16	Abstract
17	
18 19	The introduction of innovative technologies in agriculture is key not only to improving the efficiency of agricultural production, crop yields, and quality but also to balancing energy use and preserving a cleaner

19 agricultural production, crop yields, and quality but also to balancing energy use and preserving a cleaner environment. Biopreparations are environmentally friendly means of restoring the vitality of the soil on which 20 plants can thrive. Biopreparations have an impact on soil health and alter greenhouse gas emissions. The aim 21 22 of this study was to investigate the effects of different biopreparations on soil porosity, temperature, and CO_2 23 (carbon dioxide) emission from the soil in North-East Europe (Lithuania) growing winter wheat, and oilseed 24 rape. The experimental studies were carried out over three years, and each spring, after the resumption of 25 winter crops, the soil surface was sprayed with biopreparations of different properties or mixtures of biopreparations, under 7 scenarios, with one scenario left as a control. Soil porosity, temperature, and CO_2 26 27 emissions from the soil were measured regularly every month from April to August. The application of the 28 biopreparations showed a cumulative effect on the soil properties. In the third year of the study, the total 29 porosity of the soil was higher in all scenarios compared to the control, ranging between 51% and 74%. The 30 aeration porosity of the soil was also higher in all years of the study than in the control, although no significant differences were obtained. The results of the studies on CO₂ emissions from the soil showed that in the first 31 32 year, the application of the biopreparations increases emissions compared to the control. However, when 33 assessing the cumulative effect of the biopreparations on soil respiration intensity, it was found that in the third 34 year, most of the biopreparations led to a reduction in CO₂ emissions compared to the control. The lowest 35 emissions were achieved with the biopreparations consisting of essential oils of plants, 40 species of various 36 herbs extracts, marine algae extracts, Azospirillum sp., Frateuria aurentia, Bacillus megaterium, mineral oils, 37 Azotobacter vinelandi, humic acid, gibberellic acid, sodium molybdate, azototbacter chroococcum, 38 azospirillum brasilense, etc. Evaluating the effectiveness of biopreparations on soil porosity, temperature, and 39 C_{9O_2} emission from the soil, it can be stated that the best effect was achieved in all three research years in 40 SC7, and SC8 using -biopreparations with Azotobacter chroococcum, Azotospirilum brasilense and with 41 various herbs, Marine algae extracts, oils of plants, mineral substances. The multiple regression model showed

42 that soil temperature has a greater influence on the variation of CO₂ emissions than soil aeration porosity.

44 **Keywords:** GHG emissions, carbon dioxide, bioproducts, soil porosity, soil temperature

45 Introduction

- 46
- 47 1.1 Importance of biopreparations
- 48

Decades of soil degradation have led to a search for ways to contribute to soil sustainability by preserving 49 50 soil properties without harming the environment. Over the last decade, European agricultural policy has increasingly turned towards environmental sustainability, with the aim of reducing the use of chemicals and 51 52 increasing the organic area (European Commission, 2020). An increasing number of agricultural operators and 53 farmers have adopted environmentally friendly biotechnologies that use biopreparations, i.e., bioproducts 54 designed to inhibit the growth of pathogenic fungi or bacteria, stimulate plant growth, improve plant nutrient uptake, and restore soil properties and fertility (Michalak et al., 2016; Trevisan et al., 2019; Szparaga et al., 55 2019). Consumers have started to increasingly value agricultural products with high nutritional and functional 56 57 value and environmentally sustainable production (Caruso et al., 2019; Szparaga et al., 2018). Therefore, 58 bioproducts used in agricultural practice aim to enhance the biological protection of plants by reducing the 59 spread of pathogens and pests, increase crop productivity, improve soil microbiology, change the physical and chemical properties of soil, reduce environmental pollution, and weaken the properties of crop residues 60 (Khattab et al., 2009; Vaitauskiene et al., 2015; Oskiera et al., 2017; Naujokienė et al., 2018). Blaszczys et al. 61 62 (2014) stated that Trichoderma harzianum and Trichoderma atroviride are common components of 63 biopreparations used in agriculture. Fungi of the genus Trichoderma can effectively reduce phytopathogens in agricultural soils through various mechanisms (Oskiera et al., 2017). A combination of edaphic and dynamic 64 factors, including crop rotation, residue management, soil type, tillage, and climate, affect the microorganism 65 community (Bünemann et al., 2008; Gil et al., 2011; Zhang et al., 2014). A growing body of research 66 demonstrates that plant-derived phytochemicals affect the soil microbiota through interactions between plant 67 68 roots and soil (Bais et al., 2006; Kong et at., 2008; Lorenzo et al., 2013). Biopreparations have multiple effects, 69 but scientists are placing more emphasis on their positive effects on plants and soil (Tarantino et al. 2018). 70 Biopreparations are also used as seed diluents to increase germination and reduce seed contamination with 71 pathogenic microorganisms (Selby et al., 2016; Rouphael et al., 2018). Kocira et al. (2020) report that the 72 mixtures of seeds and biopreparations obtained from Archangelica officinalis L. significantly inhibit fungal 73 development on the seed surface. Biopreparations have antimicrobial activity because they contain biologically 74 active substances that can inhibit the development of microorganisms. The appropriate composition of the 75 biopreparations to be used depends mainly on the plant species (Nostro et al., 2000; Sen and Batra, 2012; 76 Shihabudeen et al., 2010). The use of biopreparations can reduce the cost of crop production and increase the 77 efficiency of soil nutrient use by reducing the incidence of diseases caused by nutrient deficiencies. However, 78 this effect is not easy to achieve, as it requires a lot of knowledge on the proper selection of biopreparations, 79 their application method, and the correct adjustment of the amount and concentration (Ertani et al., 2018; 80 Szparaga et al., 2019; Michałek et al., 2018).

