regional background sites and/or the urban sites show similar variations, except for the Vysocina  
 region (central Czech Republic) where driving route request numbers (-27 %) fell much less than in Prague (-60  
 %), and reached again their pre-lockdown value (period A) when lockdown measures were relaxed (period P).

225 According to monthly mean data available from CYSTAT, the road transport index in Cyprus decreased by -21  
 % in March 2020, by further -35 % in April 2020, and increased again by +18 % in May 2020 (Figure S2), in line  
 with the mobility data collected for the other sites.

These data suggest that at least passenger car traffic strongly decreased as lockdown measures were implemented  
 (period D) in all countries considered in this study, and particularly in Belgium, France, Italy, Spain, Greece and  
 230 Cyprus. They also suggest that the road traffic intensity was largely greater by the end of May 2020 (period P)  
 than during lockdown periods (period D) at all sites, but without reaching the intensities observed before (period  
 A) at sites in Belgium, France, Italy, Spain, Greece and possibly Cyprus. However, 2020 monthly automotive fuel  
 consumption data suggest that light and heavy-duty vehicle traffic (diesel) was much less reduced than private car  
 (diesel + gasoline) traffic during the first lockdown period across Europe (Section 2.1, Table S5).

#### 235 3.2 Impact of lockdown measures on PM mass concentrations

It is reminded here again that only sites for which the correlation between modelled and measured PM mass concentrations was satisfactory (positive slope,  $R^2 \geq 0.5$ ) across the February – May 2019 period were considered (Table S4).

240 Figure 3 shows the mean observed / expected  $PM_{2.5}$  and  $PM_{10}$  mass concentration ratios (Eq. 3) at urban sites during the 3 time periods A, D, and P. The differences between these 3 values represent our estimates of the lockdown measures' impacts on pollutant atmospheric concentrations. As already observed across Europe (EEA, 2020; Shi et al., 2021) and the USA (Bekbulat et al., 2021), there was no systematic response of PM mass concentrations to the lockdown measures at urban sites. Indeed, the implementation of lockdown measures in March led to statistically significant decreases in  $PM_{2.5}$  concentrations in Oslo, Rotterdam, and Barcelona (3 among 10 sites), and to a significant decrease in  $PM_{10}$  concentration in Barcelona and Seville (2 out of 12 sites) only. On average (Table 2), the implementation of the lockdown measures resulted in minor increases in  $PM_{2.5}$  and  $PM_{10}$  mass concentration of  $+1 \pm 42 \%$  and  $+5 \pm 33 \%$ , respectively. In contrast, the relaxation of lockdown measures in May led to statistically significant increases in  $PM_{2.5}$  concentrations in Helsinki, Rotterdam, Brussels, Prague, Bern and Barcelona (6 out of 10 sites), and to a significant increase in  $PM_{10}$  concentrations in Rotterdam, Lille, Prague, Paris, Milan, Barcelona, and Nicosia (7 out of 12 sites). On average, the relaxation of the lockdown measures led to  $PM_{2.5}$  and  $PM_{10}$  concentration increases of  $+26 \pm 21 \%$  and  $+26 \pm 24 \%$ , respectively. Where significant, lockdown measures had very similar impacts on  $PM_{2.5}$  and  $PM_{10}$  concentrations. Lockdown impacts on PM concentrations in cities did generally not well reflect the variations in road traffic intensity expected from the driving road request data (Figure 2) as illustrated by Figure S3.

255 Advection from surrounding areas have been shown to contribute to PM concentrations in European cities (e.g. Kieseewetter et al., 2015; Thunis et al., 2018; Pommier et al., 2020). For example, modelling indicates that the contribution of sources outside the greater city contribute from 35 % (Paris, Athens) to 94 % (Nicosia) to  $PM_{2.5}$  urban background concentrations in the cities considered here (Thunis et al., 2017).

260 Figure 4 shows the mean observed / expected  $PM_{2.5}$  and  $PM_{10}$  mass concentration ratios (Eq. 3) during the 3 time periods A, D, and P at regional background sites located in the regions of the cities mentioned above. The implementation of lockdown measures led to statistically significant decreases in  $PM_{2.5}$  concentration in BIR (NO), and in  $PM_{10}$  concentrations in BIR and MEL (DE) only (3 out of 16 entries), while their relaxation resulted in significant increases in  $PM_{2.5}$  concentrations in BIR, CBW (NL), MEL, KOS (CZ), SIR (FR), and in  $PM_{10}$  concentrations in BIR, CBW, MEL, SIR, PAY (CH), and IPR (IT), i.e., 11 out of 16 entries. At regional background sites, lockdown implementations resulted on average, in  $+2 \pm 39 \%$  and  $+15 \pm 42 \%$  increases in  $PM_{2.5}$  and  $PM_{10}$  mass concentrations, respectively. Their relaxation resulted in further  $+38 \pm 43 \%$  and  $+28 \pm 10 \%$  increases in  $PM_{2.5}$  and  $PM_{10}$  concentrations, respectively. Comparing PM data with the driving route request data in Figure 2 (bottom) suggests no significant impact of private car traffic intensity on regional background PM levels (Figure S4).

270 There is generally no correspondence between significant lockdown impacts on PM concentrations at twin sites (urban and regional background sites located in the same area), except for Oslo-BIR (PM decrease from A to D), and Rotterdam-CBW, Prague-KOS, Paris-SIR, and Milan-IPR (PM increase from D to P).

275 Due to the multiplicity of PM primary and secondary sources, further atmospheric variables such as gaseous pollutant concentrations and PM intrinsic characteristics shall be examined to investigate the lack of dramatic drops in PM mass concentrations resulting from the reduction in private car traffic when lockdown measures were implemented at the sites considered in this study.