- 81
- 82

1.2. Effects of biopreparations on soil

83

Soil microorganisms are an essential link in the nutrient cycle in the soil and maintain soil fertility. Their activity determines the physical and chemical properties of the soil, and these properties in turn determine how the microorganisms feel in the soil. Soil physical properties such as porosity and temperature are constantly changing under the influence of the environment. A research team from Poland investigating the influence of

88 microorganisms on soil density and porosity found no significant changes over 5 years (Pranagal et al., 2020). 89 Other researchers (Montemurro et al., 2010; Peltre et al., 2015; Juknevičius et al., 2020) have suggested that biopreparations increased the organic carbon content of the soil, which presumably led to a decrease in soil 90 density and an increase in overall porosity. Researchers have pointed out that soil water content influences soil 91 92 density (Lu et al., 2018; Tian et al., 2018; Tong et al., 2020). Naujokiene et al. (2018) reported that the use of 93 differently prepared biopreparations reduced soil hardness by up to 28% and increased total porosity by up to 94 25% in the second year of the study, which resulted in lower diesel fuel consumption and reduced GHG 95 (Greenhouse gases) emissions to the environment.

96

97 1.3. CO₂ emissions from soil

98

99 The agricultural sector is one of the most important GHG polluters of the environment, and cleaner 100 production processes in this sector are of particular interest (Hamzei and Seyyedi, 2016; Wu et al., 2017). CO₂ emissions from soil are the second largest component of the carbon cycle and contribute to climate change 101 102 (Mohammed et al., 2022). Agricultural producers are encouraged to increase agricultural production by 103 developing alternative technologies that address climate change, i.e., reducing the carbon footprint of agriculture (Dias et al., 2016; Foley et al., 2011; Tilman et al., 2002). Soil bioactivity is the set of biological 104 processes that determine soil respiration, enzyme activity, humification, and mineralization processes. A group 105 106 of researchers (Ma et al., 2021) has observed that microorganism structure (community structure) and soil 107 properties change together depending on environmental conditions and determine the dynamics of GHG emissions. After using the biological preparation, the amount of organic carbon in the soil increased from 1.8 108 109 to 2%, the difference in increase is 0.2% (Juknevičius et al., 2018). Stimulating soil microorganisms increases 110 CO₂ release and improves nutrient mobilization (Klenz, 2015). Scientific results showed that the preparation of biocrusts biopreparation significantly improved soil physicochemical properties, respiration, and alkaline 111 phosphatase, protease, and cellulose, and reduced CO₂ emissions in vegetation areas (Liu et al., 2017). 112

The dependence of soil respiration intensity, GHG emissions, and physical soil properties on tillage and 113 other technological operations has already been studied quite extensively. However, the impact of 114 115 environmentally friendly biopreparations on soil physical properties and the dynamics of CO₂ emissions during 116 the growing season has not yet been sufficiently studied (Naujokienė et al., 2018). The limited number of 117 scientific papers on this topic shows that research on the effects of biopreparations on soil under different 118 meteorological conditions is new and relevant. The aim of this study was to investigate the effects of different 119 biopreparation formulations on soil porosity, temperature, and CO₂ emission from the soil in Central Europe 120 (Lithuania) growing winter wheat, and oilseed rape.

- 121
- 122 2. Material and methods
- 123
- 124 2.1. Site description and experimental design

125

Experimental field research was carried out in 2014–2017 at the Experimental Station of Vytautas Magnus
 University Agriculture Academy (54°534'N, 23°50'E) in ugleyic satiated planosoil (*Endohypogleyic-Eutric Planosol – PLe-gln-w*) (Buivydaitė and Motuzas, 2001). Analysis of changes in soil physical properties and
 CO₂ emissions was carried out under the influence of biopreparations of different composition in North-East
 Europe (Lithuania) on the left bank of river Nemunas, in Kaunas district.

In the first year of the study, winter wheat (variety "Ada") was grown, in the second year – winter wheat
("Famulus") was grown, and in the third year – winter oilseed rape ("Cult") was grown. Eight scenarios (SC)

were selected to determine the effect of biopreparations on soil properties and CO₂ emissions from the soil, of

which SC1 (scenario 1) was the control with no biopreparations used. In the other seven SCs, mixtures of

biopreparations were used. The components of the biopreparations are given in Table 1. Mixtures of

biopreparations were applied after the resumption of winter crops in the second half of April. The experimental plots were laid out in a linear pattern. The initial size of the plots was 600 m² and the reference size was 400

- plots were laid out in a linear pattern. The initial size of the plots was 600 m^2 and the reference size was 400 m^2 (Naujokienė et al., 2018, 2019). The layout of the experimental field scenarios is presented in Figure 1.

144 2.2. Measurements of soil physical properties

145

143

Soil properties were measured in April, May, June, July, and August over a three-year period. A total of14 tests were carried out (Table 2).

148

Table 2. Soil properties assessment plan (2015–2017)

2015	2016	2017
25.04.2015	29.04.2016	05.05.2017
11.05.2015	25.05.2016	30.05.2017

04.07.2015	20.07.2016 (after harvesting)	31.07.2017 (after harvesting)
07.08.2015 (after harvesting)	08.08.2016 (after soil tillage)	01.08.2017 (after soil tillage)

150

Soil porosity was sampled with a soil sampling drill from a depth of 0-10 cm. For each scenario, 5 measurements were taken. Soil porosity was determined with a vacuum air pycnometer after drying the samples to an air-dry mass. The total porosity P_b was calculated according to the formula (Maikšténiene et al., 2007):

155 $P_b = \left(1 - \frac{\rho_d}{\rho_{k.f.}}\right) \cdot 100 \qquad , \qquad (1)$

156 where ρ_d – soil density, g cm⁻³;

157 $\rho_{k,f}$ – soil solid phase density, g cm⁻³.

158 Aeration porosity $P_{aer.}$ was calculated according to the formula (Maikšténiene et al., 2007):

159
$$P_{aer.} = P_b - (w \cdot \rho_d),$$

160 where w – soil water content, %.

Soil density was determined by weighing, taking samples with a Nekrasov drill and calculated according to the formula g=m/v i.e., mass to volume ratio. The density of the solid phase was determined with a vacuum air pycnometer, after which the obtained results were inserted into the formulas presented in the article. Aeration porosity is a very important quantity for the soil, as it determines the amount of air spaces in the soil, and air is needed for plant roots to grow and develop normally.

(2)

Soil temperature at a depth of 0–5 cm in all treatments was determined with a hand-held portable device "HH2 Moisture Meter", to which a "WET-2" type sensor was connected. The tests were carried out in 5 repetitions, and the depth of temperature measurement is indicated as 0-5 cm, as the rounding error is on the smaller side.

- 171 2.3. Measurement of CO₂ emissions from soil
- 172

173 CO_2 emissions from the soil were measured on the same dates as other physical soil properties. The 174 measurements were carried out with the ADC BioScientific Lcpro+ System, a portable CO_2 gas analyzer 175 consisting of a compact programming console, a soil respiration chamber, and a plastic ring to be inserted into 176 the soil. Carbon dioxide emissions were measured 5 times in each scenario. CO_2 gas emissions were measured 177 in each repetition 5 times, the ring was placed in the soil at a depth of 20 mm, and all measurements were made 178 in the first half of the day (from 10 a.m. to 2 p.m.). The soil temperature was measured in parallel with the 179 measurement of CO_2 gas emissions.

180 The programming console is connected to the soil breathing chamber at the selected measurement location. A 181 metal ring was inserted into the selected measurement site and the chamber attached to it. The ring is inserted 182 perpendicular to the soil and left in place. The measurement site must be free of grass or other elements that 183 could damage the sensors. The telescopic probe shall deliver CO₂ from the atmosphere at a height of 3 meters. 184 This height was chosen to prevent the measurement from being influenced by the person taking the 185 measurement. The measurement is carried out for 10 minutes, observing fluctuations in carbon dioxide. The 186 data is automatically recorded on a memory stick.

187

188 2.4. Meteorological conditions

Meteorological data received from the Kaunas Meteorological Station (KMS). The distance between the KMS and the area where the experiments were conducted is approximately 500 m. The weather station provides multi-year data averages that are available calculated from 1974 until 2017 KMS provides multi-year data averages that are calculated since 1974 until 2017.

April 2015 was unusually warm. The average temperature for the month was 1 °C above the long-term average and precipitation was 7.6 mm above the long-term average (Fig. 2). May and June 2015 were 0.9 °C and 0.2 °C colder than the long-term average, with 10 mm of precipitation in May and 46.2 mm less than the long-term average in June. July 2015 was close to the long-term average, with 8.8 mm less precipitation than the long-term average. August was hot and dry, with an average air temperature of 20.3 °C and only 6.9 mm of precipitation. These data show that the 2015 growing season was very dry and deficient in moisture.