### 3.3 Impact of lockdown measures on $NO_2$ concentrations

280 Road traffic is the major source of  $NO_x$  (nitrogen oxides) in Europe (EEA, 2020). For the 15 cities considered in this study, the contribution of road traffic to annual  $NO_x$  emissions ranges from 35 % in Rotterdam to 95 % in Athens (Degraeuwe et al., 2019). Road-traffic intensity variations are therefore expected to significantly affect  $NO_2$  concentrations. Diesel engines are by far the largest contributors to road traffic  $NO_x$  emissions in most countries across Europe, a noticeable exception being Greece (2016 data). However, for all 13 countries considered, the passenger car fleet emits the largest share of  $NO_x$  (60 – 90 %), far ahead that of the light duty plus heavy duty vehicle fleet. Since mobility restrictions presumably affected mostly passenger cars (Section 3.1), dramatic variations in driving route requests (as a proxy for vehicle kilometres) are expected to result in significant changes in road traffic  $NO_x$  emissions.

Lockdown measure implementations led to statistically significant decreases in NO<sub>2</sub> concentrations in Helsinki, Copenhagen, Rotterdam, Brussels, Lille, Paris, Bern, Milan, and Barcelona, i.e., in 9 among 13 cities. At sites where no significant reduction in NO<sub>2</sub> concentrations occurred, there was no significant decreases in nitrogen oxide (NO) concentrations either (Figure S5), indicating no substantial abatement of NO<sub>x</sub> emissions. On average, the implementation of lockdown measures resulted in NO<sub>2</sub> concentration decreasing by  $-29 \pm 17$  %. Lockdown measure relaxations led to significant rebounds in NO<sub>2</sub> concentrations in Copenhagen, Brussels, Lille, Prague, Paris, Milan, and Seville (7 among 13 cities). The mean increase in NO<sub>2</sub> concentration resulting from the lockdown termination was  $+31 \pm 30$  %. Although the impact of the lockdown measures was more systematic for NO<sub>2</sub> than for PM concentrations (Figure S6), there is no significant correlation between the impact on NO<sub>2</sub> concentration and the reduction in driving route requests from periods A to D, and only a marginally significant correlation between the impact on NO<sub>2</sub> concentration and the increase in driving route requests from periods D to P (Figure S3).

Lockdown measures also resulted in significant decreases in NO<sub>2</sub> concentrations at 7 of the 12 regional background sites (HYY, FI; CBW, NL; SIR, FR; PAY, CH; IPR, IT; CYP, CY). Their relaxation led to significant increases in NO<sub>2</sub> at 3 sites only, namely CBW (NL), MEL (DE), and SIR (FR). On average, the implementation and relaxation of lockdown measures resulted in a  $-17 \pm 24$  % decrease and  $+27 \pm 50$  % increase in NO<sub>2</sub> concentration at regional background sites, respectively. There is no statistically significant correlation (95 % confidence level) between the lockdown impact on NO<sub>2</sub> concentrations and the changes in route request data from periods A to D and D to P at the regional background sites (Figure S4).

Figure 5 shows that there is generally no matching in NO<sub>2</sub> ratio variations from periods A to D, and from periods D to P, between urban sites and regional background sites in surrounding areas (with a few exceptions including Paris-SIR and Bern-PAY), which suggests that NO<sub>2</sub> concentrations at urban and regional background sites are controlled by different sources and /or atmospheric processes.

The lack of systematic correlation between the variations in the Apple® driving route request index and the changes in NO<sub>2</sub> concentrations due to the lockdown implementation and relaxation measures suggests that the linkage between passenger car traffic and NO<sub>x</sub> emissions was not that straightforward under such circumstances. However, NO<sub>2</sub> being an important precursor of secondary PM, and the vehicles that emit most NO<sub>x</sub> being also those which emit most primary PM, the lack of dramatic impact of lockdowns on PM concentrations compared to their clear effect on NO<sub>2</sub> concentrations at many sites emphasises the variety of PM sources and the complexity of secondary formation processes.

### 3.4 Impact of lockdown measures on O<sub>3</sub> concentrations

Implementations of lockdown measures induced statistically significant increases in O<sub>3</sub> concentrations in Brussels, Lille, Paris, Barcelona, and Nicosia, i.e., in 5 cities out of 12, Milan being on the edge (Figure 6, top). There were no cities where lockdown measures led to a significant decrease in O<sub>3</sub>. This is consistent with photochemical O<sub>3</sub> production not being limited by the availability of NO<sub>x</sub> in urban areas, and with a reduction of O<sub>3</sub> titration by NO as resulting from an abatement in NO<sub>x</sub> emissions during the lockdown periods. On average, the implementation of the lockdown measures resulted in an increase of  $+11 \pm 23$  % in O<sub>3</sub> concentration in cities. Also at the regional background sites BIR (NO), KOS (CZ), SIR (FR), IPR (IT) and ARN (ES), the effect of the lockdown measures was a significant increase in O<sub>3</sub> concentrations, and at no sites was a significant decrease in O<sub>3</sub> detected. This is again consistent with an excess of NO<sub>x</sub> in O<sub>3</sub> photochemical formation at those sites, at least during this period of the year (February – April). The significant increase in O<sub>3</sub> after the lockdown measure relaxation (period P) in BIR (NO), and ARN (ES) could be explained by a shift in the O<sub>3</sub> photochemical production to the “NO<sub>x</sub> limited” regime at these regional background sites, resulting from increased emissions of biogenic volatile organic species in May. On average, the impact of the lockdown measure implementation and relaxation on O<sub>3</sub> concentration at regional background sites was estimated to  $+17 \pm 24$  % and  $+4 \pm 5$  %, respectively.