199

Fig. 2. Meteorological conditions during the study in 2015–2017

In April 2016, the average air temperature was 1 °C above the long-term average and in May it was 3.43 °C above the long-term average. April received 41.2 mm of precipitation, while May was a low-precipitation month, with only 36.4 mm, 17.4 mm below the long-term average. Warm and humid weather prevailed in summer. June was particularly warm, with an average air temperature of 17.21 °C, 1.61 °C above the longterm average. July and August were about 0.3 °C warmer than the long-term average. Compared to the longterm average, precipitation was 21.1 mm higher in June, 81.7 mm higher in July, and 34.6 mm higher in August. The summer period of 2016 was humid.

210 Although the average temperature in April 2017 (5.61 °C) was close to the long-term average (6.1 °C), 211 precipitation was 1.9 times higher than the long-term average. The weather in May was moderately warm and dry. The air temperature was 12.87 °C, 0.57 °C above the long-term average. Precipitation was very low, at 212 213 just 10.5 mm, compared with the long-term average of 53.8 mm for May. The summer weather in Lithuania was humid and cool. The average temperature in June was no different from the long-term average, but 214 215 precipitation was 1.28 times the long-term average. Meteorological conditions in July were close to the longterm average, with an air temperature of 16.77 °C and 79.6 mm of precipitation. The weather warmed up to 216 217 17.47 °C in August, with a long-term average of 16.6 °C. Precipitation in August was 25.3 mm lower than the 218 long-term average. Precipitation in the summer of 2017 was in line with the long-term average.

219

220 2.5 Statistical analysis

221

222 One-way analysis of variance (ANOVA) was used to assess the statistical significance of the results. 223 Dispersion analysis was performed on the LSD (east significant difference) test for mathematical statistics 224 (Raudonius, 2017; Olsson et al., 2007). We used the statistical software package SYSTAT, version 10. The 225 probability level was indicated as follows: * – differences are significant at $P \le 0.05 > 0.01$; ** – differences are 226 significant at $P \le 0.01 > 0.001$.

227 Multivariate linear regression was applied to investigate the relationship of CO_2 emission with respect 228 to soil aeration porosity (A. porosity), soil total porosity (T. porosity), and temperature. In this article, multiple 229 linear regression was implemented using the backward elimination technique. With stepwise selection, the 230 decision of whether to include or remove a variable from the model was based on Akaike's information 231 criterion. The following tests are performed to check multivariate linear regression assumptions: normality, homoscedasticity, and multicollinearity. The assumption of homoscedasticity was tested using Breusch-Pagan 232 test, the assumption of normality was examined by using Shapiro-Wilk test, and the multicollinearity was 233 analysed in the context of the variance inflation factor (VIF) assessment. Regression analyse was performed 234 235 using R Statistical Software (v4.1.2; R Core Team 2021).

236

237

238 3. Results and discussion

239

- 240 3.1. Soil total porosity
- 241

In the first year of the study (2015), the total porosity ranged from 50.4% to 55.4% before the application of the biopreparations (Fig. 3a). Two weeks after the spraying of the biopreparations (11 May 2015), the total porosity was measured and it was found that all treatments showed a decrease in total porosity ranging from 245 1.08% to 7.82%, except for treatments SC2 and SC8, which showed an increase in total porosity of 8.4% and 246 2.6% respectively. No studies were carried out in June due to drought. In July, total porosity varied from 47.5% 247 to 52.2% for all treatments tested. Only one scenario, SC4, showed an increase in total porosity up to 3.9% 248 compared to the total porosity found in May. Significant differences were obtained in scenarios SC3, SC4, 249 SC7 and SC8. In August, the range of treatments in total porosity was between 47.9% and 51.7%. Significant 250 differences were obtained in scenarios SC5 and SC6.

259

260 In 2016, the post-winter soil total porosity ranged from 41.8% to 53.2% (Fig. 3b). Total porosity was 261 measured on 23 May 2016 after the application of the biopreparations and showed an increase in total porosity in all SCs. In the control treatment SC1, an increase in total porosity was also found due to the meteorological 262 263 conditions, as the warm and dry month of May prevailed. Carson et al. (2010) found that bacterial diversity 264 increases with water potential ≤ 2.5 kPa in the sand and ≤ 4.0 kPa in silt + clay, which corresponds to a pore space filled with \leq 56% water. The higher precipitation in June resulted in soil compaction, which reduced the 265 total porosity in all scenarios except SC4, due to the presence of higher levels of microorganisms (Azospirillum 266 267 sp., Frateuria aurentia, Bacillus megaterium) that prevented soil compaction. July was a high-precipitation 268 month, which resulted in a decrease in total porosity of between 1.5% and 13% compared to June in all 269 scenarios except SC1. In the control scenario, an increase of 3.4% was observed in July due to the filling of 270 soil pores with water, which slightly increased the total porosity. In August, all scenarios showed an increase 271 in total porosity compared to July, with the exception of scenarios SC1 and SC2, which consisted of non-272 bacterial components. These scenarios showed a decrease but not a significant one. Comparing the results 273 obtained in April (before the application of the biopreparations) and August, it was found that the application 274 of the biopreparations which were dominated by microorganisms, resulted in a more porous soil. The increase 275 in total porosity ranged from 1.53% to 17.26% in most scenarios.