Increased O<sub>3</sub> concentrations reflect an increase in the oxidizing capacity of the atmosphere. The increased oxidizing capacity of the atmosphere was invoked to explain the lack of systematic decrease in PM concentrations resulting from the lockdown measures (e.g. Kroll et al., 2020): the expected decrease in PM primary emissions would be compensated (or even over-compensated) by an increased production of secondary aerosol resulting from a faster oxidation of PM gaseous precursors to condensable material. Actually, increased aerosol surface area and Aitken mode particle growth rates were observed for the lockdown period in Athens (Eleftheriadis et al., 2021), together with increases in O<sub>3</sub> and PM<sub>2.5</sub> concentrations. This hypothesis is to some extent also supported

340 by recent modelling works (Clappier et al., 2021) suggesting that in the areas surrounding Rotterdam, Bern, Milan, and Barcelona, reduction in  $\text{NO}_x$  emissions would lead to enhanced secondary PM formation resulting from the increased oxidizing capacity of the atmosphere. However, the magnitude of this phenomenon during the 2020 lockdown could only be assessed on the basis of detailed PM chemical composition data (including not only sulfate and nitrate, but also secondary organics), which are not available at the sites located in these areas considered under our study.

345 In the following sections, other possibilities will be examined by making use of specific aerosol properties, which are not part of the air pollution regulated metrics.

### 3.5 Impact of the lockdown measures on aerosol intrinsic characteristics

350 A reason why lockdown impacts on PM mass concentrations were smaller than expected could be the compensation of the decrease in road traffic emissions by the increase in domestic heating emissions, resulting from people “staying-at-home” (Altuwayjiri, et al., 2021). Since wood (or wood pellets) is one of the fuels used for domestic heating, any decrease in road traffic compared to domestic heating emissions would result in an increase of the AÅE. We also deemed it important to assess how clear was the lockdown effects on primary particle emissions from vehicle engines. This is why the contribution of small particles ( $D_p < 70$  nm) to the total particle number ( $N_{\text{small}} / N_{\text{tot}}$ ) was examined. The measurement data needed to calculate these intensive variables were not available for all the 28 sites considered in this study (see Table S3). Therefore, data from urban and regional background sites are not split in separate figures for these two variables.

#### 3.5.1 Particle light absorption spectral dependence

360 A statistically significant impact of the lockdown measure implementation and relaxation on the particle light absorption spectral dependence was detected in Lille (FR), Athens (GR) and ARN only (Figure 7). At both urban sites, 2020 AÅE values were very similar to the 2017 -2019 averages for periods A and P, and significantly greater during the lockdown period (D). AÅE values also significantly increased as lockdown measures were implemented in Oslo (NO) and SIR (FR), while AÅE values significantly decreased as lockdown measures were relaxed in IPR (IT). No significant change in 2020 AÅE values (as compared with 2017 - 2019) could be observed for the lockdown period (D) in BIR (NO), Brussels (BE), KOS (CZ), Bern (CH), PAY (CH), and MSY (ES). On average (all site types), the AÅE increased by  $+3 \pm 6$  % and decreased by  $-8 \pm 28$  % as lockdown measures were implemented and relaxed. In short, the expected increase in AÅE resulting from a decrease in particle emissions from traffic and a stagnation or increase in particulate emissions from wood burning during the lockdown period was not systematically observed across the sites considered in this study. Therefore, increased emissions from domestic heating during the lockdown can have contributed to maintain unexpectedly high PM mass concentrations in certain places across Europe, but this phenomenon was apparently not relevant in many areas.

#### 3.5.2 Particle number size distribution

375 At 3 of the 5 urban sites for which data were available (Leipzig, Athens, and Granada), the implementation of the lockdown measures in 2020 coincided with a statistically significant decrease in the  $N_{\text{small}} / N_{\text{tot}}$  ratio as compared to the same time periods in 2017 – 2019 (Figure 8). A significant increase in this ratio occurred as lockdown measures were relaxed at only 2 amongst the 6 urban sites with relevant data (Copenhagen and Barcelona). On average, the implementation and relaxation of lockdown measures corresponded to a decrease by  $-7 \pm 5$  % and an increase by  $+6 \pm 2$  %, respectively, in the  $N_{\text{small}} / N_{\text{tot}}$  ratio.

380 These observations suggest that the decrease in traffic resulting from the implementation of the lockdown measures led on average to a significant but moderate decrease in the number concentration of primary ultrafine particles (which dominate the 15 – 70 nm size range in urban environments). The lack of complete return to usual PNSDs after the lockdown period ended can be explained by only partial recovery in human mobility in Athens (GR) and Granada (ES), but not in Leipzig (DE) where mobility almost completely (95 %) recovered.

385 During the lockdown period (D), statistically significant changes in the contribution of small particles to the whole PNSD ( $N_{\text{small}} / N_{\text{tot}}$ ) were also detected at 4 out of 6 regional background sites, i.e. BIR (NO), RIS (DK), MEL (DE) and IPR (IT). Variations in RIS and MEL reflected quite well the variations in the nearby cities of Copenhagen and Leipzig. Clear decreases and increases in  $N_{\text{small}} / N_{\text{tot}}$  corresponding to the lockdown measures implementation and relaxation, respectively, can be noticed at both BIR (NO) and IPR (IT). The variations observed in IPR can easily be related to the variations in the driving route request index for the densely populated

390 and traffic impacted Lombardy region. In contrast, it is surprising to observe such significant changes in the PNSD  
in BIR, located in a region (Agder) where the driving mobility index remained relatively high, even during the  
lockdown period. Lockdown measures also had a huge impact on PM mass concentration in BIR (Figure 3), but  
providing a specific explanation for the case of BIR is beyond the scope of this study. On average, the  
implementation and relaxation of lockdown measures coincided with a decrease by  $-9 \pm 13 \%$  and an increase by  
 $+11 \pm 12 \%$ , respectively, in the  $N_{\text{small}} / N_{\text{tot}}$  ratio at regional background sites.

395 In short, except for the two sites located in Finland, the lockdown periods coincided with unusual low shares of  
small particles ( $N_{\text{small}} / N_{\text{tot}}$ ) at all sites, although differences were not all statistically significant. This suggests  
that the lockdown measures did have an impact on primary particle emissions. However, considering the huge  
changes in the driving route request index for a vast majority of sites in this study, the impact on PNSD was not  
quite dramatic. This suggests that private cars do not contribute a large share of the overall emission of 15-70 nm  
400 particles at the sites we studied, or that the decrease in this specific source was compensated by increases in other  
sources (possibly including nucleation and growth of new particles) during the lockdown periods.

#### 4 Conclusions

Specific impacts on air pollution of the implementation and relaxation of lockdown measures to prevent the spread  
of COVID-19 were determined by comparing observations with expected data for the period 17 February – 31  
405 May 2020 (Table 2).

Driving direction request data suggest that the reduction in car passenger traffic resulting from the lockdown  
measures was much more pronounced in the southern Europe than in northern Europe. Regardless the variations  
in these human mobility indicators, we did not observe statistically significant decreases in  $PM_{2.5}$  and  $PM_{10}$  mass  
concentrations at most of the European urban sites considered in our analysis. Consequently, the implementation  
410 of lockdown measures in March 2020 did not lead on average to a decrease in  $PM_{2.5}$  and /or  $PM_{10}$  mass  
concentrations across these sites. In contrast, the relaxation of the lockdown measures in May 2020 led to an  
increase of  $PM_{2.5}$  and /or  $PM_{10}$  concentrations at more than half of the cities studied, resulting in a mean increase  
of  $+26 \%$  in both  $PM_{2.5}$  and  $PM_{10}$  concentrations. At regional background sites, the implementation of the  
lockdown measures yielded a significant impact at an even more limited number of sites, whereas their relaxation  
415 resulted in  $PM_{2.5}$  and/or  $PM_{10}$  mass concentration increases at most of them. The asymmetrical response of PM  
mass concentrations to the implementation and relaxation of lockdown measures suggests a relationship more  
complex than expected between road traffic intensity and PM mass concentrations. By looking at a range of other  
atmospheric variables, we gained more insights into this phenomenon.

Regarding key gaseous pollutants,  $NO_2$  concentrations significantly decreased at 3/5 of the urban sites due to the  
420 implementation of lockdown measures, and significantly re-increased at 3/10 of them due to their relaxation. On  
average, the implementation and relaxation of lockdowns resulted in a notable  $-29 \%$  decrease and in a  $+31 \%$   
rebound in  $NO_2$  concentration, respectively. These figures suggest that mobility restrictions did translate into  
decreases in road traffic  $NO_x$  emissions. However, the extent of the changes in  $NO_2$  concentrations did not  
correlate well with the changes in human mobility. This disparity could be attributed to the fact that driving route  
425 request indices differently reflected the number of km driven in various countries, and by different proportion of  
vehicles complying with the various EURO emission standards across Europe.

The implementation of lockdown measures also altered the oxidizing capacity of the atmosphere, potentially  
resulting in the formation of a larger amount of secondary aerosols during lockdown periods, despite lower levels  
of gaseous precursors. Specifically, our study revealed a significant increase in  $O_3$  concentrations (an indicator of  
430 the oxidizing capacity of the atmosphere) due to the lockdown implementation at 1/2 of the urban and regional  
background sites. The production of secondary particulate matter could have been boosted at these sites.  
Modelling work by Clappier et al. (2021) demonstrated that decreases in  $NO_x$  emissions would result in increased  
secondary PM concentrations in some areas of Europe. Nevertheless, additional data pertaining to the aerosol  
chemical composition would be needed to ascertain whether this process exerted a substantial impact on PM mass  
435 concentrations as lockdown measures were implemented at the studied sites located in these areas.

Possible changes in some intrinsic aerosol properties (such as the light absorption spectrum and the particle size  
distribution shape) were also assessed in this work. The occurrence of significantly higher AÅE values during the  
lockdown periods at a few sites in Norway, France, Italy, Greece and Spain indicates a relatively larger  
contribution of black carbon from wood burning as compared to fossil fuel burning during these periods.

440 Therefore, the decrease in PM concentrations associated with traffic-related sources could have been partially offset by an increase in PM concentrations related to domestic heating activities at these sites. However, this phenomenon was apparently not generalised throughout Europe.

Regarding PNSD, a statistically significant lockdown effect was observed at most of the studied sites. On average, moderate -7 % and -9 % decreases were observed in the contribution of small particles to the total particle number concentration across urban and regional background sites, respectively. These figures indicate that the implementation of lockdown measures resulted in a decrease in primary particle emissions (predominantly in the 15 – 70 nm range) compared to the production of secondary particles (mainly in the range 100 – a few hundreds of nm). Consequently, it is suggested that measures leading to a reduction in passenger car traffic (as lockdown measures did) would likely have a larger impact on particle number concentrations (which are strongly dependent on the abundance of small particles) than on PM mass concentrations (which are more sensitive to the number of particles in the range 70 – several hundreds of nm) in urban areas.