276 In 2017, total porosity at the beginning of May varied from 46.6% to 54.8% (Fig. 3c). Significant 277 differences between the treatments compared to the control treatment were obtained in scenarios SC4, SC6, 278 SC7, and SC8 at probability $P \le 0.01 > 0.001$ and in scenario SC5 at $P \le 0.05 > 0.01$. Biopreparations with 279 higher bacterial content have a long-lasting effect, which is felt after overwintering with a higher total porosity 280 index. The measurement of total porosity after spraying the biopreparations showed that in all SCs the total porosity increased from 18.54% to 26.54% because of the biopreparations and the environmental conditions. 281 282 Scientists have found that biotreatments alter soil physicochemical properties (Banerjee, 2011; Cittenden et al., 2016). In June, when compared to the control, significant differences were obtained in scenarios SC6, SC7, 283 284 and SC8 at $P \le 0.01 > 0.001$, although almost all SCs showed a decrease in total porosity, except for scenario SC7, which used Azotobacter spp. bacteria in combination with mineral oils, seaweed, and various grass 285 286 extracts, which affected total porosity.

- 288 3.2 Soil aeration porosity
- 289

290 In the first year of the study, the aeration porosity before the application of the biopreparations ranged from 25.8% to 33.7% (Fig. 4a). Two weeks after the application of the biopreparations, the aeration porosity 291 292 was measured as well. It was found that aeration porosity increased in all treatments, except for SC4, which 293 showed a decrease of 10.13%. Scientists suggest that the application of biopreparations increases the organic 294 carbon content of the soil, therefore decrease soil density and increase porosity (Montemurro et al., 2010; 295 Peltre et al., 2015; Juknevičius et al., 2020). In July, aeration porosity varied from 23.8 % in SC1 to 30.0% in 296 SC7 for the treatments studied. In August, the variation in aeration porosity ranged from 26.9% in SC2 to 297 32.4% in SC7 and SC8. After re-vegetation of plants, the SC1 option had the lowest aeration porosity, and 298 after a month it increased 2.6 times, but in other options, where biological agents were used, the soil aeration porosity was found to be higher. It is due to meteorological conditions (soil moisture) and plant root system. 299

303

308 In 2016, in the spring, at the resumption of vegetation, aeration porosity ranging from 12.1% in SC1 to 309 23.7% in SC5 (Fig. 4b). In our case, SC1 had the lowest aeration porosity of 12.08%, while in other SCs it was 310 around 20%. Aeration porosity measurements taken two weeks after the application of the biopreparations showed an increase in aeration porosity in all the SCs compared to the April tests. The highest increase of 2.6 311 312 times in aeration porosity was found in the control scenario SC1. The increase in aeration porosity has been 313 influenced not only by the sprayed biopreparations but also by favorable meteorological conditions. Many 314 researchers suggest that porosity is particularly sensitive to environmental conditions (Cassaro et al., 2011, 315 Lipiec et al., 2012, da Costa et al., 2014). The month of June was particularly warm with an average air 316 temperature of 17.21 °C. The highest aeration porosity in June was found in SC4, SC7, and SC8. The lowest 317 aeration porosity of 23.7% was found in the control treatment. In July, the aeration porosity was similar to that 318 in June. In August, all scenarios showed an increase in total porosity compared to July, except for scenarios 319 SC1, SC2, and SC3.

In 2017, the aeration porosity at the beginning of May varied from 19.3% to 27.9% (Fig. 4c). Aeration porosity measurements after spraying biopreparations showed that in all SC2, aeration porosity increased compared to the measurements taken in May because of biopreparations and environmental conditions. The measurements carried out in the third decade of June showed a decrease in aeration porosity in all treatments compared to the measurements carried out in May. Researchers investigating effective microorganisms found no significant effect on porosity (Pranagal et al., 2020). At the end of July, aeration porosity ranged from 33.8% to 43.3%. After harvest, aeration porosity decreased in almost all scenarios except SC3 and SC8.