Our results on PM<sub>10</sub> and PM<sub>2.5</sub> align with previous studies that similarly reported limited impacts of lockdowns on PM mass concentrations over Europe and the USA (Archer et al., 2020; Bekbulat et al., 2021; Shi et al., 2021; Querol et al., 2021). However, they contrast with other findings, that indicated substantial reductions in PM mass concentrations in several big European and American cities due to the COVID-19 lockdown measures (Chauhan and Singh, 2020; Beloconi et al., 2021; Jiang et al., 2021). Several factors could help explain these contrasting observations: (i) the effectiveness of lockdown measures in reducing PM mass concentrations can vary across different regions due to variations in factors such as population density, variability of the pollution sources such as industrial activities and transportation patterns, and local meteorological conditions; (ii) the level of stringency, duration and adherence to lockdown measures can vary between different countries or even within different regions of the same country; (iii) the response of different PM chemical constituents to lockdown measures can vary, leading to varying observations across studies when only whole PM<sub>10</sub> or PM<sub>2.5</sub> mass concentrations are considered; (iv) the existing pollution levels before the implementation of lockdown measures can influence the magnitude of changes observed during the lockdown period. If the baseline pollution levels were already low, the impact of lockdown measures may be less detectable compared to areas with higher initial pollution levels.

Overall, this comprehensive study encompassing 28 European sites enhances our understanding of the human mobility restriction on particulate air pollution, leveraging the unique circumstances of COVID-19 lockdowns. In particular, we highlighted the complexity of PM mass concentration responses to the COVID lockdown measures implemented throughout Europe, which arise from a combination of several factors. These include uneven levels of stringency in the across different European countries, evidenced compensation between road traffic and domestic heating emissions at some sites, and the potential for heightened formation of secondary PM at other sites. Quantitatively assessing the distinct contributions of these phenomena across Europe remains an important task for future research that goes beyond the scope of this study. Nevertheless, the “experiment” presented by the COVID-19 lockdowns suggests that the on-going decrease in exhaust emissions by the passenger car fleet might yield quite contrasting impacts on air quality in European cities.

650

Figure 1. Location of the 28 sites across Europe (map background from ESA).

655

Figure 2. Driving route request indices during period A (17 February – 8 March), D (23 March– 3 May) and P (11 – 31 May) in cities where measurement sites were located (top), and in areas where regional background sites and/or urban sites were located (bottom). Apple® mobility indices are relative to data of 13 January 2020. Data from 11 and 12 May 2020 are missing. N-PdC and IdF stand for the French “Nord-Pas de Calais” and “Ile de France” regions, respectively. No data for Cyprus (see Fig. S1).