328 3.3 Soil temperature

329

330 Soil temperatures in April 2015 ranged from 10.5 °C to 11.8 °C (Fig. 5a). In April, compared to the control, soil temperature increased significantly in SC3, SC5, and SC7 scenarios ($P \le 0.05 > 0.01$). Soil temperature is 331 one of the most important variables influencing soil respiration and depends on environmental conditions 332 333 (Moyano et al., 2013, Sierra et al., 2015). Our studies have also shown that environmental conditions have an 334 effect on temperature changes, i.e. the use of a biopreparation influences the increase in temperature. As the 335 soil gradually warmed in May, soil temperatures were found to be about 2-5 °C higher than in May. Compared 336 to the control scenario SC1, significantly lower soil temperatures were observed in SC7 and SC8 at $P \le 0.01$ 337 > 0.001 and $P \le 0.05 > 0.01$ in SC6. In July, the soil temperature ranged from 19.08 °C (SC7) to 22.04 °C (SC2). 338 In July, a significant decrease in soil temperature was found between control SC1 and SC6 ($P \le 0.05 > 0.01$) 339 and between SC1 and SC7 ($P \le 0.01 > 0.001$) predicting that there is a denser crop. In August, the soil 340 temperature was the highest recorded. Significant increases were found between scenarios SC1 and SC6, SC1 341 and SC7 at the 95% probability level, and between SC1 and SC2, SC1 and SC8 at the 99% probability level.

Fig. 5. The effect of biopreparations on the dynamics of soil temperature: a) 2015, b) 2016, c) 2017

350

In 2016, soil temperatures varied from 13.2°C to 14.1 °C after the resumption of plant growth (Fig. 5b). A significant increase was found between scenarios SC1 and SC5 ($P \le 0.01 > 0.001$) and between SC1 and SC8 ($P \le 0.05 > 0.01$). At the end of May, soil temperature increased on average by about 10 °C. In June, soil temperature ranged from 22 °C (SC6) to 23.3 °C (SC4). In the SC4 scenario, soil temperature was significantly higher than the control ($P \le 0.05 > 0.01$). In July and August, soil temperatures were found to be similar due to the settled weather, and no significant differences were found between the scenarios and the control.

357 On 5 May 2017, the highest soil temperature was found in SC8 and the lowest in the control scenario (Fig. 358 5c). Soil temperatures were significantly higher in scenarios SC2 and SC5 ($P \le 0.05 > 0.01$), SC6, SC7, and 359 SC8 ($P \le 0.01 > 0.001$) compared to the control scenario. Soil warming at the end of May resulted in a 360 significant increase in soil temperature in all scenarios except SC2 at the 99% probability level. In SC8, a 361 substantial increase was found at the 95% probability level compared to the control SC1. In June, the lowest 362 soil temperature of 16.66 °C was found in SC1 and the highest of 21 °C in SC7. Significantly higher soil temperatures compared to the control were found in scenarios SC4, SC6, SC7, and SC8 at the 99% probability 363 364 level. An increase in soil thermal conductivity increases temperature whereas an increase in soil heat capacity 365 reduces temperature (Obia et al, 2020). At the end of July, soil temperatures ranged from 21.8 to 24.3 °C. A 366 significant increase was found between control and SC4 ($P \le 0.01 > 0.001$) and between control and SC5 and 367 SC6 scenarios ($P \le 0.05 > 0.01$). On 1 August, soil temperature increased in most of the scenarios studied 368 compared to soil temperature at the end of July. However, a significant decrease in soil temperature ($P \le 0.01$

Notes: * – significant differences from control treatment (SC1) at P \leq 0.05>0.01, ** – at P \leq 0.01 > 0.001. Intervals mean standard deviation.

369 > 0.001) was obtained after the harvest between control and SC5, and at the 95% probability level soil temperature was significantly lower in the control scenario than in SC4, SC6, and SC7. In all scenarios the higher soil surface temperatures were due to tillage, which allowed warm air to enter the soil. The data of other authors do not confirm these researches, because all the research of ours and other authors were in other spheres of soil composition and climate, so this was added as additional information, as it was obtained in other countries, but perfectly parallel studies were not found, only similar ones, due to the soil and the diversity of the area.

- 376
- 377 3.4 CO_2 emissions from soil

378

379 In April 2015, the highest CO₂ emissions were observed in scenario SC7 with 2.29 μ mol m⁻² s⁻¹ (Fig. 6a) and the lowest in SC2 with 0.73 µmol m⁻² s⁻¹. Soil moisture, temperature, and biopreparation composition were 380 the main influences on soil respiration. Research groups suggest that soil moisture influences CO₂ emission, 381 with continuous moisture conditions increasing the bacterial content of the soil, resulting in higher CO_2 382 emissions from the soil compared to reirrigation (Jiao et al. 2023; Gultekin et al., 2023; Barnard et al., 2015). 383 384 Canarini et al. (2017) found that in soils with more than 2% organic carbon, CO₂ emissions increase after 385 drought, in contrast to soils with low carbon content. In our case, substantial increases between the control 386 SC1 and SC5 scenarios were found at the 95% probability level, and between SC1 and SC7 at the 99% 387 probability level. In May, soil respiration increased or remained the same compared to April. A substantial 388 increase was found between the control and scenarios SC4, SC5, SC6, SC7, and SC8 at the 99% probability level. It is likely that the bacteria present in the bioassay (Azospirillum sp., Frateuria aurentia, Bacillus 389 390 megaterium, Azotobacter chroococum, Azospirillum brasilense, Azobacter vinelandii) contributed to the 391 substantial increases. Scientists suggest that soil microorganisms can increase CO₂ release (Klenz, 2015) under 392 certain environmental conditions. According to the results of the May study, soil temperature had a significant influence on CO_2 emissions. Although in the following months of July and August, CO_2 emissions were 393 394 increasing due to higher ambient temperatures in all scenarios. A group of researchers (Tóth et al., 2018) investigated that soil emissions may be higher during the growing season. In August, the highest CO₂ emissions 395 were found in SC3 at 4.26 µmol m⁻² s⁻¹ and the lowest in SC2 at 2.15 µmol m⁻² s⁻¹. Significant increases 396 between control and SC8 were found at the 95% probability level, and at the 99% probability level – between 397 398 scenarios SC1 and SC4.