660

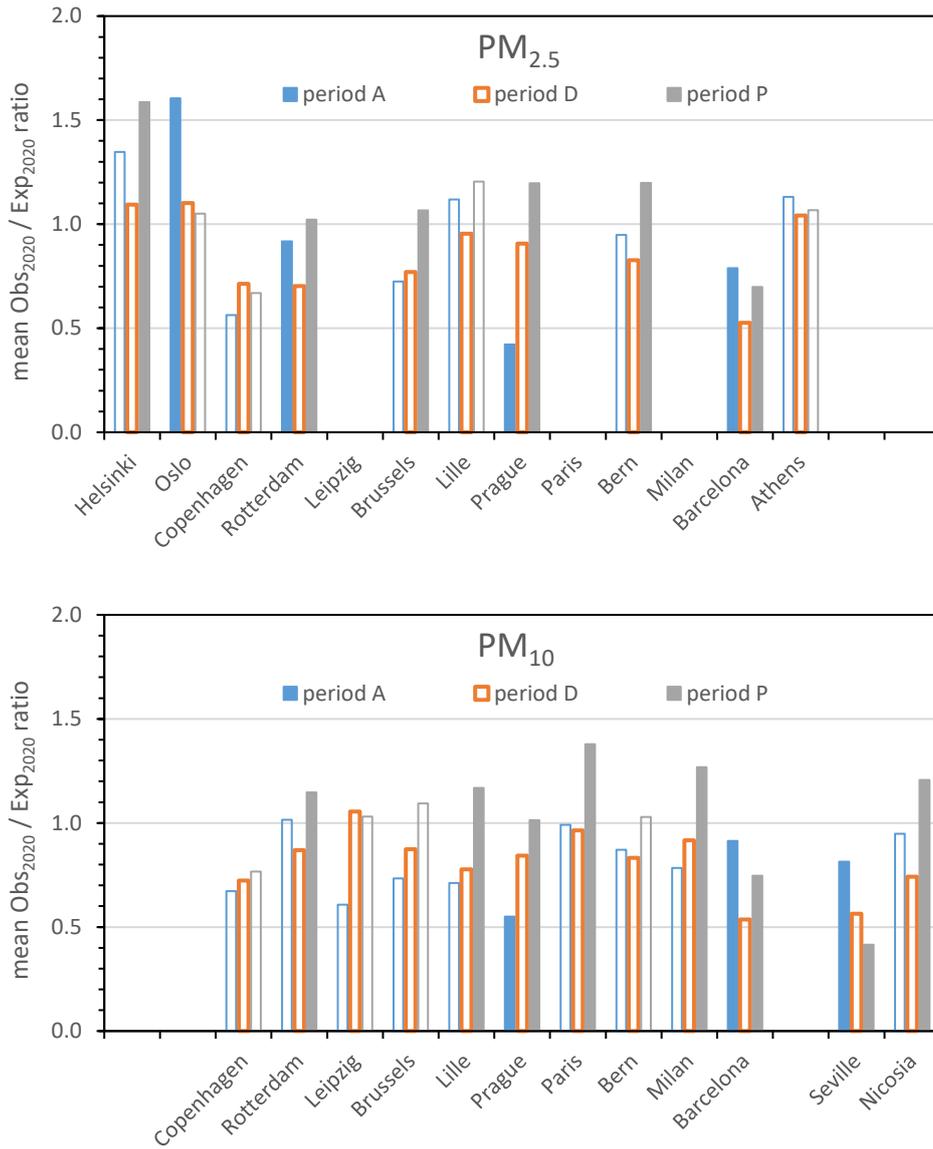

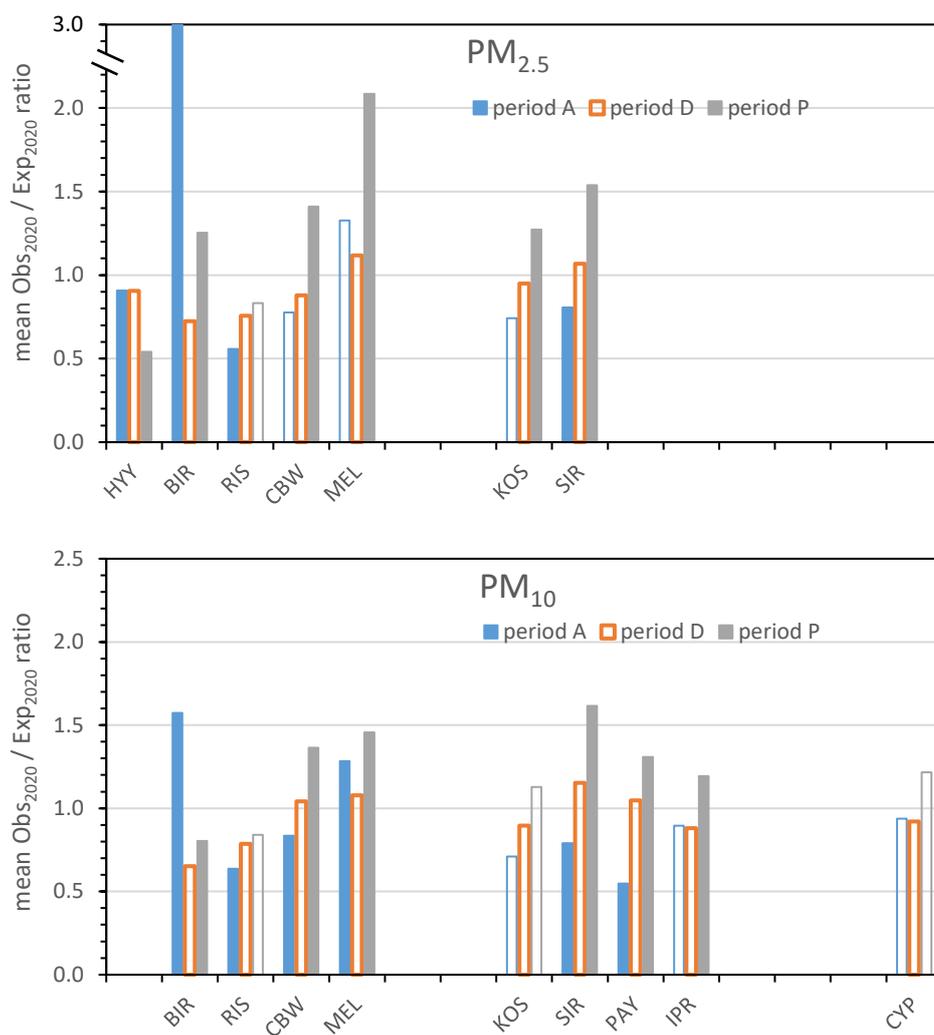

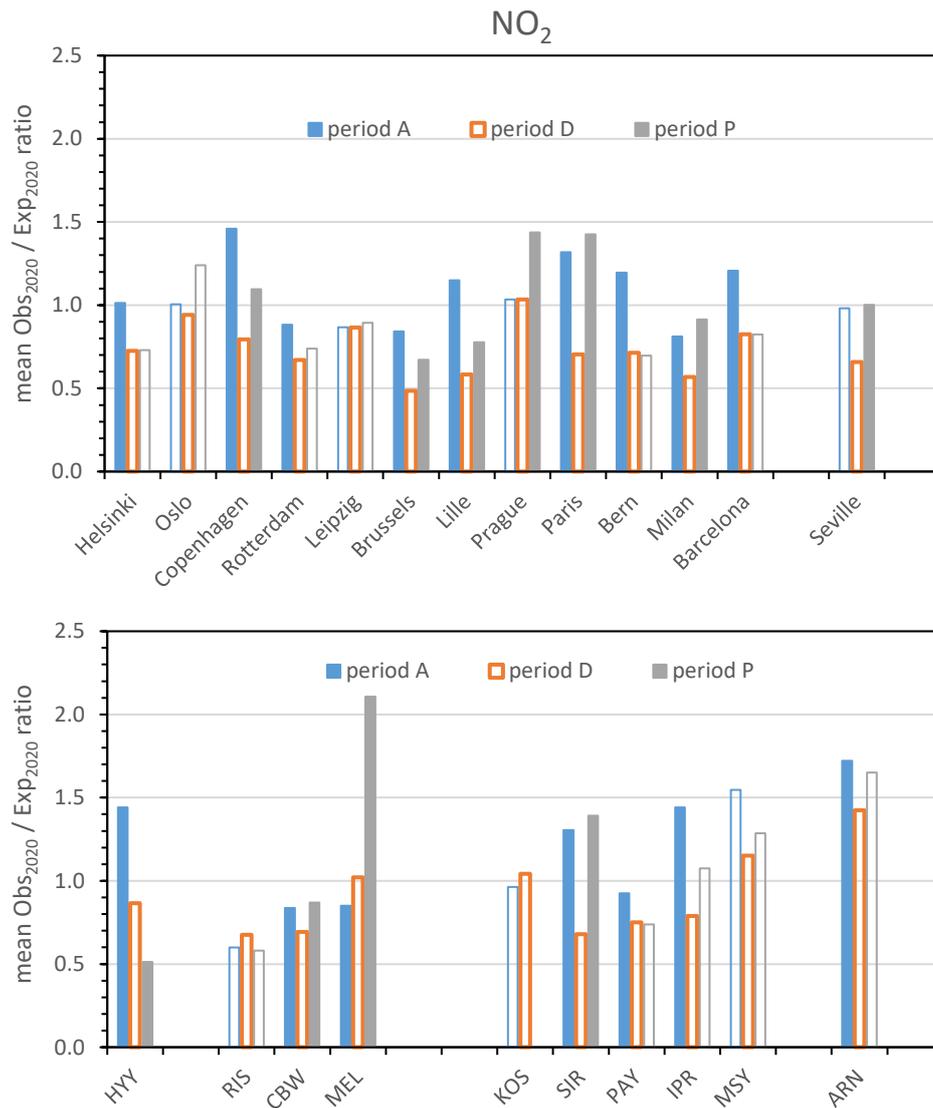

Figure 3. Mean observed / expected PM<sub>2.5</sub> (top) and PM<sub>10</sub> (bottom) concentration ratios (Eq. 3) during periods A (before), D (during lockdowns) and P (after) at urban sites. Filled bars indicate means which are statistically different from the mean during lockdown periods (D).

665

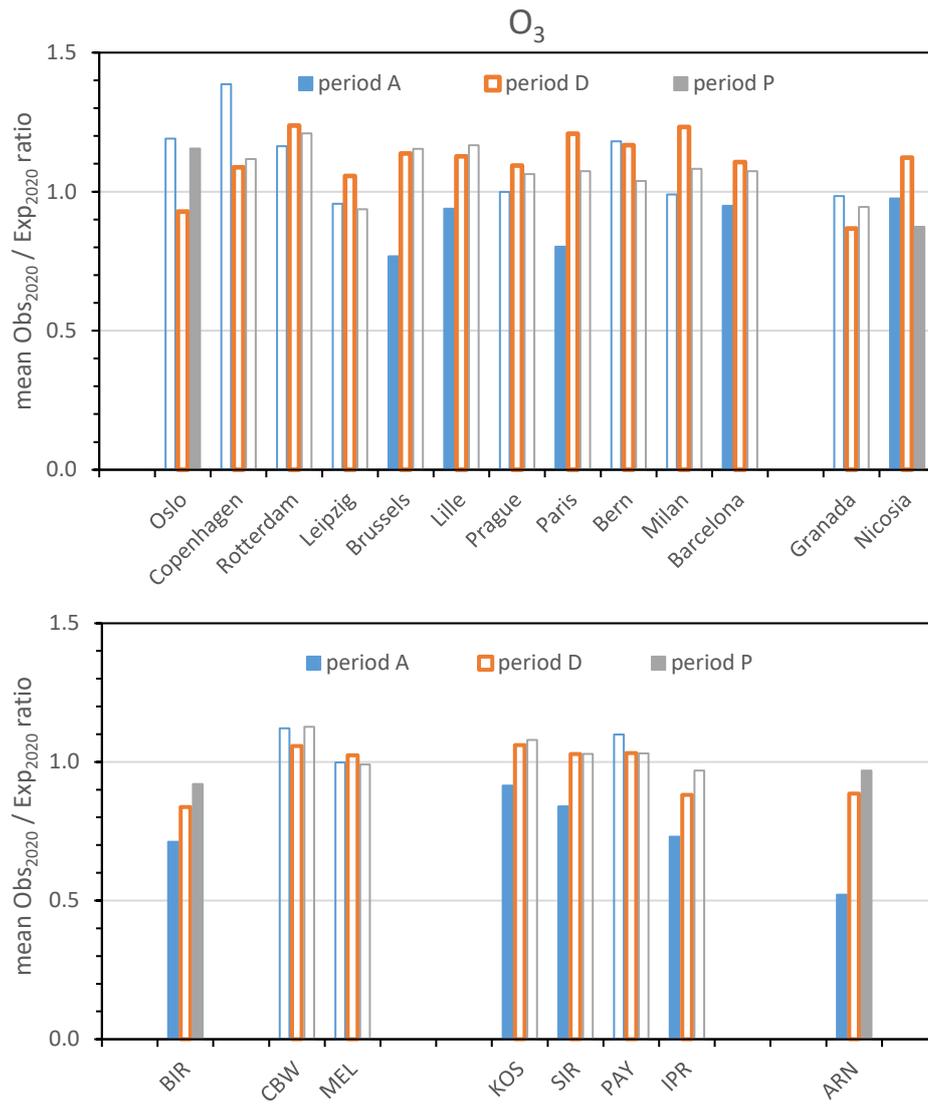

670 Figure 4. Mean observed / expected PM<sub>2.5</sub> (top) and PM<sub>10</sub> (bottom) concentration ratios (Eq. 3) during periods A (before), D (during lockdowns) and P (after) at regional background sites. Filled bars indicate means which are statistically different from the mean during lockdown periods (D).