LSD(B).05=0.53 µmol m ⁻² s ⁻¹	$LSD(B)_{.01}=0.71 \mu mol m^{-2} s^{-1}$
LSD(D).05=0.76 µmol m ⁻² s ⁻¹	LSD(D).01=1.03 µmol m ⁻² s ⁻¹
LSD(E) _{.05} =0.71 µmol m ⁻² s ⁻¹	LSD(E).01=0.96 µmol m ⁻² s ⁻¹

404 Fig. 6. The effect of biopreparations on the dynamics of CO₂ emissions from soil a) 2015, b) 2016, c) 2017 **405** Notes: * – significant differences from control treatment (SC1) at P \leq 0.05>0.01, ** – at $P \leq$ 0.01 > 0.001. **406** Intervals mean standard deviation.

407 In 2016, CO₂ emissions from the resumption of vegetation ranged from 0.69 µmol m⁻² s⁻¹ to 1.06 µmol m⁻ 408 2 s⁻¹ (Fig. 6b). Other researchers (Forte et al., 2017) who studied conventional tillage reported that it leads to 409 higher CO₂ emissions due to higher decomposition rates of soil organic matter and higher temperature 410 fluctuations. At the end of May, soil respiration was more intense in all scenarios, and a substantial increase 411 compared to the control was found in SC7 and SC8 at $P \le 0.05 > 0.01$. In June, with a decrease in air temperature 412 of 1-2 °C, CO₂ release slowed down and varied between 1.31 µmol m⁻² s⁻¹ and 2.64 µmol m⁻² s⁻¹. A significant 413 increase at $P \le 0.01 > 0.001$ was found between SC1 and SC7. In July, CO₂ emissions increased, but at the 414 95% confidence level, a significant increase was found between SC1 and SC7. Soil respiration increased 415 further after harvest in August, ranging from 2.79 to 5.78 µmol m⁻² s⁻¹. CO₂ emissions increased significantly 416 compared to the control in SC6 and SC7 at the 99% probability level and in SC5 at the 95% probability level. 417 At the beginning of May 2017, CO₂ emissions were in the range of 0.55-1.37 µmol m⁻² s⁻¹ (Fig. 6c). In the SC1 scenario, soil respiration was found to peak at 1.37 umol m⁻² s⁻¹. At the end of May, all scenarios had 418 419 higher CO₂ emissions due to ambient conditions and were significantly different from the control, with all SCs at the 99% probability level except SC2. Many field experiments have shown that CO₂ is significantly and 420 421 positively correlated with soil organic carbon (Liu et al., 2014) and soil temperature (Cartwright and Hui, 422 2014), but in our case, it is the opposite. In June, CO_2 emissions increased significantly in SC1 compared to 423 SC2 ($P \le 0.05 > 0.01$) and to the SC4 scenario ($P \le 0.01 > 0.001$). Significant reductions were obtained in scenarios SC5 ($P \le 0.05 > 0.01$) and SC3 ($P \le 0.01 > 0.001$). The settled temperature in July, which was close 424 to the long-term average (around 10 °C), resulted in more intense soil respiration in all scenarios except SC7 425 and SC8. A significant decrease ($P \le 0.01 > 0.001$) was found between the control SC1 and SC7, SC8 426 427 scenarios, which could be influenced by the different compositions of the biopreparations. Drulis et al. (2022) 428 state that bioproducts are substances that can improve crop productivity and quality, increase nutrient 429 availability in the soil, improve plant nutrient use efficiency, and promote organic matter decomposition and humification in the soil. In all scenarios, CO₂ emissions increased by a factor of 3 to 5 in the range of 4.89-430 431 11.07 μ mol m⁻² s⁻¹ after the harvest and tillage in August. These changes are due to the fact that the study was carried out immediately after tillage. The process of tillage greatly intensifies CO_2 emissions to the 432 environment (Buragiene et., 2015). However, the differences between the scenarios were influenced by the 433 434 different compositions of the biopreparations. Emissions were significantly higher only in scenario SC4 435 compared to the control ($P \le 0.01 > 0.001$) and significantly lower in scenarios SC3, SC7, and SC8 compared 436 to the control ($P \le 0.01 > 0.001$).