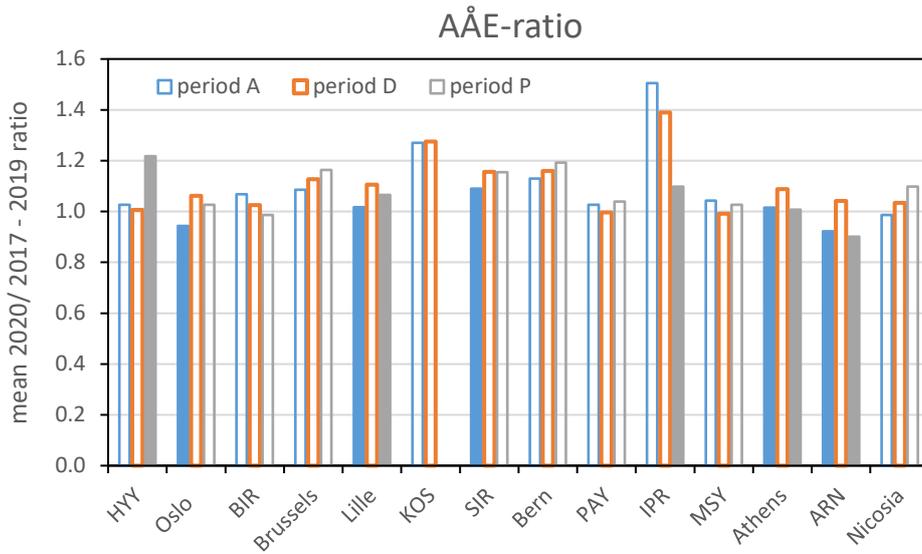

675

Figure 5. Mean observed / expected NO<sub>2</sub> concentration ratios (Eq. 3) during periods A, D and P. Filled bars indicate means which are statistically different from the mean during lockdown periods (D). No data available from KOS for time period P.

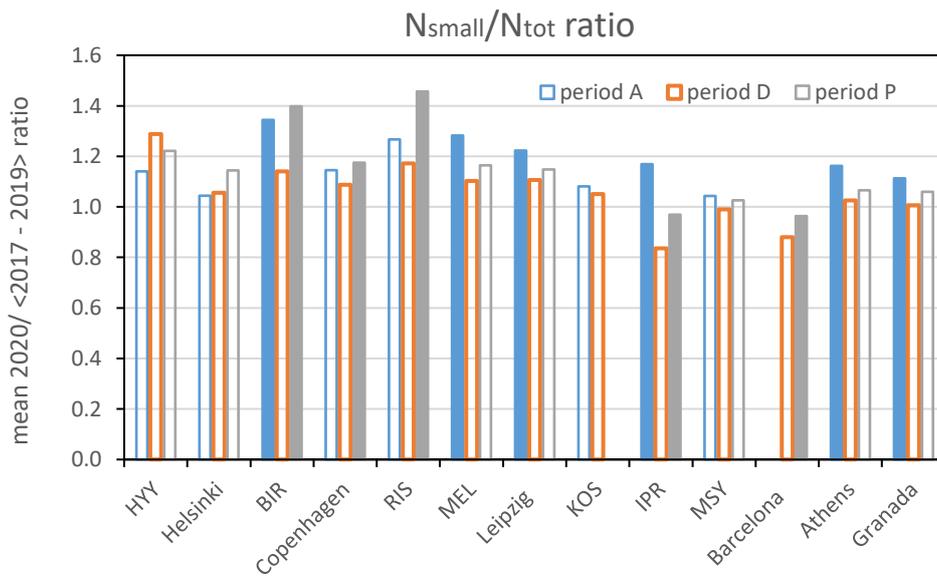

680

Figure 6. Mean observed / expected  $O_3$  concentration ratios (Eq. 3) during periods A, D and P. Filled bars indicate means which are statistically different from the means during lockdown periods (D).

685 Figure 7. Mean 2020 / <2017 - 2019> AAE ratios during periods A, D and P. Filled bars indicate means which are statistically different from the means during lockdown periods (D). No data available for KOS during period P.

690 Figure 8. Mean 2020 / <2017 - 2019> N<sub>small</sub> / N<sub>tot</sub> ratios during periods A, D and P. Filled bars indicate means which are statistically different from the means during lockdown periods (D). No data available for KOS during period P, and for Barcelona during period A.

Table 1. Measurement site details.

Country	Site	Urban sites			Regional background sites			
		Type <sup>(1)</sup>	Latitude (°N)	Longitude (°E)	Site	Code	Latitude (°N)	Longitude (°E)
FI	Helsinki <sup>(2)</sup>	Background	60.19	24.95	Hyytiala	HYY	61.85	24.28

(1) "Background" and "Traffic" stand for "urban background" and "traffic" sites, respectively.

(2) Helsinki PNSD data are from the University of Helsinki science campus area located at 60.20 °N, 24.96 °E.

(3) Leipzig PNSD data are from the Leipzig Science Park area located at 51.35°N, 12.43°E.

695

Table 2. Mean impacts of the lockdown measures implementation and relaxation (%) as computed from the 2020 observed / expected ratios shown in Figures 2 to 8.

Variable	Site Type	Impact of lockdown measures			
		implementation		relaxation	
PM <sub>2.5</sub>	Urban	+1 %	± 42 %	+26 %	± 21 %
	Regional background	+2 %	± 39 %	+38 %	± 43 %
PM <sub>10</sub>	Urban	+5 %	± 33 %	+26 %	± 24 %
	Regional background	+15 %	± 42 %	+28 %	± 10 %
NO <sub>2</sub>	Urban	-29 %	± 17 %	+31 %	± 30 %
	Regional background	-17 %	± 24 %	+27 %	± 50 %
O <sub>3</sub>	Urban	+11 %	± 23 %	-3 %	± 12 %
	Regional background	+17 %	± 24 %	+4 %	± 5 %
AÅE	Urban	+7 %	± 4 %	0 %	± 5 %
	Regional background	0 %	± 7 %	-14 %	± 37 %
N <sub>small</sub> /N <sub>tot</sub>	Urban	-7 %	± 5 %	+6 %	± 2 %
	Regional background	-9 %	± 13 %	+11 %	± 12 %