437 438

439 3.5. Multiple regression model

440 A multiple regression model including the dependent variable soil CO₂ emissions, and the independent 441 variables soil temperature, aeration porosity (A.Porosity), total porosity (T.Porosity) showed that A.Porosity, 442 T.Porosity were statistically unreliable and multicollinearity (VIF > 9) was found. Therefore, a stepwise model 443 selection was performed to select a model that included two independent variables, Temperature and 444 A.Porosity (R2=0.39, AIC=378). Unfortunately, the model analysis showed that the assumptions of normality 445 and homoskedasticity of the residual errors are violated in this case. Given that the dependent variable CO₂ 446 does not have a normal distribution (W=0.78, p=1.165e-11), the dependent variable was log-transformed, and 447 another model was composed:

448
$$Log(CO_2) = -0.67 - 0.02 A. porosity + 0.09 Temperature$$
 (3)

In this model, both independent variables are statistically significant (p<0.001), coefficient of determination R2 = 0.51, Akaike Information Criterion AIC = 135. Residual error diagnostics plots show that the assumptions of normality (W=0.98, p=0.073), and homoskedasticity (BP=2.303, p=0.3162) of the residual errors are satisfied. It can be concluded that CO₂ emissions from the soil decrease with increasing aeration porosity and CO₂ emissions increase with increasing soil temperature. Since the variable CO₂ was logarithmic, we calculate the exponents of the coefficients:

455
$$Exp(-0.019) = 0.981$$
 (4)

456
$$Exp(0.093) = 1.098$$
 (5)

457 Calculating the exponents of the coefficients, it was found that a 1 unit increase in soil aeration porosity 458 decreases CO_2 emissions from the soil (0.019%), while a 1 unit increase in soil temperature increases CO_2 459 emissions (0.098%).

460 Considering the standardized coefficients of the multiple regression model (beta_A.porosity = 0.29, 461 beta_Temperature = 0.78), it can be assumed that CO_2 variation is more influenced by soil temperature than

462 by soil aeration porosity.

463

464 Conclusions

465

- 466 <u>Due to the interaction between the long-term use of biopreparations and meteorological conditions In the first</u>
 467 and second years of the study, <u>it was fixed increase of the total porosity of the soil till 74 %.</u>
- 468 varied between 41% and 62%, while in
- 469 the third year, the total porosity of the soil increased in all scenarios and over the whole study period ranging
- 470 from 51% to 74%. This increase was due to the interaction between the long-term use of biopreparations and
 471 meteorological conditions.
- 472 -In the first year, It was established that due to half of biopreparations usage the soil temperature in August
- 473 showed a significantly increasing e compared to the control ($P \le 0.05 > 0.01$) in scenarios SC6, SC7, SC2, and 474 SC8. Similar trends were confirmed in the second and third years.
- 475 -<u>The cumulative effect of biopreparation application on CO₂ emissions from soil was most pronounced in the</u>
- 476 <u>third year. The use of biopreparations had an impact on CO₂ emissions from soil. In the first year, it was found</u> 477 that, just
- 478 scenario SC2 reduced CO₂ emissions from soil. The cumulative effect of biopreparation application was most
 479 pronounced in the third year.
- Studies confirmed that <u>biopreparations components Marine algae extracts and bacteria</u> <u>biopreparations</u>
 (SC3, SC7, SC8) can significantly reduce the CO₂ emission intensity from the soil after tillage., predictable
 due to the overlap of biocomposite components such as Marine algae extracts and bacteria.
- -Evaluating the effectiveness of biological preparations on soil porosity, temperature and $C0_2$ -CO₂ emission from the soil, it can be stated that the best effect was achieved in all three research years in SC7, when the
- compound of biopreparations-were 40 species of various herbs, Marine algae extracts, Essential oils of plants,
 Mineral oils, 4.5% of humic acids, 0.5% gibberellic acid, 0.01% copper (Cu), 0.01% zinc (Zn), 0.01%
 manganese (Mn), 0.01% iron (Fe), 0.01% calcium (Ca), 0.005% sodium molybdate (Na₂MoO₄), *Azotobacter spp.* mixed with water, and SC8 Marine algae extracts, *Azotobacter chroococcum*, *Azotospirilum brasilense*,
- 489 Phosphorus P (P_2O_5), Potassium K(K_2O), and water.
- The multiple regression model showed that as soil aeration porosity increases, CO₂ emissions from the soil decrease, while CO₂ emissions increase as soil temperature increases. It was established that soil temperature has a greater influence on the variation of CO₂ emissions than soil aeration porosity. When aeration porosity increases by 1 unit, CO₂ emissions decrease (0.019%), when temperature increases by 1 unit, CO₂ emissions decrease (0.019%), when temperature increases by 1 unit, CO₂ emissions decrease (0.019%).
- 495

Future research on the use of bacteria-based and environmentally friendly bioproducts should focus on increasing CO_2 storage in soil, simplifying agricultural operations, reducing inputs, and increasing the efficiency of crop production.
